Chapter 1

Small Animal Clinical Nutrition: An Iterative Process

Craig D. Thatcher
Michael S. Hand
Rebecca L. Remillard

"Things should be made as simple as possible, but not simpler."
Albert Einstein

CLINICAL IMPORTANCE

The public has become increasingly more aware of the importance of nutrition to health during the past four decades as a result of the growing recognition that food is associated with disease processes such as coronary artery disease, hypertension, obesity, diabetes mellitus and cancer. *Healthy People 2010* is a comprehensive set of disease prevention and health promotion objectives for the United States. *Healthy People 2010* uses 10 leading health indicators that reflect the major health concerns in the nation at the beginning of the 21st century. These indicators were selected based on their importance as public health issues and their ability to motivate action and provide data to measure progress against specific goals. One of the focus areas is nutrition, especially overweight/obesity conditions (Healthy People 2010).

The discipline of veterinary nutrition and its relationship to the practice of veterinary medicine have benefited from these changes. Food animal veterinarians have long recognized that no aspect of the production enterprise has more impact on health and production than nutrition; many health problems are associated with inadequate feeding programs. Food animal veterinarians recognize that optimizing feeding programs improves food animal health and productivity and, as a result, the economic status of producers. Food animal veterinarians who provide their clients with high-quality production medicine programs become unbiased nutritional consultants.

Similarly, small animal practitioners must improve their nutritional counseling skills because they cannot truly meet their patients' health needs without optimizing nutrition. Small animal veterinarians can improve the quality of medicine delivered to their patients by knowledgeably and systematically addressing the nutritional aspects of each case, whether the goal is treating or preventing disease. Veterinarians must emphasize health maintenance and wellness strategies for companion animals to provide the most beneficial service. Total disease prevention requires lifelong dedication to proper nutrition, immunizations, dental care and parasite control programs. Nutritional factors are a cornerstone in maximizing health, performance, longevity and disease prevention. Nutritional counseling and intervention, however, are beneficial only if done properly.

Veterinarians and their health care teams have considerable influence on the foods clients feed their pets. A study conducted by *Veterinary Economics* in 1990 found that 87% of veterinarians felt that offering nutritional services improved their practices (Gants, 1990). Ninety-four percent of these veterinarians said that their clients were somewhat or very receptive to nutrition-related information. A 1995 study conducted by the American Animal Hospital Association found that 54% of pet owners interviewed sought veterinary advice on pet foods at least once and 43% had received a recommendation from their veterinarian on which manufacturer's pet food to feed their puppies or kittens. Seventy percent of the latter group fed the brand of food recommended by their veterinarian (AAHA, 1995).

The word *recommend* means to counsel or advise (American Heritage Dictionary). The implication is that the advice proceeds from actual knowledge of the subject. Veterinarians should know how food needs vary with each lifestage, with mental, physical and environmental stresses and with diseases. Causes and effects of dietary imbalances should be considered so that the resulting disorders can be prevented or diagnosed and treated. Veterinarians should also be familiar with the various pet foods available to help clients choose the most appropriate ones. Veterinarians also need to understand the benefits and shortcomings of various feeding methods. After a feeding plan has been instituted, veterinarians need the skills to monitor the program to assess and reassess outcomes and to modify the feeding plan when necessary. The primary goal of this chapter is to provide practicing veterinarians, veterinary technicians and students with the basic problem-solving processes needed to successfully manage the nutrition of companion animal patients.

The Two-Step Iterative Process of Clinical Nutrition

A brief review of instructional systems design (ISD) is in order to better understand iterative (repetitive) processes. ISD emerged after World War II as a set of recognized standard procedures used to develop well-structured materials in response to the need for more efficient training techniques (Moore and Kearsley, 1996). ISD embodies various perspectives on learning, teaching, systems theory, behavioral psychology, communications and information theory. The ISD model breaks instruction into a series of phases or steps with defined procedures; a defined service or product must be delivered at each step. Steps include: 1) design, 2) development, 3) implementation, 4) evaluation and 5) analysis. Then, the process repeats itself as a continuous loop and may involve many cycles. The American College of Veterinary Nutrition (ACVN) has recommended that nutrition problem solving include assessment of the patient, the food and the feeding method (Bauer et al, 1995).

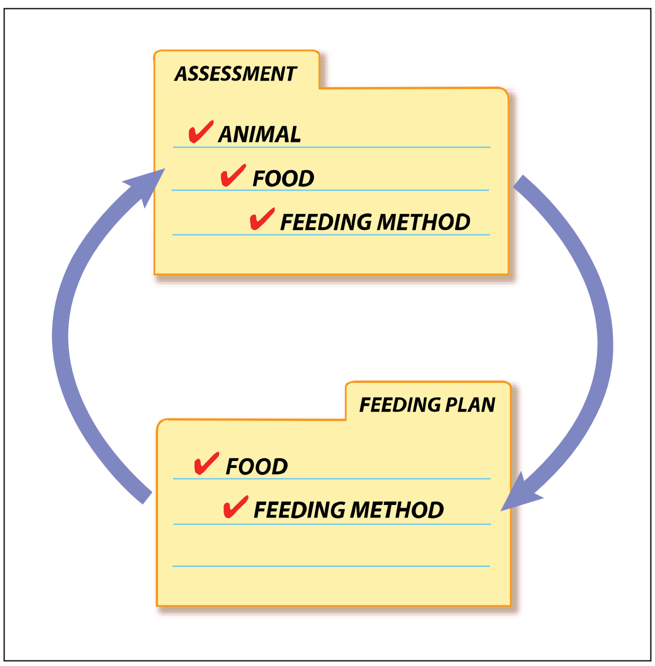

Figure 1-1. The two-step process of veterinary clinical nutrition.

Figure 1-1 depicts the iterative process used in this book. The first step is patient assessment, which allows the determination of the patient's key nutritional factors and their levels (the concept of key nutritional factors is described below). Determination of the key nutritional factors is the basis for the second step: the feeding plan. The feeding plan includes recommendations for food and feeding methods. If assessment of the current food and feeding methods indicates that they are appropriate, the current feeding plan can remain in place. However, if the assessment indicates otherwise, a new feeding plan should be formulated and implemented.

After a suitable period of time (the length of which depends on the patient's condition), the two-step process is repeated to determine the appropriateness or effectiveness of the new feeding plan. Thus, the patient is reassessed and, if necessary, a new feeding plan is developed and implemented. This is the iterative or repetitive part of the process. Any number of iterations of the two-step process can occur, depending on the needs of each patient. A critically ill patient may need to be reassessed every few hours, whereas a normal adult dog or cat may be reassessed annually. The subsequent reassessment of the patient at each cycle is also referred to as monitoring. This information is discussed under the heading of reassessment in the chapters that deal with patient assessment and feeding plans.

PATIENT ASSESSMENT

The goal of patient assessment is to establish a dog's or cat's key nutritional factors and their target levels in light of its physiologic or disease condition. The patient's key nutritional factors are the benchmark for assessing the animal's food and selecting a food. Assessment of dogs and cats to determine their key nutritional factor status should be a structured process that includes: 1) review of the history and medical record, 2) physical examination and 3) laboratory tests and other diagnostic procedures (Remillard and Thatcher, 1989). These first three steps determine the patient's physiologic state and medical diagnosis and are the basis for the fourth step, which is the determination of the key nutritional factors and the estimation of their target levels.

Obtain an Accurate History and Review the Medical Record

Obtaining the animal's history and reviewing the medical record help determine the nutritional status of the patient. The signalment is part of the history and defines the patient's physiologic state and includes: 1) species, 2) breed, 3) age, 4) gender, 5) reproductive status, 6) activity level and 7) environment.

A complete history should also include questions about the pet's weight and therapies (medical, surgical, etc.) that may affect appetite, nutrient metabolism or both. An accurate

description of the current feeding plan, including the animal's food, eating and drinking habits and feeding methods should be obtained from the client. Intakes of treats and nutritional supplements should be recorded.

Review of the medical record provides objective historical information and documents the pet's previous health status, health maintenance procedures that were performed and medications that were prescribed. Veterinarians should evaluate this information to determine if any of these factors are related to the animal's current nutritional status. This review permits early nutritional intervention in the treatment of established malnutrition (under- or overnutrition) and in the prevention of malnutrition in individuals at risk (**Box 1-1**).

A patient's food is usually changed because of altered requirements or alterations in nutrient intake, digestion, absorption, metabolism, excretion or a combination of these factors. Knowledge of normal nutritional physiology and of diseases and their nutritional pathophysiology is important to identify patients at risk for malnutrition. The history and medical record are tools to help identify these risks.

Conduct a Physical Examination

A thorough physical examination can help define an animal's nutritional status and identify diseases that may have a nutritional component. Physical findings should be recorded in the patient's medical record. Veterinarians should examine each body system for problems that are responsive to nutritional intervention. An animal's body condition will likely reflect abnormalities of major organ systems.

Body condition can be subjectively assessed by a process called body condition scoring. In general, this process assesses a patient's fat stores and, to a lesser extent, muscle mass. Fat cover is evaluated over the ribs, down the topline, around the tailbase and ventrally along the abdomen. Body condition score (BCS) descriptors have been developed with respect to the species (dogs and cats) and age of the patient (**Figures 1-2** and **1-3**). Score descriptors vary due to the structural differences between species and between young and adult pets. The scores range from 1 to 5 with 1 being very thin and 5 being grossly obese. A body condition score of 3/5 is generally referred to as being ideal. An "ideal" body condition, however, depends on the dog's or cat's lifestage, lifestyle and intended use. For example, a BCS of 2/5 to 2.5/5 may be desirable for a racing greyhound, whereas a BCS of 3.5/5 might be better for a pregnant queen at the end of its first trimester to help support the upcoming lactation. A BCS of 2.5/5 to 3/5 is probably ideal for most mature dogs and cats for optimal health and resultant longevity. Thus, overall, an ideal BCS is a range of numbers rather than simply a "3/5."

Body condition scoring reasonably estimates an animal's body composition. Studies assessing scorer repeatability and variations between scorers have found agreement between 80 to 90% of the measurements (LaFlamme et al, 1994; Graham et al, 1982; Croxton and Stollard, 1976; Burkholder, 1994). Research with cats found a correlation of 0.9 or higher between BCS and body composition predicted from morphometry (LaFlamme, 1993). Veterinarians should routinely assign BCSs, obtain body weights and record both in the medical record.

The patient's body weight can be compared with breed standards (Appendix 14) or with the animal's previous body weight from the medical record. The patient's pre-illness body weight or usual body weight during health can serve as a standard for determining the effect of illness on body weight. A history of rapid weight loss and a reduced BCS may indicate a catabolic condition with a marked loss of lean tissue, dehydration or both. A history of progressive weight gain and an increased BCS may indicate an anabolic condition with an excessive accumulation of fat, water or both.

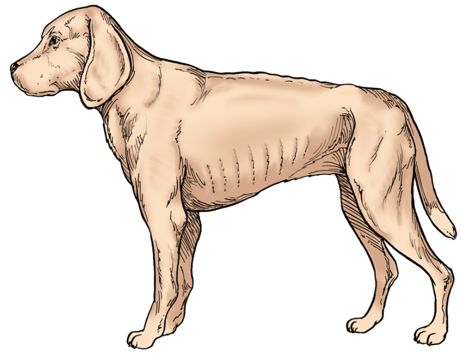
Box 1-1. Malnutrition Includes Excesses.

Malnutrition is defined as any disorder of nutrition with inadequate or unbalanced nutrition. Many veterinarians and animal owners think only of nutritional deficiencies when they hear the term malnutrition. Muscle wasting and a distended abdomen in a starving third-world child or a heavily parasitized puppy is often our first mental image of malnutrition. In first-world societies, however, malnutrition is usually due to overnutrition or excessive intake of nutrients. Obesity due to consumption of excessive levels of fat and calories is a common example of malnutrition in people and their pets. Another example of malnutrition due to unbalanced nutrition is developmental orthopedic disease seen in rapidly growing large- and giant-breed puppies as a result of excessive calcium and energy intake. Malnutrition due to either nutrient deficiencies or excesses can be harmful to dogs and cats.

Conduct Necessary Laboratory Tests and Other Diagnostics

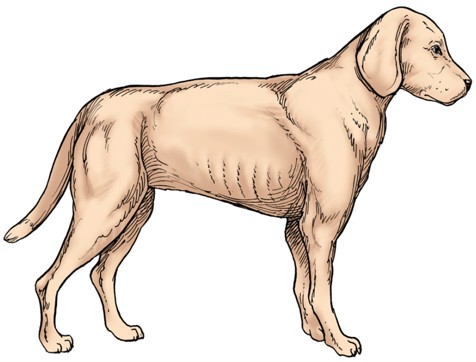
No single laboratory test or other diagnostic procedure can accurately assess a patient's nutritional status. Routine complete blood counts, urinalyses and biochemistry profiles, however, can provide insight into the presence of metabolic disorders and other diseases. Albumin concentration, lymphocyte count, packed cell volume and serum total protein values may serve as general indicators of nutritional status. Other chapters in this textbook will discuss specific laboratory tests and other diagnostic procedures that may help assess healthy and sick patients.

Serum protein concentrations in people provide an estimate of long- and short-term changes in nutritional status and correlate with morbidity and mortality (Giner et al, 1996). For example, low serum albumin concentrations may indicate protein depletion due to chronic undernutrition or protein loss. Shorter half-life serum protein concentrations such as prealbumin, transferrin, retinol-binding protein and fibronectin are used in human medicine to assess short-term changes in nutritional status. However, these tests have not been routinely available in veterinary medicine. Although not used widely, serum creatine kinase concentrations are elevated in anorectic cats and decline after 48 hours of nutritional support. Serum



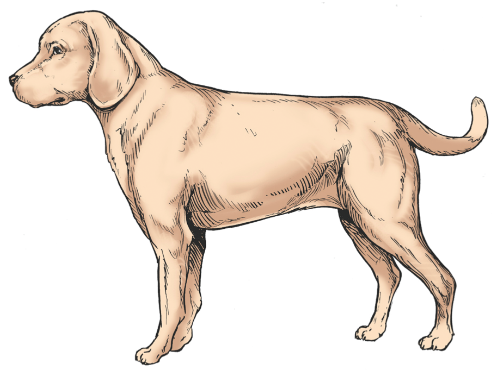
BCS 1. Very thin ▶

The ribs are easily palpable with no fat cover. The tailbase has a prominent raised bony structure with no tissue between the skin and bone. The bony prominences are easily felt with no overlying fat. Dogs over six months of age have a severe abdominal tuck when viewed from the side and an accentuated hourglass shape when viewed from above.



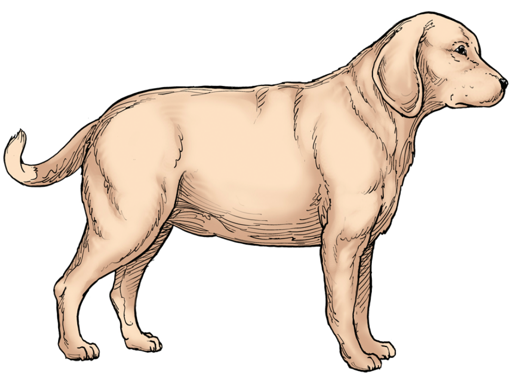
◀ BCS 2. Underweight

The ribs are easily palpable with minimal fat cover. The tailbase has a raised bony structure with little tissue between the skin and bone. The bony prominences are easily felt with minimal overlying fat. Dogs over six months of age have an abdominal tuck when viewed from the side and a marked hourglass shape when viewed from above.



BCS 3. Ideal ▶

The ribs are palpable with a slight fat cover. The tailbase has a smooth contour or some thickening. The bony structures are palpable under a thin layer of fat between the skin and bone. The bony prominences are easily felt under minimal amounts of overlying fat. Dogs over six months of age have a slight abdominal tuck when viewed from the side and a well-proportioned lumbar waist when viewed from above.



◀ BCS 4. Overweight

The ribs are difficult to feel with moderate fat cover. The tailbase has some thickening with moderate amounts of tissue between the skin and bone. The bony structures can still be palpated. The bony prominences are covered by a moderate layer of fat. Dogs over six months of age have little or no abdominal tuck or waist when viewed from the side. The back is slightly broadened when viewed from above.

BCS 5. Obese ▶

The ribs are very difficult to feel under a thick fat cover. The tailbase appears thickened and is difficult to feel under a prominent layer of fat. The bony prominences are covered by a moderate to thick layer of fat. Dogs over six months of age have a pendulous ventral bulge and no waist when viewed from the side due to extensive fat deposits. The back is markedly broadened when viewed from above. A trough may form when epaxial areas bulge dorsally.

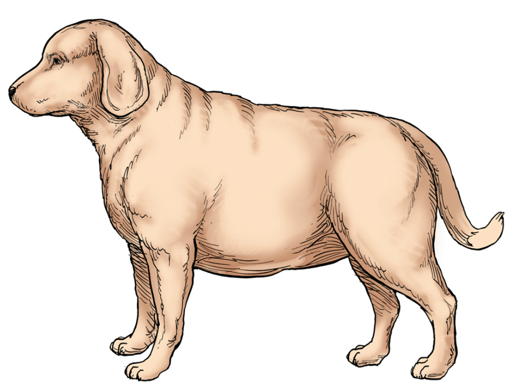


Figure 1-2. Body condition score (BCS) descriptors for dogs in a five-point system.

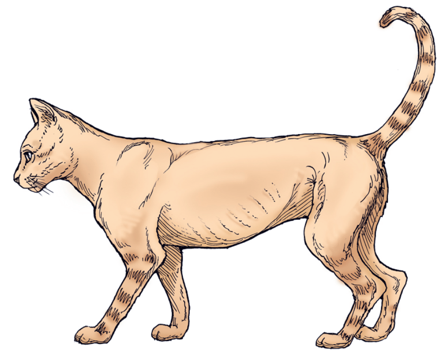
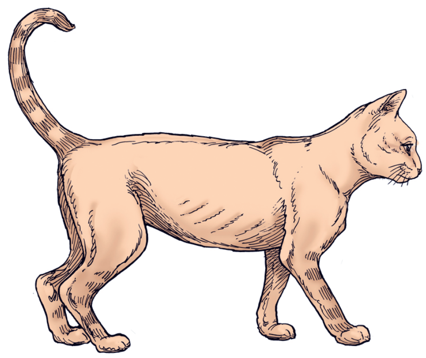
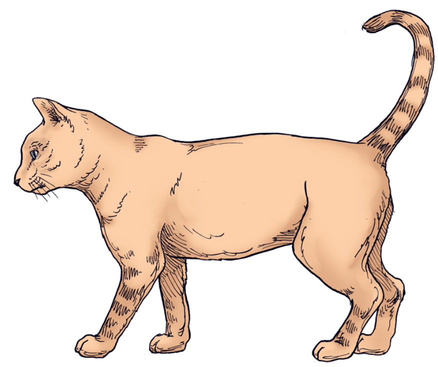
BCS 1. Very thin ▶
The ribs are easily palpable with no fat cover. The bony prominences are easily felt with no overlying fat. Cats over six months of age have a severe abdominal tuck when viewed from the side and an accentuated hourglass shape when viewed from above.

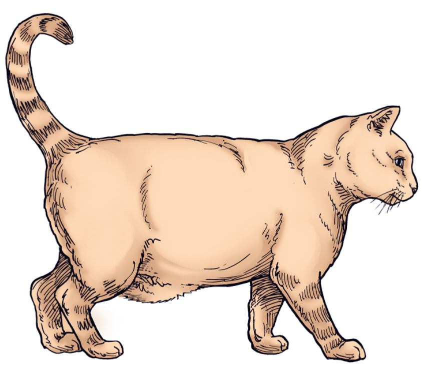




◀ **BCS 2. Underweight**
The ribs are easily palpable with minimal fat cover. The bony prominences are easily felt with minimal overlying fat. Cats over six months of age have an abdominal tuck when viewed from the side and a marked hourglass shape when viewed from above.

BCS 3. Ideal ▶
The ribs are palpable with a slight fat cover. The bony prominences are easily felt under a slight amount of overlying fat. Cats over six months of age have an abdominal tuck when viewed from the side and a well-proportioned lumbar waist when viewed from above.





◀ **BCS 4. Overweight**
The ribs are difficult to feel with moderate fat cover. The bony structures can still be palpated. The bony prominences are covered by a moderate layer of fat. Cats over six months of age have little or no abdominal tuck or waist when viewed from the side. The back is slightly broadened when viewed from above. A moderate abdominal fat pad is present.

BCS 5. Obese ▶
The ribs are very difficult to feel under a thick fat cover. The bony prominences are covered by a moderate to thick layer of fat. Cats over six months of age have a pendulous ventral bulge and no waist when viewed from the side due to extensive fat deposits. The back is markedly broadened when viewed from above. A marked abdominal fat pad is present. Fat deposits may be found on the limbs and face.

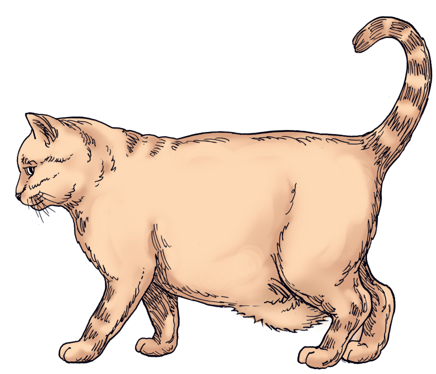


Figure 1-3. Body condition score (BCS) descriptors for cats in a five-point system.

creatine kinase concentrations may become a useful marker for assessing and monitoring nutritional status in animals (Fascetti et al, 1997).

Results of a single measurement or test must be interpreted cautiously, because over- or under-hydration can alter concentrations of these proteins. Diagnostics such as radiography and ultrasonography, including echocardiography, may be indicated to further characterize the health status of patients. Results of laboratory and diagnostic tests should always be viewed in the context of findings from the history, physical examination and the patient's medical record.

Determine the Key Nutritional Factors and Their Target Levels

The concept of key nutritional factors is fundamental to the practical application of clinical nutrition used in this text. However, to better understand the basis for this concept, a brief review of nutrient requirements vs. nutrient allowances precedes the description of key nutritional factors.

Researchers traditionally have used normal dogs and cats to determine nutrient requirements. In the United States, the primary sources for minimum nutrient requirements of healthy dogs and cats are the National Research Council (NRC) Nutrient Requirement bulletins published in 1985 and 1986, respectively and recently updated as a combined edition (NRC, 1985; NRC, 1986; NRC, 2006). The requirements published in 1985 and 1986 were determined by feeding dogs and cats purified diets rather than commercially available foods. These NRC values, therefore, were minimum nutrient requirements that had to be extrapolated to the types of foods normally fed to dogs and cats. In 1993 and 1994, the Association of American Feed Control Officials (AAFCO) published recommended nutrient profiles for dog and cat foods, respectively (Nutrient Profiles for Dog Foods, 1993; Nutrient Profiles for Cat Foods, 1994). These nutrient profiles have been republished yearly and are the official source for nutrient profiles for commercial dog and cat foods in the United States.

The AAFCO nutrient profiles include safety factors similar to those in the recommended dietary allowances (RDAs) that have been established for people (NRC, 1989). These safety factors compensate for changes in a food's nutrient availability due to ingredient and processing variables and for individual differences in nutrient requirements within dog and cat populations. Because of these safety factors, the term "allowance" is better suited to describe AAFCO values than "requirements." AAFCO values are adequate to meet the known nutrient needs of almost all healthy dogs and cats and are a better source of feeding recommendations for most dogs and cats than are minimum requirements. The earlier NRC bulletins published for dogs and cats in 1974 and 1978, respectively, also included safety factors and therefore were actually "allowances." Besides recommendations for lower limits, AAFCO prescribes upper limits for certain nutrients with the obvious implication that some nutrient excesses can be harmful. As with RDAs for people, AAFCO allowances for pet food nutrient profiles are not necessarily optimal.

Instead of separate dog and cat editions, the recently updated NRC includes information about both species. It provides nutrient requirements in three formats: minimum requirement, adequate intake and recommended allowance (2006). Minimum requirement is defined as the minimal concentration or amount of a maximally available nutrient that will support a defined physiologic state. Adequate intake is defined as the concentration or amount of a nutrient demonstrated to support a defined physiologic state when no minimum requirement has been demonstrated. Recommended allowance is defined as the concentration or amount of a nutrient in a diet formulated to support a given physiologic state. The recommended allowance is based on the minimum requirement with consideration for the normal variation in bioavailability of the nutrient in typical-quality feed ingredients. If no minimum requirement is available, the recommended allowance is based on adequate intake. Like the old editions, the more recent NRC edition also includes safe upper limit levels for a nutrient when data are available (NRC, 2006).

Neither NRC nor AAFCO has established nutrient profiles for geriatric dogs and cats and those with specific disease processes.

Key Nutritional Factors

Key nutritional factors encompass nutrients of concern and other food characteristics. The concept of nutrients of concern greatly simplifies the approach to clinical nutrition because most commercial pet foods sold in the United States provide at least AAFCO allowances of all nutrients. Thus, if a commercial food is fed, veterinarians and their health care teams need only to understand and focus on delivering the target levels for a few nutrients (nutrients of concern) rather than the 40 plus nutrients currently recognized for cats and dogs (NRC, 2006).

Nutrients of concern encompass nutritional risk factors for disease treatment and prevention as well as nutrients that are key to optimizing normal physiologic processes such as growth, gestation, lactation and physical work. The following elements must be considered in determining key nutritional factors and their target levels: 1) the patient's lifestage and physiologic state, 2) environmental conditions such as temperature, housing and pet-to-pet competition, 3) the nature of any disease or injury, 4) the known nutrient losses through skin, urine and gastrointestinal tract, 5) the interactions of medications and nutrients, if applicable, 6) the known capacity of the body to store certain nutrients and 7) the interrelationships of various nutrients.

Besides requiring specific levels of certain nutrients, some patients have other food-related needs. These needs might include management of acute or chronic systemic acid-base balance, maintenance of a specific urinary pH range, certain kibble texture, a specific range of digestibility or osmolality, avoidance of certain protein sources and presence of specific ingredients. Some nutrients and ingredients that are added to foods provide other non-nutritive functions that can be important to health and performance. Thus, specific food characteristics or factors other than the nutrient content may

be important to consider. Information about such food characteristics should be available from product manufacturers. Pet food labels contain addresses and toll-free phone numbers of the manufacturer.

Chapters 12 through 24 determine and list key nutritional factors and their target levels for healthy dogs and cats. The key nutritional factors and their target levels for dogs and cats with specific disease complexes can be found in Chapters 25 through 68. For convenience, these chapters also contain levels of key nutritional factors in commercial foods typically marketed for use in patients with various medical conditions. Regardless of which nutrients are considered as key nutritional factors, the reader should understand the various ways nutrient needs are expressed. **Box 1-2** describes the methods and units for expressing an animal's nutrient needs.

In summary, the primary goal of patient assessment is to establish the patient's key nutritional factor needs. The key nutritional factors are the benchmark for assessing the adequacy of a patient's food. Additionally, the results of patient assessment are the basis for determining an appropriate feeding method.

FEEDING PLAN

The feeding plan can be developed after the key nutritional factor needs have been determined. The feeding plan includes what food or foods to feed and which feeding methods to use. Thus, the first step is to assess the current food and to select the best food to feed.

Assess and Select the Food

The primary components of food assessment should include: 1) evaluation of the current food's key nutritional factor content relative to the patient's needs (determined during Patient Assessment, above) and 2) determination whether or not feeding tests or clinical trials were conducted.

Determine the Food's Key Nutritional Factor Content

The key nutritional factors and their levels for most of the commonly used commercial foods are listed in the food tables in the individual chapters. In most instances, these profiles will provide the necessary information. If the key nutritional factor information of the food in question is not listed in the food tables, the manufacturer should be contacted for that information. Pet food labels contain addresses and toll-free phone numbers of the manufacturer.

Although much less convenient, there are other ways to determine most of a food's key nutritional factor content. Many, if not most, key nutritional factors are nutrients. **Box 1-3** describes various ways to determine the nutrient content of a food. **Box 1-2** describes methods and units used in expressing the nutrient content of food.

Key Nutritional Factor Comparison

Comparing a food's key nutritional factor content with the patient's needs will help identify any significant imbalances in the food being fed. If the patient's current food is adequate (key nutritional factors in balance with the patient's needs) then the food currently being fed can continue to be fed. However, if important excesses or deficiencies exist, the patient's current food must be "balanced."

There are numerous approaches to balancing foods. Some are rather extensive (**Boxes 1-4** and **1-5**). This section will review the most practical methods including: 1) food replacement and 2) simple mathematical ration balancing (Pearson square). Alternatively, veterinarians can contact a veterinary nutritionist who accepts referrals. Both the ACVN and the European College of Veterinary Nutrition (ECVN) have diplomates who do referral work. Contact the executive director of the ACVN to obtain a list of diplomates who do nutrition referral work. Contact information for the executive director can be found in the AVMA Directory or online at www.ACVN.org.

When comparing a food's key nutritional factor nutrient content with a patient's needs, methods of expressing nutrient content of the food and nutrient requirements of the animal must be compatible (same units). In this textbook, compatible units are used in the food tables for comparing the food's key nutritional factor content and the patient's target values. See **Box 1-2** for more details about how food content and animal needs are expressed.

Food Replacement

If food assessment indicates that an animal's key nutritional factor requirements are not being met, the most practical way to balance a food is to simply select a different food (i.e., one that does a better job of meeting the patient's requirements). The most likely application of this method occurs when one commercial food is substituted for another. If homemade foods are being used, they can be replaced by appropriate commercial foods or another homemade food if other recipes are available (Chapter 10).

The process is straightforward and simple. The nutrient content of other foods is evaluated to see which food most closely meets the animal's requirements. Assuming comparable palatability, the most acceptable food replaces the previous food. **Case 1-3** demonstrates food replacement. This process is greatly facilitated by the food tables in the feeding healthy dog and cat chapters (Chapters 12 through 17 for dogs and 19 through 24 for cats) and the feeding clinically ill patient chapters (Chapters 25 through 68). These tables list the key nutritional factor targets and the key nutritional factor contents of commercial foods commonly marketed for patients at various lifestages and those having specific diseases.

Changing foods for most healthy dogs and cats is of minor consequence. Some owners switch their pets from one food to another daily. Most dogs and cats tolerate these changes. However, vomiting, diarrhea, belching, flatulence or a combination of signs may occur with sudden, rapid switching of foods, probably because of ingredient differences. It is prudent, therefore, to recommend that owners change their pet's food over the course of at least three days. A seven-day period is even

Box 1-2. Typical Methods and Units for Expressing a Patient's Nutrient Needs and a Food's Nutrient Content and Methods for Conversion to the Same Units.

When comparing a patient's nutrient requirements to a food's nutrient content to determine adequacy of the food, the same quantifying units must be used to make the comparison meaningful. The units used for expressing food nutrient content and patient nutrient requirements are compared in **Table 1**.

PATIENT'S NUTRIENT NEEDS

The three methods for expressing an animal's nutrient needs are: 1) dry matter, energy density defined and 2) energy basis and 3) absolute basis.

Dry matter basis, energy density defined is the percentage or quantity of a nutrient in the food's dry matter that is needed by the animal. This measure is the most common method of expressing an animal's nutrient needs. It describes what is required in a food and indicates an animal's nutrient needs. Dry matter refers to that weight of the food remaining when the water content is subtracted. (**Tables 2** and **3** demonstrate methods of calculating dry matter.) Dry matter values are most meaningful if the energy density of the food's dry matter is specified because most animals eat, or are fed, to meet their energy requirements.

Energy basis refers to the quantities of nutrients per animal's energy requirement. Units of measure are typically nutrient amounts per 100 kcal or 1 MJ metabolizable energy (ME). Occasionally an animal's protein, fat and digestible (soluble) carbohydrate needs are expressed as a percentage of the animal's total energy needs (**Table 4**).

Absolute basis refers to the unit measure (usually weight) of a nutrient that is needed by an animal in a 24-hour period. These needs are expressed as quantities per kg of body weight per day.

FOOD'S NUTRIENT CONTENT

Although there are three methods for expressing an animal's nutrient needs, there are four methods for expressing a food's nutrient content: 1) as fed basis, 2) dry matter basis, 3) dry matter basis, energy density defined and 4) energy basis.

As fed basis simply refers to the quantity of nutrients in a food as it is fed. This method ignores moisture and energy content. The units of measure are percentages or quantities of nutrients per unit weight (kg) of food.

Dry matter is that weight of the food remaining after the water content has been subtracted from the as fed amount. Dry matter basis, therefore, is the amount of nutrients in the food's dry matter. It accounts for variability in water content but not variability in energy density. The units of measure are percentages or quantities of nutrients per unit weight (kg) of food dry matter. The usefulness of dry matter basis is limited because the energy density of individual foods can vary widely. This consideration will be further explained below (dry matter basis, energy density defined). **Tables 2** and **3** show the conversion from as fed basis to dry matter basis.

Dry matter basis, energy density defined is the same as dry matter but specifies a food's energy density, thus accounting for potential variability. The units of measure are the same as those used with dry matter basis but are further qualified by expressing the energy density of the food. For example, recommended nutrient values for canine and feline foods are based on an energy density of 3.5 and 4.0 kcal ME/g (14.64 and 16.74 kJ ME/g) of food dry matter, respectively. Dry matter basis, energy density defined is probably the most widely used method of expressing a food's nutrient content.

Energy basis refers simply to the amount of nutrients per 100 kcal or 1 megajoule ME of food. Occasionally, a food's protein, fat and digestible carbohydrate content is expressed as a percentage of the food's total energy content (**Table 4**).

Both dry matter basis, energy density defined and energy basis are reasonably accurate methods of expressing a food's nutrient content. However, even these methods have limitations.

Animals require less food to meet their energy requirements when foods with higher energy densities are fed. Under these circumstances, the concentrations of the other nutrients in the food need to be increased proportionately, to ensure the animal receives the minimum amount of all nutrients needed in a smaller amount of food.

When foods with lower energy densities are fed, a lower concentration of the other nutrients may be required, assuming the dog or cat could eat, or would be fed, enough of the food to meet its energy requirement. In these instances, the nutrient levels need to be decreased proportionately, so that the animal would not receive toxic levels of nutrients in a larger amount of food.

Foods of low energy density, particularly those low in fat and high in fiber, are usually intended for animals that have a tendency to be overweight. These animals should be fed fewer calories than animals with normal body weights and body condition scores. The nutrient content of foods in this category should not be corrected for their lower energy density. During weight loss, there is a disproportionately lower energy intake relative to the non-energy nutrients. Although these animals require fewer calories to lose weight, as far as is known, their requirement for other nutrients has not changed. Thus, they are essentially being fed the same amount of dry matter but fewer calories. On an energy basis (g/kcal), the food's nutrient values will be higher than if the animal had normal energy requirements.

On the other end of the spectrum are situations in which foods of high energy density are fed to animals with an unusually high need for energy-providing nutrients relative to non-energy nutrients. A working sled dog is an example. In this case, on an energy basis, the food's non-energy nutrient content could be lower than if the animal had normal energy needs.

CONVERTING TO SAME UNITS

Comparing food on an as fed basis to an animal's requirement on an absolute basis requires: 1) mathematical calculation and 2) either the energy density of the food or the amounts of the energy-supplying nutrients in the food. **Table 5** provides an example of such a calculation.

When using dry matter basis, energy density defined to compare foods or to compare foods with animal requirements, the energy densities must be the same for the comparisons to be meaningful. **Table 6** shows how to convert to the same energy density. In some cases it will be desirable to convert food nutrient content on an as fed basis to dry matter basis, energy density defined (**Case 1-1**).

Box 1-2 continued

Table 1. Comparisons of methods to express food nutrient content and animal requirements/allowances for nutritional assessment of food.

Food nutrient content (units)
As fed basis (% or amount of nutrient/kg food)
Dry matter basis (% or amount of nutrient/kg of food dry matter)
Dry matter basis, energy density defined (% or amount of nutrient/kg of food dry matter, at a specified energy density)
Energy basis (amount of nutrient/100 kcal or 1 megajoule ME of food's energy content)

Dog/cat requirements/allowances (units)
Absolute basis (amount of nutrient/kg animal)
Dry matter basis, energy density defined (% or amount of nutrient/kg of food dry matter, at a specified energy density)
Energy basis (amount of nutrient/100 kcal or 1 megajoule ME of animal's energy requirement)

Table 2. How to convert from as fed basis to dry matter basis.

Step 1. Obtain the food's dry matter content by subtracting the water content from the as fed amount of the food.

Example A: If a moist food contains 75% water, 25% of the food is dry matter:
100% as fed – 75% water = 25% food dry matter

Example B: If a dry food contains 10% water, 90% of the food is dry matter:
100% as fed – 10% water = 90% food dry matter

Step 2. Convert the percentage as fed nutrient content of the food to a dry matter basis by dividing the percentage of the nutrient content on an as fed basis by the percentage dry matter.

Example A: If the moist food above contained 10% protein on an as fed basis, on a dry matter basis it would contain 40% protein:
10% protein as fed basis ÷ 25% dry matter = 40% protein dry matter basis

Example B: If the dry food above contained 18% protein on an as fed basis, on a dry matter basis, it would contain 20% protein:
18% protein as fed basis ÷ 90% dry matter = 20% protein dry matter basis

Table 3. Shorthand method for converting from as fed basis to dry matter basis.

A less accurate, shorthand method for converting from an as fed basis to a dry matter basis is to simply multiply the percentage nutrient content on an as fed basis by four for moist foods or add 10% for dry foods. This method is based on the assumption that moist foods contain approximately 75% water and dry foods contain approximately 10% water. Check the guaranteed analysis on the product label.

Example A: If a moist food contains 10% protein on an as fed basis, on a dry matter basis it would contain 40% protein:
10% protein as fed basis x 4 (factor for moist foods) = 40% protein dry matter basis*

Example B: If a dry food contains 18% protein on an as fed basis, on a dry matter basis it would contain 20% protein:
18% protein as fed basis + 10% (factor for dry food) = approximately 20% protein dry matter basis*

*Compare these results with those obtained in **Table 2** for moist and dry foods with the same moisture content.

Table 4. How to determine the protein, fat and carbohydrate content as a percent of the food's total energy content.

Practically speaking, the available energy in foods for dogs and cats is provided by digestible carbohydrates, protein and fat; dietary fiber provides little if any energy to these species. Occasionally an animal's need for, or a food's content of, any or all of these three nutrients is expressed in terms of the fraction of the total energy they provide. The method is simply another way to express the relative amounts of these three nutrients. The following example demonstrates how to calculate the percentage of kcal and kJ from protein, fat and digestible carbohydrate of a pet food.

Nutrient	%	kcal/g of nutrient	kJ/g of nutrient	kcal/g of food**	kJ/g of food**
Protein	22	3.5*	14.64*	0.77	3.22
Fat	9	8.5*	35.56*	0.77	3.20
Digestible carbohydrate	51	3.5*	14.64*	1.79	7.47
Total	-	-	-	3.33	13.89

% kcal from protein = 0.77 ÷ 3.33 = 23.1
% kJ from protein = 3.22 ÷ 13.89 = 23.2
% kcal from fat = 0.77 ÷ 3.33 = 23.1
% kJ from fat = 3.20 ÷ 13.89 = 23.0
% kcal from digestible carbohydrate = 1.79 ÷ 3.33 = 53.8
% kJ from digestible carbohydrate = 7.47 ÷ 13.89 = 53.8

*"Modified" Atwater values.
See **Box 1-6, Table 3 for a more detailed explanation for calculation of energy density of pet foods.

Table 5. Example illustrating the mathematical process required to compare a food's nutrient content on an as fed basis to an animal's needs on an absolute basis.

Example: If an intact male cat weighing 4.5 kg requires 31 mg of magnesium (Mg) per day (recommended allowance) and the cat's food as fed contains 0.12% Mg, 20% fat, 35% protein and 27% digestible carbohydrate, does the cat receive adequate amounts of Mg? The answer is calculated as follows:

1) First find out how much food is to be fed. Because animals are fed to meet their energy requirements, the first step is to determine the energy density of the food, if it is unknown. This is done by calculating the amount of energy provided by each of the energy-supplying nutrients. Using the "modified" Atwater energy values of 3.5, 8.5 and 3.5 kcal metabolizable energy (ME)/g (14.64, 35.56 and 14.64 kJ ME/g) for protein, fat and digestible carbohydrate respectively (See **Box 1-6**, **Table 2**), multiply the percentage of each nutrient in the food (as fed basis) by 1 g of food. Then multiply the answer by the energy density of each nutrient. The sum of the three separate energy values is the energy density of the food.

In kcal ME/g of food:
35% protein x 1 g food x 3.5 kcal ME/g
= 1.23 kcal ME/g from protein

20% fat x 1 g food x 8.5 kcal ME/g
= 1.70 kcal ME/g from fat

27% digestible carbohydrate x 1 g food x 3.5 kcal ME/g
= 0.95 kcal ME/g from carbohydrate

Sum
3.88 kcal ME/g food (total)

Box 1-2 continued

2) The next step is to determine the daily energy requirement (DER) of the animal. Multiply the formula for resting energy requirement (RER) by the appropriate modifier for maintenance of an adult cat (**Box 6, Table 1**).

RER (kcal ME/day) = $70(BW_{kg})^{0.75}$
RER (kJ ME/day) = $293(BW_{kg})^{0.75}$

= $70(4.5\ BW_{kg})^{0.75}$ = 216 kcal ME/day
= $293(4.5\ BW_{kg})^{0.75}$ = 904 kJ ME/day

Modifier for feline adult maintenance = 1.4 x RER = DER
Modifier for feline adult maintenance = 1.4 x RER = DER

DER (kcal ME/day) = 1.4 x 216 kcal ME = 302 kcal ME
DER (kJ ME/day) = 1.4 x 904 kJ ME = 1,266 kJ ME

3) Determine the amount of food to be fed by dividing the cat's energy requirement by the energy density of the food.
302 kcal ME/day ÷ 3.88 kcal ME/g = 78 g food/day
1,266 kJ ME/day ÷ 16.18 kJ ME/g = 78 g food/day

4) Determine the amount of Mg provided by the food by multiplying the amount of food fed by the percentage of Mg in the food.
78 g food x 0.12% Mg = 0.090 g (90 mg) Mg
The amount of Mg provided by the food (90 mg) compared with the animal's requirement of 31 mg indicates more than an adequate (threefold) amount of Mg.

Table 6. How to convert to the same energy density.

Correcting energy densities in order to make valid nutrient comparisons, either between foods or between a food and an animal's requirement, is based on the assumption that the relationship between nutrient content and energy density is directly proportional. A simple ratio can be established to generate a multiplier that converts the units of the animal's requirements to those of the food; then the animal's requirement and the food's nutrient content can be compared. The multiplier is obtained by dividing the energy density of the food by the requirement energy density.

Example: Is a food that provides 0.72% potassium and 4 kcal (16.74 kJ)/g, on a dry matter (DM) basis, adequate for canine adult maintenance?
1) The requirement for potassium is 0.6% DM basis in an adult dog food that provides 3.5 kcal (14.64 kJ)/g.

2) Convert the requirement to the same energy density as the food by generating the multiplier.
Multiplier
= Food energy density ÷ requirement energy density
= 4.0 kcal (16.74 kJ)/g DM ÷ 3.5 kcal (14.64 kJ)/g DM
= 1.14

3) To obtain the equivalent nutrient requirement for a food providing 4 kcal (14.74 kJ)/g, on a DM basis, multiply the requirement by the multiplier.
Equivalent nutrient requirement
= 1.14 x 0.06% potassium
= 0.68% potassium, 4 kcal (14.74 kJ)/g, on a DM basis

4) The amount of potassium in the food (0.72%) is compared to the animal's equivalent nutrient requirement (0.68%) and is found to be adequate.

5) The multiplier obtained above (1.14) can be used to convert the other nutrient requirements to the same basis as the food to compare the adequacy of their levels, if desired.

After the energy densities of the food and the animal's needs are converted to the same units, the comparison is simple.

better, as owners increase the proportion of new food and decrease the proportion of old food (**Table 1-1**). Nearly all pets readily tolerate a seven-day transition period. A much longer transitional period is recommended in cases in which the food change is known to be significant, the pet has demonstrated a poor tolerance to such changes in the past or food refusal is expected (**Table 1-1**). For example, a long transition schedule is likely to be needed for an old cat recently diagnosed with kidney disease when the food must be switched from a highly palatable grocery "gourmet" food to an appropriate veterinary therapeutic food.

Table 1-1. Recommended short- and long-term food transition schedules for dogs and cats.

Short schedule*	Long schedule**		Food percentages	
Dogs and cats (days)	Dogs (days)	Cats (weeks)	Previous food	New food
1,2	1-3	1	75	25
3,4	4-6	2	50	50
5,6	7-9	3	25	75
7	10	4	0	100

*Recommended for most healthy dogs and cats.
**Recommended for situations in which the food change is known to be significant, the dog or cat has demonstrated low tolerance to such changes in the past or food refusal is anticipated.

Simple Mathematical Ration Balancing (Pearson Square)

The Pearson square is another useful diet balancing tool. This handy method can be used to combine any two foods, supplements or ingredients to yield a mixture with a desired nutrient content. **Figure 1-4** shows how the Pearson square method is used to balance a diet. Here's how to use the Pearson square:

- A small square is drawn and the desired nutrient concentration of the proposed mixture is written in the middle of the square.
- The nutrient concentration of one component of the mixture is written at the upper left corner of the square.
- The nutrient concentration of the other component of the mixture is written at the lower left corner of the square.
- The nutrient values at the corners are subtracted from those in the center of the square. The smaller number is always subtracted from the larger and the differences written diagonally at the right corners of the square.
- The differences are added together and the sum is written below each difference as the denominator of a fraction.
- The fractions are converted to percentages. These percentages are the proportion of each component of the mixture in the corners directly to the left. When combined in those percentages, the constituent components will yield a mixture

Box 1-3. Four Ways to Determine the Nutrient Content of a Food.

The nutrient content of a food can be determined one of four ways:

1) Obtain the target values from the manufacturers of commercially prepared foods.
2) Order a laboratory analysis.
3) Calculate the content based on the published values for the ingredients.
4) Use the information found in the label guaranteed analysis and typical analysis (Chapter 9).

Only the first three are recommended because of the severe limitations of label guarantees and typical analyses.

Most pet food manufacturers, upon request, will supply target values for the nutrient content of their products. This approach is simple and inexpensive. Although these values usually reflect actual average nutrient levels, occasionally they vary significantly from actual values, thus this method is not always accurate. No laws govern the accuracy of target nutrient levels. In most instances, however, these values will be adequate.

The basic laboratory analysis is the proximate analysis (Figure 5-3), which provides the percentage moisture, crude protein, crude fat, ash and crude fiber in a food and allows calculation of the digestible carbohydrate fraction (also referred to as the nitrogen-free extract [NFE]). Most commercial laboratories will also conduct more expansive nutrient analyses including amino acids, fatty acids, minerals, vitamins and various fiber fractions. Analysis of food samples for nutrient content is very straightforward and usually accurate. Limitations include proper sampling, the potential issue of analytical variance for certain nutrients and the expense and time involved for a complete analysis.

Calculations require nutrient contents of ingredients and a formula for the food in question. Published average nutrient contents of ingredients can be obtained from NRC nutrient requirement booklets and listings of average nutrient contents of human foods. This approach would likely be used for determining the nutrient content of a homemade food. One limitation of this method is the time and knowledge required to do such calculations. Another limitation is accuracy (i.e., how closely the published average nutrient content of the ingredients represents the ingredient's actual nutrient content). Values can vary markedly.

The use of guaranteed analyses (United States and Canada) or typical analyses (Europe) listed on the label of commercially prepared foods as a means of establishing nutrient content has severe limitations:

In the case of guaranteed analysis, the quantities listed are minimums or maximums only.

It is only necessary to list a fraction of the nutrients in the food (e.g., guaranteed analysis only requires crude protein, crude fat, crude fiber and moisture; typical analysis only requires crude protein, crude fat, crude fiber, ash and moisture if more than 14%).

Guaranteed analysis values are not the nutrient content of the food. They are a guarantee by the manufacturer that the food contains not more, or less, than the stated amount. Label guarantees can provide a general idea of the nutrient content for a limited number of nutrients and the classification of the food (growth-type food, maintenance food, etc.).

Use caution when using guaranteed and typical analyses to compare specific nutrient levels between foods. When such comparisons are made, be sure to compare similar forms of foods (i.e., dry to dry or moist to moist). Label guarantees are listed on an as fed basis. Different forms of food can be compared if the foods are converted to the same moisture or energy content (**Tables 2, 3** and **6** in **Box 1-2**).

Box 1-4. Computerized Food Evaluation/Balancing Programs.

There are two categories of food evaluation/balancing software programs listed below. The category entitled "Veterinary Clinical Nutrition Software" is a special application designed for use by veterinarians and veterinary nutritionists. It contains commercial pet food and human food nutrient data that enable users to select foods and make feeding and weight-loss feeding plans for individual patients. Additional tools for automatic formulation of homemade pet foods from recipes are also available.

A cautionary reminder: software programs are tools intended to make the mathematical work of food evaluation/balancing/formulation easier and faster. Their accuracy depends entirely on the accuracy of the databases from which they are working and they do not account for nutrient availability regarding ingredient sourcing and cooking, nor do they ensure a palatable food.

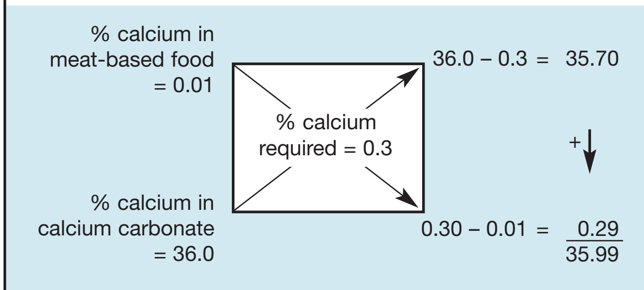
Box 1-5. Food Formulation and Extensive Food Balancing.

It is not the intention of this book to teach complete food formulation or extensive food balancing. Few practitioners need to know how to formulate balanced foods from scratch. Nutrient requirement information is readily available; however, accurate/relevant ingredient nutrient databases, an understanding of the availability of nutrients in various ingredients, knowledge of the effect of cooking on nutrient availability and knowledge of all of these variables on palatability are complex issues. Such information is not readily available, and usually requires assimilation by a team of experts, including veterinarians, nutritionists and food scientists to ensure proper formulation of complete and balanced foods.

Fortunately, numerous complete pet food options are readily available from commercial pet food manufacturers. Many homemade food recipes have also been published. Be sure to obtain homemade food recipes from reliable sources as discussed in Chapter 10.

As an example, the Pearson square can be used to solve the following problem: How much calcium carbonate containing 36% calcium must be added to a meat-based food to increase its calcium content from 0.01% to 0.3% on an as fed basis? Assume you are making 5 kg of the mixture. The problem is set up and worked as follows:



The final step converts fraction to percentages by dividing the numerator of the fractions by the denominator and multiplying by 100.

Meat-based food: (35.70 ÷ 35.99) x 100 = 99.19%

Calcium carbonate: (0.29 ÷ 35.99) x 100 = 0.81%

If the total mixture is 5 kg, then 99.19% (4.96 kg) should be a meat-based food and 0.81% (0.04 kg, or 40 g) should be calcium carbonate.

Figure 1-4. Example of how to use the Pearson square.

having the same concentration as the number in the center of the square.

Feeding Tests and Clinical Trials

Evaluation of the product label of commercial foods can provide feeding test information. Determining if a food has been evaluated in clinical trials is a more complicated matter and is covered in Chapter 9 and in various clinical chapters.

Whether or not commercial foods for healthy pets have been animal tested can usually be determined from the nutritional adequacy statement on the product's label (Chapter 9). Published clinical trials and case reports for commercial veterinary therapeutic foods can be obtained from the product's manufacturer. As mentioned above, manufacturers' addresses and toll-free phone numbers are found on pet food labels. However, some brands of these products have passed regulatory agency (AAFCO) prescribed feeding tests although the product label may not include such information.

Commercial pet foods that have undergone AAFCO-prescribed or similar feeding tests provide reasonable assurance of nutrient availability and sufficient palatability to ensure acceptability (i.e., food intake sufficient to meet nutrient needs). Feeding tests also provide some assurance that a product will adequately support certain functions such as gestation, lactation and growth. However, even controlled animal testing is not infallible.

In the United States, the AAFCO testing protocol for adult maintenance lasts six months, requires only eight animals per group and monitors a limited number of parameters (Chapter 9). Passing such tests does not ensure the food will be effective in preventing long-term nutrition/health problems or detect problems with prevalence rates less than 15%. Likewise, these protocols are not intended to ensure optimal growth or maximize physical activity. Besides feeding tests, AAFCO prescribes other methods to assure nutritional adequacy (Chapter 9). Thus, in addition to meeting AAFCO requirements, the food should be evaluated to ensure that key nutritional factors are at levels appropriate for promotion of long-term health or for optimal performance. Few, if any, homemade recipes have been animal tested according to prescribed feeding protocols.

Although not considered feeding tests, the personal observations of veterinarians and pet owners about the performance of specific foods or recipes can be valuable. Such experiences are, in a sense, uncontrolled feeding tests. Through experience, veterinarians and pet owners form impressions about a food's value in disease management, its ability to support various lifestages and work, its palatability, resultant stool quality and skin and coat benefits. Limitations of personal observations include the lack of controls and the length of time it takes (months to years) to gather sufficient information about a wide variety of products. Also, some commercial products are continuously improved; therefore, yesterday's product does not necessarily reflect the capabilities of the "same" product today. However, personal observations can augment controlled feeding tests such as published clinical trials and regulatory agency prescribed feeding protocols for healthy pets.

Physical Evaluation of the Food

Conducting a physical evaluation of the food is of limited usefulness. It can provide information about a food's consistency and whether or not there are extraneous materials in the food. It can also determine package quality, which may or may not reflect product quality. Physical evaluation of the food is probably most useful for assessing whether or not the food has spoiled (Chapter 11).

Box 1-6. A Method for Calculating the Food Dosage Estimate.

Calculations to estimate food dosage are based on the assumption that if a food contains the proper proportions of nutrients relative to its energy density, and is fed to meet an animal's energy requirement, then the animal's requirements for non-energy nutrients will automatically be met. This calculation has three steps:

1) Estimate the energy requirement of the animal (**Table 1**).
2) Determine the energy density of the food (kcal or kJ ME/g food, as fed basis). Sources include product labels, product literature, contacting the product's customer service department by phone or e-mail (phone numbers or e-mail addresses can often be found on the product label). The energy density can be calculated using Atwater values (**Tables 2** and **3**).
3) Divide the energy requirement of the patient by the energy density of the food to determine the daily amount to feed (food dosage).

Table 1. Calculation of energy requirements.

Calculation of daily energy requirement (DER) is based on the resting energy requirement (RER) for the animal modified by a factor to account for normal activity or production (e.g., growth, gestation, lactation, work). RER is a function of metabolic body size. RER is calculated by raising the animal's body weight in kg to the 0.75 power. The average RER for mammals is about 70 kcal/day/kg metabolic body size: RER (kcal/day) = $70(BW_{kg})^{0.75}$ or $30(BW_{kg}) + 70$ (if the animal weighs between 2 and 45 kg). RER values can also be obtained from Table 5-2, Part 3. Expressed in kJ, the average RER for mammals is about $293(BW_{kg})^{0.75}$. These energy requirements should be used as guidelines, starting points or estimates of energy requirements for individual animals and not as absolute requirements.

Feline DER

Maintenance (0.8 to 1.8 x RER)

Neutered adult	= 1.2-1.4 x RER
Intact adult	= 1.4-1.6 x RER
Inactive/obese prone	= 1.0 x RER
Weight loss	= 0.8 x RER
Senior adult (7-11 years)	= 1.1-1.4 x RER
Very old adult (>11 years)	= 1.1-1.6 x RER
Critical care	= 1.0 x RER
Weight gain	= 1.2-1.8 x RER at ideal weight

Gestation

Energy requirement increases linearly during gestation in cats. Energy intake should be increased to 1.6 x RER at breeding and gradually increased through gestation to 2 x RER at parturition. Free-choice feeding of pregnant queens is also recommended.

Lactation

Lactation is nutritionally demanding and the physiologic and nutritional equivalent of heavy work. Recommend 2 to 6 x RER (depending on number of kittens nursing) or free-choice feeding. The following table may also be used to estimate the DER of lactating queens:

Weeks of lactation	**DER**
Weeks 1-2	RER + 30% per kitten
Week 3	RER + 45% per kitten
Week 4	RER + 55% per kitten
Week 5	RER + 65% per kitten
Week 6	RER + 90% per kitten

Growth

Daily energy intake for growing kittens should be about 2.5 x RER. Free-choice feeding is recommended.

Canine DER

Maintenance (1.0 to 1.8 x RER)

Neutered adult	= 1.6 x RER
Intact adult	= 1.8 x RER
Inactive/obese prone	= 1.2-1.4 x RER
Weight loss	= 1.0 x RER
Critical care	= 1.0 x RER
Weight gain	= 1.2-1.8 x RER at ideal weight

Work

Light work	= 1.6-2.0 x RER
Moderate work	= 2.0-5.0 x RER
Heavy work	= 5.0-11.0 x RER

Gestation

First 42 days: feed as an intact adult.
Last 21 days: use 3 x RER. (This quantity may need to be increased to maintain normal body condition for some dogs, especially larger breeds.)

Lactation

Lactation is nutritionally demanding and the physiologic and nutritional equivalent of heavy work.
Recommend 4 to 8 x RER (depending on number of puppies nursing) or free-choice feeding.
The following table may also be used to estimate the DER of lactating bitches:

Puppies (No.)	**DER**
1	3.0 x RER
2	3.5 x RER
3-4	4.0 x RER
5-6	5.0 x RER
7-8	5.5 x RER
9	≥6.0 x RER

Growth

Daily energy intake for growing puppies should be 3 x RER from weaning until four months of age.
At four months of age energy intake should be reduced to 2 x RER until the puppy reaches adult size.

Table 2. Energy available from protein, fat and digestible carbohydrate (nitrogen-free extract).

Metabolizable energy (kcal/g)

Species	Crude protein	Crude fat	Digestible carbohydrate
All*	4.4 x digest.*	9.4 x digest.*	4.15 x digest.*
Dogs and cats**	3.5**	8.5**	3.5**

Metabolizable energy (kJ/g)

Species	Crude protein	Crude fat	Digestible carbohydrate
All*	18.41 x digest.*	39.33 x digest.*	17.36 x digest.*
Dogs and cats**	14.64**	35.56**	14.64**

Key: digest. = digestibility
*The most accurate value to use when the digestibility of the three nutrients is known. (Adapted from Lewis et al, 1987)
**"Modified" Atwater values (Dog Food Nutrient Profiles and Cat Food Nutrient Profiles). Association of American Feed Control Officials 2007.

Box 1-6 continued

Table 3. Example calculation of caloric density of a pet food.*

Analysis			**Metabolizable energy (kcal)**		
	%		kcal/g of nutrient**		kcal/g of food
Protein	22	x	3.5	=	0.77
Fat	9	x	8.5	=	0.77
Fiber***	3	x	0	=	0
Moisture	10	x	0	=	0
Ash***	5	x	0	=	0
Digestible carbohydrate†	51	x	3.5	=	1.79
Total					**3.32††**

Analysis			**Metabolizable energy (kJ)**		
	%		kJ/g of nutrient**		kJ/g of food
Protein	22	x	14.64	=	3.22
Fat	9	x	35.56	=	3.20
Fiber***	3	x	0	=	0
Moisture	10	x	0	=	0
Ash***	5	x	0	=	0
Digestible carbohydrate†	51	x	14.64	=	7.47
Total					**13.89††**

3.33 kcal/g (13.89 kJ/g) x amount of food/measuring cup = kcal/measuring cup†††

*As fed basis.
From **Table 1-8.
***If not available, these may be estimated as 3% fiber and 9% ash in dry foods, 1% fiber and 6% ash in soft-moist foods and 1% fiber and 2.5% ash in moist foods.
†Percent digestible carbohydrate (nitrogen-free extract) usually is not stated but can be calculated on an as fed basis by subtracting the percent protein, fat, fiber, moisture and ash from 100.
††If the nutrient percentages were obtained from the label guarantee, multiply the food's caloric density by 1.2 for moist pet foods and 1.1 for semi-moist and dry pet foods. In this example, 3.33 (13.89 kJ) x 1.1 = 3.66 kcal (15.28 kJ)/g of dry food.
†††An 8-oz. (volume) measuring cup holds 3 to 3.5 oz. by weight (85 to 100 g) of most dry pet foods or 3.5 to 5 oz. by weight (100 to 150 g) of most semi-moist pet foods. It is more accurate to use the average weight of three individual measuring cups of food in determining kcal or kJ/cup.

Label Evaluation

The ingredient panel of the pet food label provides general information about which ingredients were used and their relative amounts. The ingredients used in the product are listed in descending order by weight in many countries. The ingredient panel can be useful if specific ingredients are contraindicated for certain animals or an owner has an ingredient concern. However, the quality of the ingredients cannot be determined from the label and there is much misinformation and, as a result, misunderstandings about pet food ingredients (Chapter 8). As mentioned above, the presence or absence of specific protein sources or other ingredients in a food can be obtained from the product label.

Depending on the country, product labels will also provide information that indicates by what means the product has been shown to be nutritionally adequate (Chapter 9).

Assess and Determine the Feeding Method

Feeding methods relate directly to the physiologic or disease state of the animal and the food or foods being fed. Thus, the information obtained by assessing the animal and the food is fundamental to assessing the feeding method. There are at least three things to consider regarding feeding methods: 1) feeding route, 2) amount fed and 3) how the food is offered (when, where, by whom and how often). In addition, feeding factors that affect compliance should be considered, such as whether or not the animal has access to other foods and who provides the food.

Feeding Route

Whether or not the feeding route is appropriate depends on the animal's condition. Although most animals are able to feed themselves, orphans and some critical care patients may require assistance. Assisted-feeding methods are described in detail in Chapters 25 and 26. Assisted-feeding methods include enteral feeding by syringe or tube (several approaches) and parenteral feeding.

Amount Fed

The nutrient needs of an animal are met by a combination of the nutrient levels in the food and the amount of food offered and eaten. Even if a food has an appropriate nutrient profile, significant over- or undernutrition could result if too much or too little is consumed. Thus, it is important to know if the amount being consumed is appropriate.

The amount of food offered should be determined when taking the patient's history. Although many animals are fed free choice, owners should still be able to provide a reasonable estimate of the actual amount being consumed. The owner may need to return home and measure the amount the pet consumes to provide an accurate report or estimate the amount based on the purchasing frequency of bags or cans. The amount actually being consumed can then be compared with the amount that should be fed. If the animal in question has a normal BCS (3/5) and no history of weight changes, the amount fed is probably appropriate. Exceptions to this generalization include growing animals, animals that are gestating or lactating and hunting dogs and other canine athletes early in the athletic event season.

The appropriate amount to feed can be difficult to determine precisely, but can be estimated. For most commercial pet foods, food dosage estimates can be found in the feeding guidelines on the product label. However, food dosages can be calculated if guidelines are unavailable. The precision of feeding guidelines or calculated food dosages is limited because the efficiency of food use varies among individuals because of differences in physical activity, metabolism, body condition, insulative charac-

teristics of the coat and external environment. Even when environmental conditions and physical activity are similar, sizable individual differences can exist.

Figure 1-5 contains data generated from several controlled studies about the amount of food (energy content standardized) consumed by mature, non-reproducing dogs and cats kept in kennels or runs under similar environmental conditions while maintaining body weight. The total amount of energy needed by dogs and cats for maintenance, even under similar environmental conditions can vary two- to threefold. Even when the extremes are excluded (the top and bottom 2.5%), the amount of energy needed varied more than twofold (Lewis et al, 1987). Therefore, a commercial product's amount to feed guideline or a calculated food dosage should only be considered an estimate or a starting point that may very likely need adjustment.

Calculations to estimate food dosage are based on the assumption that if a food contains the proper proportions of nutrients relative to its energy density, and is fed to meet an animal's energy requirement, then the animal's requirements for non-energy nutrients will be met automatically. This is an important concept. **Box 1-6** demonstrates the method for calculating food dosage estimates. **Case 1-2** includes an example of a food dosage problem.

How the Food is Offered

The amount fed is usually offered in one of three ways: 1) free-choice feeding (dogs and cats), 2) food-restricted meal feeding (dogs and cats) and 3) time-restricted meal feeding (dogs). The number of feedings per day must be considered when the last two methods are used.

Free-choice feeding (also referred to as ad libitum or self feeding) is a method in which more food than the dog or cat will consume is always available; therefore, the animal can eat as much as it wants, whenever it chooses. The major advantage of free-choice feeding is that it is quick and easy. All that is necessary is to ensure that reasonably fresh food is always available. Free-choice feeding is the method of choice during lactation. Free-choice feeding also has a quieting effect in a kennel and timid dogs have a better chance of getting their share if dogs are fed in a group.

Disadvantages include: 1) anorectic animals may not be noticed for several days, especially if two or more animals are fed together, 2) if food is always available, some dogs and cats will continuously overeat and may become obese (such animals should be meal fed) and 3) moist foods and moistened dry foods left at room temperature for prolonged periods can spoil and are inappropriate for free-choice feeding (Chapter 11).

When changing a dog from meal feeding to free-choice feeding, first feed it the amount of the food it is used to receiving at a meal. After this food has been consumed and the dog's appetite has been somewhat satisfied, set out the food to be fed free choice. This transitioning method helps prevent engorgement by dogs unaccustomed to free-choice feeding. Engorgement is generally not a problem when transitioning cats to free-choice feeding. Although dogs and cats unaccustomed to free-choice feeding may overeat initially, they generally stop doing so within a few days, after they learn that food is always available. Avoid taking the food away at any time during this transition period. Each time food is taken away increases the difficulty in changing the animals to a free-choice feeding regimen.

With food-restricted meal feeding, the dog or cat is given a specific, but lesser, amount of food than it would eat if the amount offered were not restricted (i.e., free choice). Time-restricted meal feeding is a method in which the animal is given more food than it will consume within a specified period of time, generally five to 15 minutes. Time-restricted meal feeding is of limited usefulness with dogs and has little if any practical application in cats. Many dogs can eat an entire meal in less than two minutes. Both types of meal feeding are repeated at a specific frequency such as one or more times a day. Some people combine feeding methods, such as free-choice feeding a

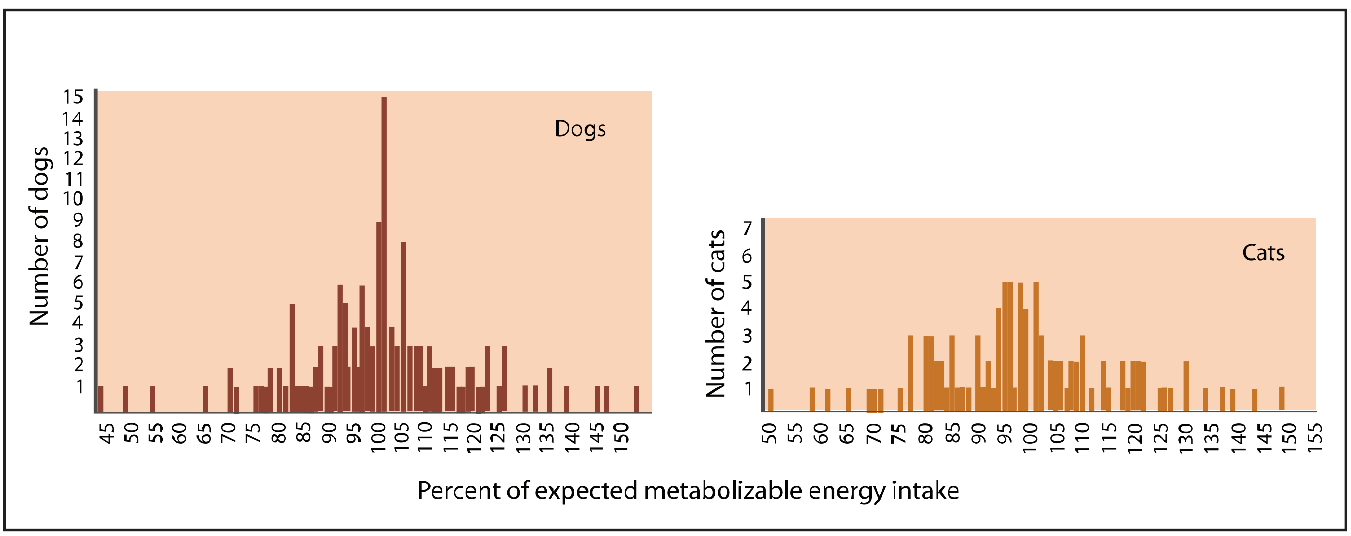


Figure 1-5. Variation in expected energy intake required to maintain optimal body weight in dogs and cats. Data were collected from 120 dogs and 76 cats kept under similar conditions and fed the amount of a variety of commercial pet foods necessary to maintain body weight (Adapted from Lewis et al, 1987).

dry or semi-moist food and meal feeding a moist food or other foods such as meat or table scraps.

Food consumption resulting from frequent meal and free-choice feeding has several advantages. Small meals fed frequently throughout the day result in a greater loss of energy due to an increase in daily meal-induced heat production. Also, providing frequent small meals generally result in greater total food intake than does less frequent feeding (Mugford and Thorne, 1980). Frequent feeding of small meals benefits animals with dysfunctional ingestion, digestion, absorption or use of nutrients.

Frequent feeding is also desirable in normal animals that require a high food intake. Puppies and kittens less than six months old, some dogs engaged in heavy work (high levels of physical activity), dogs and cats experiencing ambient temperature extremes, bitches and queens during the last month of gestation and during lactation should be fed at least three times per day to ensure that their nutritional needs are met. These animals may require one and one-half to four times as much food per unit of body weight than most normal adult dogs and cats. A reduced frequency might limit total food intake in these situations. Also, more frequent feeding during periods of variable appetite suppression, such as occurs with psychologic stress or high ambient temperatures, helps ensure adequate food intake.

Most clinically normal adult dogs that are not lactating, working or experiencing stress will have a sufficient appetite and physical capacity to consume all of the food required daily in a single 10-minute period (assuming food of typical nutrient density [about 3.5 kcal/g or 14.64 kJ/g dry matter]). Cats are less likely to eat their entire meal in one 10-minute sitting, but once-a-day feeding is adequate for most healthy adults. Although many dogs and cats are fed once daily without noticeable detrimental effects, at least twice daily feeding is generally recommended.

In summary, how the food is provided and how often it is fed depend on the animal's condition and in some cases the lifestyle of the owner. Each animal's situation will dictate which feeding method is most desirable (free choice, time-restricted meal feeding or food-restricted meal feeding). For many physiologic and disease conditions this consideration will not be important. For others it will be very important. Recommendations for the best method of providing the food and the number of times per day the food is offered are included in each individual chapter.

Compliance

Owner compliance is necessary for effective clinical nutrition. Feeding methods should reinforce or enable compliance. Enabling compliance includes limiting access to other foods and knowing who provides the food. An animal from a multi-pet household may have access to the other pets' food. If so, such access needs to be denied or limited. Restriction can be difficult in some homes. In such cases the veterinary health care team and pet owner may need to compromise.

Compliance can be eroded if everyone in the family does not support the feeding plan. Whoever feeds the pet must understand the consequences when the wrong foods are fed or even the right foods are fed in the wrong amounts. Client education is essential for the successful outcome of any feeding plan. Specific client education must be provided for feeding healthy pets and for those with specific disease problems. Both oral and written instructions encourage compliance with feeding plans.

Veterinarians and their health care teams should actively involve clients in the formulation of the feeding plan to ensure commitment to the plan. The hospital staff should strive to uncover issues that clients may have about the feeding plan and negotiate mutually acceptable solutions. Open communication about the client's and the health care team's objectives, concerns and shared responsibilities is necessary for successful implementation of the feeding plan. Authoritarian approaches are unlikely to be effective because they discount the high degree of independent decision making that clients have based on their own perceptions of nutrition. Veterinarians and their health care teams can guide clients and enable them to make informed decisions. For more about compliance see Chapter 3.

REASSESSMENT

Finally, monitoring, or reassessing the animal, should be performed at appropriate intervals to evaluate the effectiveness of the feeding plan. For patients undergoing intensive care, reassessment may need to be done every few hours, whereas pets in a health maintenance program could be reassessed annually. Reassessment signals the initiation of the iterative step of the clinical nutrition process. Involving the client in an action plan is an essential component of the veterinarian-client relationship. The reader is referred to the remaining chapters of this book for information about specific feeding plans and practices according to nutritional needs of pets in health and in specific diseases.

CASE 1-1

Calcium Supplementation in a Great Dane Puppy

Michael S. Hand, DVM, PhD, Dipl. ACVN*
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment

A 10-week-old male Great Dane puppy weighing 15 kg was examined as part of its routine health maintenance procedures. The results of a physical examination were normal. The puppy's body condition score was 3/5.

Assess the Food and Feeding Method

The puppy is fed a dry lamb and rice-based commercial food. The owner feeds the puppy four 8-oz. measuring cups of food daily. The owner also provides eight calcium tablets daily as a supplement to "ensure enough calcium." A phone call to the pet food company's customer service department determined that the food's calcium content is 2.3% and that it provides 3.6 kcal/g (15.1 kJ/g) on an as fed basis (10% moisture). The customer service department also indicates that the food density is 94 g/cup. Product literature included with the calcium tablets indicates that each tablet provides 0.5 g of calcium carbonate, and that calcium carbonate contains 36% calcium (0% moisture). The owner asked if this is enough calcium for the puppy.

Questions

1. How many g of food and how many g of calcium carbonate are being fed (dry matter [DM])?
2. Determine the total amount of calcium (DM) provided by the food and supplement.
3. Determine the percentage of calcium in the DM of the combined food and supplement.
4. Convert the energy density on an as fed basis to DM.
5. Does the combination of the food and supplement meet the calcium requirement for a giant-breed puppy?

Answers and Discussion

1. Four cups x 94 g/cup = 376 g of food. Because the two components being evaluated have differing moisture contents (food = 90% DM and calcium carbonate tablets = 100% DM), it is advisable to convert the food to DM at this point: 376 g of food on an as fed basis x 90% DM = 338 g food DM.

   The owner feeds eight calcium tablets daily. The calcium carbonate source has no moisture so as fed basis equals DM: eight calcium tablets x 0.5 g calcium carbonate per tablet = 4 g calcium carbonate (as fed and DM).

2. According to the manufacturer, the food provides 2.3% calcium on an as fed basis. To convert this to DM, divide the as fed percentage by the DM percentage: 2.3% calcium as fed basis ÷ 90% DM = 2.6% calcium DM.

   We have already determined that the calcium tablets provide 4 g calcium carbonate and that calcium carbonate contains 36% calcium. To determine how much calcium is provided by each component, multiply the amount of each component being fed by the amount of calcium in each component and add them:

   338 g food dry matter x 2.6% calcium = 8.8 g calcium
   4 g calcium carbonate x 36% calcium = <u>1.4 g calcium</u>
   10.2 g total calcium (DM)

3. Total food DM is the sum of the two components:

   338 g food DM + 4 g calcium carbonate DM = 342 g total food DM
   10.2 g total calcium (DM) ÷ 342 g total food DM = 3.0% calcium

4. We need to consider the effect of the supplemental calcium source on the energy density of the food and convert the energy density to DM. In this case, we ignore any dilutional effect the 4 g of calcium carbonate has on the energy density of the food because it would be inconsequential (4 g ÷ 342 g = 1%). To convert 3.6 kcal ME/g (15.06 kJ ME/g) as fed to DM, as described previ-

ously, divide the as fed basis by the DM percentage:

3.6 kcal ME/g as fed ÷ 90% DM = 4 kcal ME/g (DM), or
15.06 kJ ME/g as fed ÷ 90% DM = 16.74 kJ ME/g (DM)
Thus, the total food contains 3.0% DM calcium and provides 4 kcal ME/g (16.74 kJ) DM.

5. To compare a food's nutrient content with a recommended target level requires that the energy density of the food and that specified for the target level be similar or the same. Calcium is a key nutritional factor (nutrient of concern) for large- and giant-breed puppies. Calcium levels in foods intended for large- and giant-breed growth should not exceed 1.2% DM in foods that provide <3.8 kcal ME/g (<15.90 kJ) **(Chapter 33).** As described above, the conversion is made by generating a multiplier that converts the requirement to the same energy density as the food. This is done by dividing the food energy density by the requirement energy density and multiplying the requirement by the multiplier: 4 kcal ME/g ÷ 3.6 kcal ME/g = 1.1 (multiplier), or 16.74 kJ ME/g ÷ 15.06 kJ ME/g = 1.1 or 1.1 x 1.2% maximum = 1.32% maximum.

In this case, the combined food and supplement are providing excessive calcium for this giant-breed puppy (3% in food vs. 1.32% maximum recommended) (Chapter 33).

CASE 1-2

Food Dosage Estimate for a Lactating Queen

Michael S. Hand, DVM, PhD, Dipl. ACVN*
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment
A 4-kg, three-year-old queen is presented for weight loss. The cat is nursing five, three-week-old kittens. The queen's body condition score is 2/5 and the patient record indicates the cat has lost 1 kg since its postpartum checkup.

Assess the Food and Feeding Method
The cat is being fed one cup of a commercial dry food daily, free choice. The food is suitably balanced for feline lactation. The energy density of the food is 535 kcal metabolizable energy (ME)/cup (2,238 kJ ME/cup) on an as fed basis.

Questions
1. What is this queen's estimated daily energy requirement (DER)?
2. What should the food dosage be based on this queen's DER?

Answers and Discussion
1. Resting energy requirement (RER) (kcal ME/day) = $70(BW_{kg})^{0.75}$
   $= 70(4\ kg)^{0.75} = 70(2.83) = 198$ kcal ME/day, or
   $= 293(4\ kg)^{0.75} = 293(2.83) = 829$ kJ ME/day
   Modifier for adult feline = 1.5 x RER = DER
   DER = 1.5 x 198 kcal ME/day = 297 kcal ME/day, or
   1.5 x 829 kJ ME/day = 1,243.5 kJ ME/day
   Modifier for feline lactation = (1 + 0.25[number kittens nursing]) x DER
   = [1 + 0.25(5)] x 297 kcal ME/day
   = 2.25 x 297 kcal ME/day = 668 kcal ME/day, or
   2.25 x 1,243.5 kJ ME/day = 2,798 kJ ME/day
2. The food being fed has a nutrient profile that is satisfactory for feline lactation. The energy density of the food is 535 kcal (2,238 kJ) ME/cup. Divide the energy requirement by the energy density of the food to determine how much to feed the cat:
   668 kcal ME/day requirement ÷ 535 kcal ME/cup = 1.25 cups/day, or
   2,798 kJ ME/day requirement ÷ 2,238 kJ ME/cup = 1.25 cups/day
   According to these calculations the cat is being underfed. The amount offered free choice should be increased by at least 25%.

CASE 1-3

Altering the Food and Feeding Method for a Young Rottweiler

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

A four-month-old, female Rottweiler was examined for diarrhea of five days' duration. The puppy had escaped from a fenced yard on trash pickup day and the owners suspected it had eaten garbage. The puppy appeared bright and alert, weighed 18 kg and had a body condition score of 3/5. The results of the physical examination were normal except for fluid-filled intestines on abdominal palpation. The owners described the stools as being small volume but frequent (eight to 10/day) and liquid with some bright red blood and mucus. A fecal examination was negative for intestinal parasites.

Assess the Food and Feeding Method

The puppy was fed a commercial dry puppy food three times per day until its escape. The puppy still had a good appetite, but seemed to be drinking more than usual amounts of water. On Day 1 of the diarrheic episode, the veterinarian examined the puppy and asked the owner to feed a moist commercial veterinary therapeutic food (poultry, egg and rice based) with moderate fat (13%) and low fiber (<1%) (Prescription Diet i/d Canine[a]). However, the diarrhea had not resolved after feeding the food for three days.

Question

What is the appropriate food and feeding method for this patient with large bowel diarrhea?

Answer and Discussion

The food was replaced with a moist commercial veterinary therapeutic food that contained 13% fat and 12% crude fiber on a dry matter basis (Prescription Diet w/d Canine[a]). The owners were instructed to feed the puppy at its estimated resting energy requirement (805 kcal [3,368 kJ]/day) with two cans of the new food divided into four meals per day for one to two days; then to feed at the estimated daily energy requirement (1,600 kcal/day [6,694 kJ]) with four cans of the new food divided into three to four meals per day for another two days. The owners were instructed to return for a recheck if the puppy did not have a normal stool by the fourth day. If the puppy's stool was normal, the owners were instructed to transition the food back to the original puppy food using the short schedule outlined in **Table 1-1.**

Progress Notes

No stool was produced within the first 24 hours of feeding the higher fiber food. By the end of the second day the dog had a normal bowel movement with no blood or mucus. The owners continued to feed the higher fiber food for another two days as instructed. The puppy was then switched back to the dry puppy food over seven days with no problems.

CASE 1-3

Altering the Food and Feeding Method for a Young Rottweiler

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

A four-month-old, female Rottweiler was examined for diarrhea of five days' duration. The puppy had escaped from a fenced yard on trash pickup day and the owners suspected it had eaten garbage. The puppy appeared bright and alert, weighed 18 kg and had a body condition score of 3/5. The results of the physical examination were normal except for fluid-filled intestines on abdominal palpation. The owners described the stools as being small volume but frequent (eight to 10/day) and liquid with some bright red blood and mucus. A fecal examination was negative for intestinal parasites.

Assess the Food and Feeding Method

The puppy was fed a commercial dry puppy food three times per day until its escape. The puppy still had a good appetite, but seemed to be drinking more than usual amounts of water. On Day 1 of the diarrheic episode, the veterinarian examined the puppy and asked the owner to feed a moist commercial veterinary therapeutic food (poultry, egg and rice based) with moderate fat (13%) and low fiber (<1%) (Prescription Diet i/d Canine[a]). However, the diarrhea had not resolved after feeding the food for three days.

Question

What is the appropriate food and feeding method for this patient with large bowel diarrhea?

Answer and Discussion

The food was replaced with a moist commercial veterinary therapeutic food that contained 13% fat and 12% crude fiber on a dry matter basis (Prescription Diet w/d Canine[a]). The owners were instructed to feed the puppy at its estimated resting energy requirement (805 kcal [3,368 kJ]/day) with two cans of the new food divided into four meals per day for one to two days; then to feed at the estimated daily energy requirement (1,600 kcal/day [6,694 kJ]) with four cans of the new food divided into three to four meals per day for another two days. The owners were instructed to return for a recheck if the puppy did not have a normal stool by the fourth day. If the puppy's stool was normal, the owners were instructed to transition the food back to the original puppy food using the short schedule outlined in **Table 1-1.**

Progress Notes

No stool was produced within the first 24 hours of feeding the higher fiber food. By the end of the second day the dog had a normal bowel movement with no blood or mucus. The owners continued to feed the higher fiber food for another two days as instructed. The puppy was then switched back to the dry puppy food over seven days with no problems.

Endnote

a. Hill's Pet Nutrition Inc., Topeka, KS, USA.

ously, divide the as fed basis by the DM percentage:

3.6 kcal ME/g as fed ÷ 90% DM = 4 kcal ME/g (DM), or
15.06 kJ ME/g as fed ÷ 90% DM = 16.74 kJ ME/g (DM)
Thus, the total food contains 3.0% DM calcium and provides 4 kcal ME/g (16.74 kJ) DM.

5. To compare a food's nutrient content with a recommended target level requires that the energy density of the food and that specified for the target level be similar or the same. Calcium is a key nutritional factor (nutrient of concern) for large- and giant-breed puppies. Calcium levels in foods intended for large- and giant-breed growth should not exceed 1.2% DM in foods that provide <3.8 kcal ME/g (<15.90 kJ) **(Chapter 33).** As described above, the conversion is made by generating a multiplier that converts the requirement to the same energy density as the food. This is done by dividing the food energy density by the requirement energy density and multiplying the requirement by the multiplier: 4 kcal ME/g ÷ 3.6 kcal ME/g = 1.1 (multiplier), or 16.74 kJ ME/g ÷ 15.06 kJ ME/g = 1.1 or 1.1 x 1.2% maximum = 1.32% maximum.

In this case, the combined food and supplement are providing excessive calcium for this giant-breed puppy (3% in food vs. 1.32% maximum recommended) (Chapter 33).

CASE 1-2

Food Dosage Estimate for a Lactating Queen

Michael S. Hand, DVM, PhD, Dipl. ACVN*
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment
A 4-kg, three-year-old queen is presented for weight loss. The cat is nursing five, three-week-old kittens. The queen's body condition score is 2/5 and the patient record indicates the cat has lost 1 kg since its postpartum checkup.

Assess the Food and Feeding Method
The cat is being fed one cup of a commercial dry food daily, free choice. The food is suitably balanced for feline lactation. The energy density of the food is 535 kcal metabolizable energy (ME)/cup (2,238 kJ ME/cup) on an as fed basis.

Questions
1. What is this queen's estimated daily energy requirement (DER)?
2. What should the food dosage be based on this queen's DER?

Answers and Discussion
1. Resting energy requirement (RER) (kcal ME/day) = $70(BW_{kg})^{0.75}$
   = $70(4\ kg)^{0.75}$ = 70(2.83) = 198 kcal ME/day, or
   = $293(4\ kg)^{0.75}$ = 293(2.83) = 829 kJ ME/day
   Modifier for adult feline = 1.5 x RER = DER
   DER = 1.5 x 198 kcal ME/day = 297 kcal ME/day, or
   1.5 x 829 kJ ME/day = 1,243.5 kJ ME/day
   Modifier for feline lactation = (1 + 0.25[number kittens nursing]) x DER
   = [1 + 0.25(5)] x 297 kcal ME/day
   = 2.25 x 297 kcal ME/day = 668 kcal ME/day, or
   2.25 x 1,243.5 kJ ME/day = 2,798 kJ ME/day
2. The food being fed has a nutrient profile that is satisfactory for feline lactation. The energy density of the food is 535 kcal (2,238 kJ) ME/cup. Divide the energy requirement by the energy density of the food to determine how much to feed the cat:
   668 kcal ME/day requirement ÷ 535 kcal ME/cup = 1.25 cups/day, or
   2,798 kJ ME/day requirement ÷ 2,238 kJ ME/cup = 1.25 cups/day
   According to these calculations the cat is being underfed. The amount offered free choice should be increased by at least 25%.

Chapter 2

Evidence-Based Clinical Nutrition

Philip Roudebush
Timothy A. Allen
Bruce J. Novotny

"Each time we learn something new and surprising, the astonishment comes with the realization that we were wrong before.... In truth, whenever we discover a new fact it involves the elimination of old ones. We are always, as it turns out, fundamentally in error."
Lewis Thomas

INTRODUCTION

Practitioners should know how to determine risks and benefits of nutritional regimens, including for nutritional care, and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not based on rigorous assessment of evidence for or against particular management options. Journals and textbooks, even those designed to rapidly access decisions while patients are in a clinical situation, may not help determine specific risks and benefits of nutritional management. Consequently, veterinarians have often had to rely on clinical experience and judgment, aided by opinions of colleagues and consultants who practice similarly. Evidence-based medicine (EBM) represents a major, but still untested, intellectual advance when making clinical decisions and determining patient care (Geyman, 2000; Keene, 2000; Moriello, 2003). This chapter will apply the basic elements of EBM to veterinary clinical nutrition and provide a statistical primer to help veterinarians interpret available information.

EBM CONCEPTS

EBM and its associated concepts were first advanced by a group at McMaster University Health Sciences Centre in Canada. The first publications emerged in the early 1990s (EBM Working Group, 1992; Sackett et al, 1996). The underlying concepts are rooted in clinical epidemiology and are not new. EBM seeks to establish clinical medicine as a verifiable scientific activity (Naldi et al, 2000).

Initially, EBM was defined as the "conscientious, explicit and judicious use of current best evidence from clinical care research in making decisions about the care of individual patients" (Sackett et al, 1996). EBM was later refined to integrate the best research evidence, clinical expertise and patient values (Sackett et al, 2000). Best research evidence means clinically relevant research, especially from patient-centered clinical studies. Clinical expertise is the ability to use clinical skills and past experiences to rapidly identify each patient's unique health state, establish a diagnosis and determine the risks and benefits of potential interventions facing that patient. Patient values include unique preferences, concerns and expectations that each person brings to a clinical encounter; these must be integrated into clinical decisions that best serve the patient. Integration of these three elements supposedly helps clinicians and patients form a diagnostic and therapeutic alliance that optimizes clinical outcomes and quality of life (Sackett et al, 2000).

EBM concepts also apply to dogs, cats and other nonhuman animals. Patient values must be extended to include the unique preferences, concerns and expectations of owners and their pet (i.e., patient). Regardless of the definition, use of current best evidence should not replace clinical skills, judgment or experi-

Table 2-1. Guidelines for quality of evidence that can be used for veterinary clinical nutrition.

Evidence grade	Evidence guidelines	Examples of nutritional studies
1	Evidence obtained from at least one properly randomized, controlled, clinical study that used the nutritional product in the target species with animals that had developed the disease naturally.*	Dietary modification for treatment of cats and dogs with naturally developing chronic kidney disease.
2	Evidence obtained from randomized, controlled, clinical studies conducted in a laboratory setting that used the nutritional product in the target species with animals that had developed the disease naturally.*	Effects of a dental food on plaque accumulation and gingival health in dogs. Energy restriction in obese cats and dogs fed foods varying in protein, fat, fiber and carbohydrate content.
3	Evidence obtained from one or more of the following:* At least one appropriately designed clinical study without randomization. Cohort or case-controlled analytic studies. Studies that used acceptable models of disease or simulations in the target species. Case series. Dramatic results from uncontrolled studies.	Use of foods using novel or hydrolyzed protein sources for animals with adverse food reactions. Myocardial failure in cats associated with taurine deficiency.
4	Evidence obtained from one or more of the following: Opinions based on clinical experience (textbooks, monographs or proceedings). Descriptive studies. Studies conducted in other species. Pathophysiologic justification. Reports of expert committees.	Hepatic disease and nutritional therapy. Nutritional management of most diarrheal diseases.

*Data published in peer-reviewed journals is preferred.

ence; however, it does provide another dimension to the decision-making process that also considers the patient's and owner's preferences (Forrest and Miller, 2002). Evidence-based clinical nutrition (EBCN) attempts to efficiently integrate medical and nutritional research with clinical practice.

Figure 2-1 is a conceptual model for evidence-based clinical decisions (Hayes et al, 1996). Analysis reveals that the best evidence-based clinical decisions are made when clinical expertise, research evidence, owner or patient preferences and available resources overlap. This model can be easily adapted to veterinary clinical nutrition in which assessment of the patient, food and feeding method lead to a comprehensive feeding plan based on the best current evidence (Thatcher et al, 2000). Clinical expertise is needed to obtain a dietary history and assess a patient's nutritional and health status. This assessment must often include other pets in the household. Clinical and nutritional expertise provides individualized care for a specific patient's needs. Owners exercise their preferences for medical and nutritional care by seeking second opinions, choosing alternate treatments, exercising economic constraints and adhering (or not) to recommended feeding or therapeutic plans. Today, more clinical and nutritional information is available to pet owners than ever before. Pet preferences are most commonly recognized in veterinary clinical nutrition through palatability choices for certain types of foods.

Integrating clinical expertise with current best evidence from medical and nutritional research is complex. Veterinarians usually attempt to base their decisions on the best evidence available. This evidence often represents extrapolations of pathophysiologic principles, studies conducted in other species and logical conclusions based on data derived from patients in clinical studies (Rosenberg and Sackett, 1996). The advent and proliferation of randomized, controlled clinical studies increased the quantity and quality of clinically valid evidence. When possible, veterinarians should use information derived from systematic, rigorously controlled clinical studies (obviously, larger trials involving more patients are preferable) to make diagnostic and therapeutic decisions. EBM and EBCN do not always provide definitive answers, but they do provide a framework for making decisions and understanding the risk-benefit relationship of various feeding and therapeutic plans. Understanding the rules of evidence is necessary to understand EBM and EBCN (Sackett, 1993; Berg, 2000).

RULES OF EVIDENCE

Scientific evidence is the product of appropriately designed and carefully controlled research. A single study does not constitute evidence; rather, it contributes to knowledge derived from multiple studies that have investigated the same scientific question. Unfortunately, no central repository for clinical nutrition information exists nor is there a system for establishing quality evidence. Several classification schemes are useful for establishing rules of evidence for recommendations about clinical nutrition.

One method is to use a pyramid to rank clinical evidence (**Figure 2-2**) (Forrest and Miller, 2002; SUNY, 2003). Traditional sources of evidence include textbooks, personal

journal collections, conference proceedings and clinical guidelines. Unfortunately, much of this evidence is not based on appropriately conducted clinical studies in the target species. Many clinical and nutritional interventions are used because the basic pathophysiologic rationale was reasonable, although clinical outcome data to document positive effects were lacking.

Strong EBM and EBCN evidence includes randomized, controlled clinical studies or systematic reviews of more than one study (i.e., meta-analysis). Epidemiologic studies (cohort studies or case-control studies), models of disease and case series are the next best evidence. Hierarchy of evidence is based on causation and bias control. As one ascends the pyramid, the number of studies and, correspondingly, the available literature decreases, whereas the relevance to answering clinical questions increases.

Quality of evidence guidelines, adapted from the U.S. Preventive Services Task Force, are excellent, rigorous applications of evidence-based appraisal systems (Geyman, 2000; Berg, 2000; McGowan et al, 1992; Polzin, 2003; Polzin, 2003a). Those guidelines have been modified to better fit the types of evidence encountered in veterinary clinical nutrition (**Table 2-1**) (Roudebush et al, 2004). Other classification schemes have been recommended for rules of evidence; however, they are very similar to the evidence pyramid and grades outlined here (Rosenberg and Sackett, 1996; Olivry and Mueller, 2003; Cook et al, 1995). It is beyond the scope of this chapter to describe strategies for finding clinical nutrition evidence. Numerous excellent articles, textbooks and websites provide detailed explanations about the evidence gathering process (Sackett et al, 2000; Miser, 1999; Safranek and Dodson, 2000; Hunt et al, 2000; Jahad and Haynes, 2000; Chi-Lum et al, 1997; Klemenez and McSherry, 1997; Greenhalgh, 1997).

APPLYING EVIDENCE TO SPECIFIC PATIENTS

Many activities veterinarians perform in clinical medicine and nutrition have not been subjected to suitably designed scientific studies. Randomized, controlled studies are the reference criterion standard for therapeutic and nutritional interventions; however, these studies are imperfect and do not apply to studies of cause, diagnosis and prognosis (Sackett, 1993; Berg, 2000). Randomized, controlled studies are often not conducted on patients similar to those encountered in practice, and many clinical and nutritional interventions will never be subjected to such investigations. For example, randomized, controlled studies are often not conducted on patients with naturally occurring disease and many clinical and nutritional interventions will never be subjected to such investigations due to ethical or other reasons. Nonetheless, evidence from randomized, clinical studies currently is most likely to predict results in clinical practice. Randomized, clinical studies also serve as a scientific entry point for discussions with owners about therapeutic and nutritional options.

Several questions can be used to decide the applicability of evidence from clinical studies to nutritionally manage a specific patient (Strauss and Sackett, 1999; Dans et al, 1998; McAlister et al, 2000).

- Were study outcomes clinically relevant?
- Are there differences between animals in the study and my patient that may alter expected treatment response?
- Are there potential drug-nutrient interactions that may alter the expected treatment response?

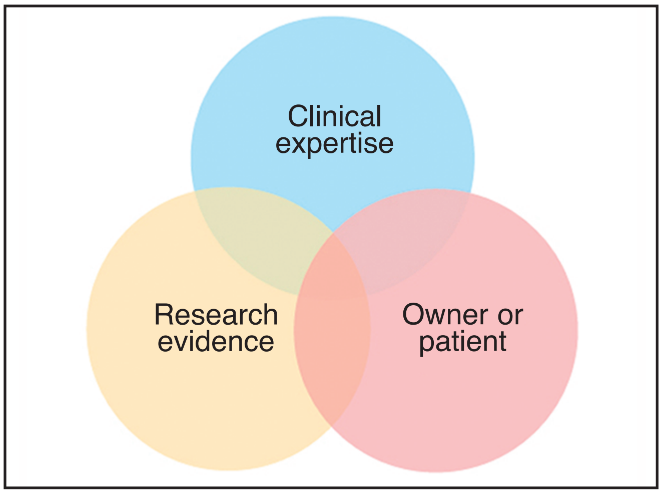

Figure 2-1. A conceptual model for making evidence-based clinical decisions. The best clinical decisions are made when clinical expertise, high-quality evidence obtained in controlled studies and owner or patient preferences overlap. (Adapted from Haynes RB, Sackett DL, Gray JMA, et al. Transferring evidence from research into practice: 1. The role of clinical care research evidence in clinical decisions. American College of Physicians Journal Club 1996; 125: A14-A16. Reprinted with permission).

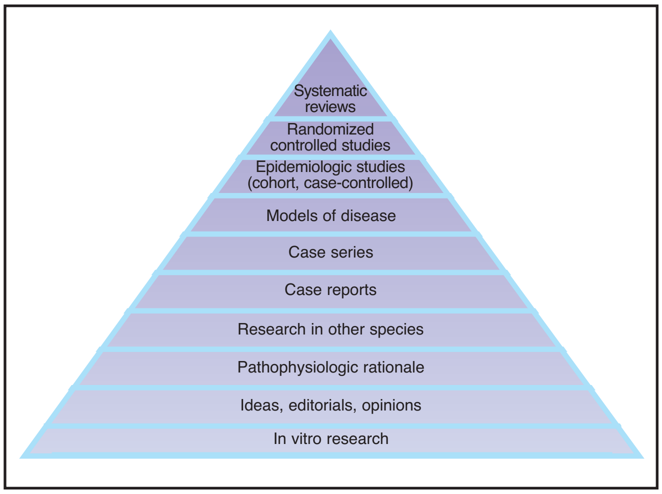

Figure 2-2. The evidence pyramid. The level of evidence for use of a diagnostic or therapeutic intervention increases as one progresses up the pyramid. (Adapted from SUNY Downstate Medical Center. Guide to research methods: the evidence pyramid. Medical Research Library of Brooklyn Web site. Available at http://library.downstate.edu/dbm. Accessed on November 2, 2003. Reprinted with permission.)

- Are there differences in the nutrient contents of the food (or supplements) that may alter the expected treatment response?
- Is the food (or supplement) readily available and economically feasible?
- Is the feeding plan intervention feasible in the owner's setting?
- What are the patient's likely benefits and risks from the various nutritional management options?
- How will the owner's values and patient's preferences influence the decision about nutritional management?
- Does the patient have other health conditions that substantially alter the potential benefits and risks of nutritional management?

EVIDENCE-BASED TREATMENT DECISIONS: A FRAMEWORK FOR CLINICAL PRACTICE

EBM involves making clinical decisions by carefully identifying, evaluating and applying the most relevant information. In EBM, the first step is to identify and define the medical problem to learn what additional information is required. After the need for additional information is identified, it must be retrieved and evaluated to ensure validity. After the information is judged valid, it is next necessary to apply it to the care of your patient. This brief section will focus on how to evaluate information about treatment after it has been retrieved and conclude with a few general comments about applying treatments to individual patients.

The first step in making good treatment decisions is to decide whether the patient requires treatment or not and to identify the specific goals of treatment. Potential treatment goals include eliminating or decreasing current clinical signs, preventing recurrence of disease, slowing progression of disease and curing the disease. After the treatment goals have been identified and treatment has been initiated it is important to periodically assess progress toward these goals and to make changes as appropriate.

After the decision to treat has been made and the treatment goals identified, the next step is to decide on the specific treatment modality or modalities (pharmacologic agents, surgery and nutrition) that will achieve the treatment goals. Experienced clinicians make treatment decisions based on their own uncontrolled clinical experience. Clinicians judge the efficacy of a treatment by comparing current clinical impressions with clinical impressions before the new treatment was available. Unfortunately, this approach can lead to erroneous conclusions. Part of human nature is to remember our successes and either forget our treatment failures or attribute them to other factors (e.g., poor owner compliance). Another risk when judging the efficacy of a treatment based on clinical impressions is that neither the clinician nor the pet owner is masked to treatment so there is increased potential for bias in subjective assessments (placebo effect).

Alternatively, treatment decisions can be based on critical analysis of formal, prospective randomized clinical trials designed to determine if differences exist in clinically relevant outcomes between treatments. In clinical trials, researchers apply a treatment or intervention and observe the effect of treatment on outcome. The value of interventional compared to observational studies is the ability to determine causality.

The purpose of clinical research is to draw inferences about what really happened in the study patients and to apply those inferences to the universe of all patients with the same problem. Errors are inherent in all clinical research studies. The key issue is whether the errors change the conclusions of a study significantly. The challenge is to design and complete a study that adequately controls for random and systematic errors. Randomly assigning patients to treatment can eliminate the influence of confounding variables. Masking the veterinarian and pet owner to treatment can reduce the possibility that clinical assessments are biased. Randomized, controlled masked clinical trials are considered the gold standard of clinical research because they provide the best way to reduce bias. Bias is anything that produces results or conclusions that differ from the truth. Sources of bias can be found in the design, implementation and analysis of the study.

In general, clinical trials are expensive, time consuming and difficult to conduct. Consequently, well-designed, well-executed clinical trials are unavailable to guide every treatment decision. Nonetheless, a systematic approach to evaluating support for each treatment option is valuable to the clinician. The critical evaluation of a clinical trial depends on more than checking for appropriate randomization and the presence of a control group. The following series of questions can guide the clinician through a systematic assessment of the validity of a clinical trial.

Was Assignment to Treatment Truly Randomized?

Did every patient enrolled in the study have an equal and known probability of receiving the treatment(s) compared? Proper randomization applies a previously established method for assigning patients to a treatment group using a set of computer-generated random numbers. The random assignment of patients to treatment groups is critical for establishing the basis for statistical testing of the differences in the clinical outcomes observed between groups. In blocked randomization, age, sex and other baseline characteristics that may influence clinical outcomes are distributed equally between treatment groups and do not confound interpretation of results. When block randomization is done properly any differences in baseline characteristics between the groups are due to chance and addressed by the statistical tests. Proper random assignment guarantees that no one can influence assignment to treatment. This prevents the investigator from knowingly or unknowingly assigning a particular patient to a specific treatment because the patient seems particularly suited to receive the active or control treatment, thereby eliminating an important potential source of bias.

Are the Subjects in the Clinical Trial Adequately Described and Similar to your Patient?

Is there sufficient demographic and clinical detail provided about the study patients for you to determine similarity between them and your patient? Are the patients in the study similar enough to your patient that you are comfortable applying the study results?

Were Treatment Groups Similar at the Start of the Study?

Were there any differences in key baseline characteristics that might influence the clinical outcome between the treatment groups at the start of study? For example, in a study of spontaneous chronic kidney disease was the severity of kidney disease comparable in the treatment groups at the onset of the study?

Aside from the Investigated Treatment, were the Groups Treated Equally?

With the exception of the treatment under investigation, were all disease-related interventions identical between treatment groups? Are the details of patient management adequate to make this assessment? Could the difference in outcome be attributable to treatment differences that are not part of the stated objective of the study?

Were all Patients that Entered the Study Accounted for at the Conclusion of the Study?

Can you reconcile the number of patients in the title or methods section of the article with the tally of the final disposition of patients? If patients were lost to follow-up or dismissed from the study, were they included in the statistical analysis of the data? If yes, how were these missing data points handled? Does management of these missing data points change the study conclusions?

Are the Study Results Believable?

Was the clinical outcome of interest defined based on clear, explicit and, if possible, objective criteria? Are the results of the clinical trial consistent with those of other studies? Are the results of the clinical trial biologically plausible? Is there a biologic precedent for the putative mechanism of action?

Were Findings both Clinically and Statistically Significant?

Clinical significance refers to the medical importance of the findings. Was the magnitude of the observed treatment effect large enough to make a difference in how you manage your patient? A finding in a clinical trial can be statistically significant but clinically insignificant. Was the endpoint studied a clinical or surrogate outcome? Clinically relevant endpoints, such as survival and quality of life, are the most meaningful to veterinarians and pet owners. Surrogate markers indirectly assess the risk of a clinical outcome (e.g., serum creatinine in kidney disease and shortening fraction in heart disease). Showing a treatment causes favorable changes in surrogate markers doesn't necessarily prove better clinical outcomes. Surrogate markers are frequently used in veterinary medicine because resources are limited and studies with clinical outcomes typically take longer and are more expensive. Statistics can be viewed as a quantitative method of good clinical decision making. From a clinician's perspective, statistics provide a way to assess the level of confidence in whether the treatment described in a clinical trial will be effective in your patient. The probability of accepting an ineffective treatment (false positive) is expressed by the p value. The p value describes how often differences in the treatment effect as large or larger than those observed in the clinical trial will occur in a long series of identical trials if in fact no true treatment effect exists. If $p = 0.05$ and the identical study is repeated 20 times the same result will be obtained 19 of 20 times. The smaller the p value, the more accurate the conclusion that a treatment effect truly exists. Most articles describing veterinary clinical trials specify the likelihood of accepting an ineffective treatment (a type I error) but relatively few specify the risk of not recognizing an effective treatment (a type II error). The risk of not recognizing an effective treatment can be calculated and is known as β. In clinical trials it is typical to set the risk of accepting an ineffective treatment (p value) at 0.05 and the risk of not recognizing an effective treatment at 0.20 (20% risk). These risk levels are known as standard or conventional levels of statistical significance. If the true state of affairs is that the treatment is different than the control and the study is designed to accept the conventional levels of risk, then the power of the study is 1 - 0.20 or 80%. The power of a clinical trial is analogous to the sensitivity of a diagnostic test.

Was the Study of Sufficient Size and Duration?

The p value is influenced by group size and the variability in the measurement in question. In general, if a measurement is very precise and has nearly the same value each time it is measured it is possible to demonstrate statistical significance with smaller numbers of patients. The number of patients in a study indirectly influences clinician confidence in the results. Group size is related by square root to confidence in the research findings. In order to double confidence in the research findings, it is necessary to quadruple the number of patients in the study. The duration of a study must be adequate to assess the treatment goal. For example, if the goal is to prevent the recurrence of calcium oxalate uroliths, the duration of the study must be long enough to assess whether the treatment under investigation has a clinically significant effect.

Were Those Making Clinical Assessments (Veterinarian and Pet Owner) Masked (Blinded) to Treatment?

Masking prevents biased assessments of subjective outcomes. Unmasked clinicians may also give special attention to patients receiving the "test" material. This can take the form of additional diagnostic tests or additional treatments. This is sometimes called co-intervention. For example, an unmasked investigator consciously or unconsciously eager to demonstrate a positive "test" effect in a trial of an obesity drug might recom-

mend increased exercise. Masking can be difficult to achieve and maintain because of logistical considerations or telltale effects of a treatment on clinical signs or laboratory tests. Logistical considerations include the physical appearance and aroma of the test material. At the conclusion of the study participants can be asked to pick the "test" material if an investigator is concerned about masking. If the percent guessing correctly is high, this should be taken into consideration when evaluating the results of the study.

CASE 2-1

Lethargy and Inappetence in a Scottish Terrier

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A six-year-old intact male Scottish terrier was examined for lethargy of several days' duration and mild inappetence. The dog weighed 9.5 kg (20.9 lb), and had a normal body condition score (3 on a 5-point scale). Several peripheral lymph nodes were enlarged and splenomegaly was diagnosed. Results of per rectal palpation and ocular fundic examination were normal. Analysis of a hemogram revealed mild normocytic, normochromic, nonregenerative anemia. Results of a serum biochemistry analysis were within reference ranges, except for mild increases in hepatic enzyme activity. Thoracic radiography revealed sternal lymphomegaly. Abdominal ultrasonography revealed mesenteric lymph node enlargement; however, the liver and spleen appeared normal. Microscopic examination of a fine-needle aspirate obtained from a peripheral lymph node revealed a homogenous population of immature lymphoid cells consistent with high-grade lymphoma.

The tentative diagnosis and treatment options were discussed with the owner, who selected chemotherapy. The owner wanted to know whether nutritional therapy or dietary supplements would be appropriate for the dog.

Question

As the attending veterinarian, you must answer the following question: In dogs with lymphoma, do dietary supplements or therapeutic foods influence survival or quality of life when used in conjunction with standard treatments such as chemotherapy?

Answer

A literature search revealed two, randomized, controlled clinical studies in which clinicians used single-agent chemotherapy (i.e., doxorubicin) and a therapeutic food in dogs with lymphoma. One of these studies was published in a peer-reviewed journal, whereas the other was a research abstract at a major veterinary meeting. Both studies indicated that dogs with lymphoma that consumed a therapeutic food supplemented with fish oil and arginine, combined with doxorubicin therapy had a significantly longer disease-free interval, longer survival time and improved quality of life, compared with dogs eating a standard food while receiving similar chemotherapy. These published data are Grade 1, which is the highest quality of evidence for recommending nutritional management for dogs with lymphoma. The patient described in the case is similar to dogs enrolled in the published studies, and the food used in those studies is identical to a commercially available therapeutic food.[a]

Another literature search did not reveal published clinical studies in which nutritional supplements were effective in dogs with multicentric lymphoma. Any recommendations for use of supplements should be made on the basis of expert opinions, clinical experience, studies in other species or pathophysiologic justification. These are Grade 4 evidence, which is the weakest form of evidence for making a nutritional recommendation.

CASE 2-2

Polydipsia and Polyuria in a Male Domestic Shorthair Cat

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A 12-year-old neutered male domestic shorthair cat was examined for routine health maintenance. The cat's body weight was 3.4 kg (7.5 lb) with a normal body condition score (3 on a 5-point scale). The owners reported a recent increase in water consumption and frequency of urination. Results of physical examination were unremarkable, except for mild periodontal disease. Laboratory tests performed included a hemogram, urinalysis and serum biochemistry profile. Azotemia was detected, with an increase in serum creatinine concentration (2.5 mg/dl; reference range, 0.4 to 1.8 mg/dl) and a urine specific gravity of 1.018. Results of other laboratory tests were within reference ranges. Subsequent microbial culture of a urine sample yielded negative results. The tentative diagnosis was naturally developing, Stage 2 chronic kidney disease.

Question

As the attending veterinarian, you must answer the following question: For cats with chronic kidney disease, does dietary management delay the onset of uremic crises, reduce the risk of future uremic crises or delay death?

Answer

A literature search found a randomized, controlled clinical study that evaluated the effect of dietary modification for treatment of cats with naturally developing chronic renal failure. Analysis of that study indicated that a food formulated for renal conditions benefited cats with uremic crises and decreased mortality in those with mild to moderate naturally developing chronic kidney disease, compared with results attained with an adult maintenance food. Cats fed the therapeutically formulated food had reduced mortality compared with cats fed the adult maintenance food.

The study represents Grade 1 evidence, which is the highest quality. Your patient is similar to cats enrolled in a published clinical study, and the food used in the study is a commercially available therapeutic food that is readily available and economically feasible.[a] Based on this evidence, use of the therapeutically formulated food and other tenets of conservative medical management should be recommended for your patient, providing owner and patient preferences are satisfied.

CASE 2-3

Severe Halitosis and Reluctance to Eat in an Irish Setter

Philip Roudebush, DVM, Dipl. ACVIM (Small Animal Internal Medicine)
Hill's Scientific Affairs
Topeka, Kansas, USA

Patient Assessment

A seven-year-old, 30-kg (66-lb) male Irish setter was examined for severe halitosis and reluctance to eat dry food. Abnormal findings during examination of the oral cavity included moderate accumulations of plaque and calculus on both dental arcades, periodontitis, exposure of the furcation of tooth roots and loss of attachment; these findings were most prominent around the caudal mandibular premolars and molars. Results for the remainder of the physical examination were unremarkable. The dog was given antibiotics to help control infection of oral tissues while further diagnostic evaluations were performed. Results of a hemogram, serum biochemistry analysis and urinalysis were within reference ranges.

The dog was anesthetized, and supragingival scaling followed by root planing and subgingival curettage was performed. Severe periodontal disease was found around the left mandibular teeth (fourth premolar and first molar). These teeth were extracted. An

osseopromotive bioactive material[a] was placed into the sockets, and extraction sites were sutured. The remaining teeth were polished. Oral antibiotics and a canned recovery-type food were dispensed. Two weeks later, the extraction sites were healed, and the owner commented that the dog is more active.

Question

As the attending veterinarian, you must answer the following question: For dogs treated to correct dental plaque and calculus, gingivitis and oral malodor, does dietary management delay the onset or reduce the severity of further dental disease?

Answer

A literature search revealed a number of randomized, controlled clinical studies that evaluated the effect of dietary modification for dogs with plaque and calculus accumulation, gingivitis and oral malodor. Those studies were conducted in a laboratory setting and involved use of a nutritional product in dogs with naturally developing oral disease. Analysis of results of those studies revealed a significant reduction of plaque, calculus, gingivitis and oral malodor when feeding a therapeutic food specially formulated for dogs with dental conditions, compared with feeding a typical dry food. This constitutes Grade 2 evidence, or the second highest quality of evidence. This patient's condition is similar to that of dogs used in the published studies; the food used was a commercially available therapeutic food[b] that is readily available and economically feasible. Based on this evidence, use of the therapeutic food specially formulated for dogs with dental conditions should be recommended for patients, providing owner and patient preferences are satisfied.

HEALTH LITERACY

Introduction

According to the 1993 National Adult Literacy Survey (NALS), the average educational attainment of adults in the United States is above the 12th grade level (Kirsch et al, 1993). However, educational level doesn't translate into a corresponding level of reading or comprehension. Forty to 44 million adults surveyed have difficulty locating the expiration date on a driver's license, determining the location of a meeting on a form or reading a medicine label. Another 50 million Americans have only marginal literacy skills; these people have difficulty locating an intersection on a street map and identifying and entering background information on a Social Security application. Unfortunately, despite increasing education, the average reading skills of U.S. adults are between the 8th and 9th grade levels (Stedman and Kaestel, 1991).

Much of health care information, including insurance forms and advertising, is often written far above the high school level. Several studies report that the reading level of patients with various chronic diseases falls between grade levels six and 10, whereas the readability of health materials prepared for them falls between seven and 13 (IOM, 2004). More than 300 studies, conducted over three decades assessed various health-related materials (e.g., informed consent forms and medication package inserts), found that a mismatch exists between the reading levels of the materials and the reading skills of the intended audience. Most of the assessed materials exceeded the reading skills of the average high school graduate (Rudd et al, 2000). **Table 3-1** lists several problems associated with inadequate health literacy (Zarcadoolos et al, 2006).

Implications to Veterinary Medicine

For the most part, pet owners mirror the general population. That being the case, it is highly likely that the same issues the human health care system faces related to health literacy reside in the pet-owning population. Unfortunately, this has never been studied to any great degree in veterinary medicine, but the ramifications of this revelation are alarming.

Clients depend on our medical expertise and our ability to translate that skill into information they can relate to and act upon. The pet's health and well-being depend on our ability to effectively communicate our intended meaning to the owner. Although we may believe we are communicating with pet owners, we may in fact be adding substantially to their confusion, uncertainty and frustration about doing what's best for their pet.

Poor communication with clients can result in less than optimal short- and long-term care. As preventive and therapeutic medical advocates for pets, veterinarians and other health care team members have an obligation to help pet owners make informed decisions about their pet's care. Providing accurate information about proper pet nutrition is

Table 3-1. Problems caused by inadequate health literacy.*
Improper use of medications
Inappropriate use or no use of health services
Poor self-management of chronic conditions
Inadequate response in emergency situations
Poor health outcomes

as necessary as appropriate medicine and surgery. It is a sobering thought to consider that the number of pet deaths attributable to poor communication may meet or exceed surgical or anesthetic-related deaths.

Because there is little in the way of insights about this problem in veterinary medicine, issues about the human health literacy crisis will be discussed. Readers should associate these data to the client-pet-veterinary and veterinary team interface and challenge themselves to make a concerted effort to enhance communication skills to better care for the pets and people they serve.

Definitions

Health literacy may be defined as "the degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions" (Ratzan and Parker, 2000; Healthy People 2010). A 1999 report from the Council on Scientific Affairs of the American Medical Association refers to functional health literacy as "the ability to read and comprehend prescription bottles, appointment slips and other essential health-related materials" (AMA, 1999).

Other proposed definitions include:

- Health literacy is a constellation of skills, including the ability to perform basic reading and numerical tasks required to function in the health care environment (AMA Ad Hoc Committee).
- Health literacy has three levels: 1) functional health literacy, which refers to the communication of information, 2) interactive health literacy, which deals with the development of personal skills and 3) critical health literacy, which is needed for personal and community empowerment (Nutbeam, 1998).

Understanding Health Literacy

Health literacy includes more than simply obtaining information. Health literacy embraces writing, numeracy, listening, speaking and conceptual knowledge (IOM, 2004). Health literacy emerges when expectations, preferences and skills of individuals seeking health information meet equivalent goals of those providing information and services (IOM, 2004). Education, language and culture mediate health literacy skills (IOM, 2004). Equally important are the communication and assessment skills of health care professionals. Furthermore, their patients must navigate the media, marketplace and governmental agencies to obtain health information (IOM, 2004).

Even people with strong literacy skills may have trouble obtaining, understanding and using health information; for example, an accountant may not know when to schedule a pap smear and a chef may be unable to prepare health conscious meals (IOM, 2004).

As mentioned above, 90 million adults (47% of the adult population) may lack the literacy skills to effectively use the U.S. health care system (IOM, 2004). The majority of these adults were born in the U.S. and speak English. Literacy levels are lower among elderly persons, those who have lower educational levels, those who are poor, minority populations and groups with limited English proficiency such as recent immigrants (IOM, 2004). The gap between knowledge and practice is widened by inadequate health literacy. People who lack an understanding of health care usually present with more advanced disease, receive fewer preventive care services and have poorer health outcomes (IOM, 2004). As one example, diabetics with poor health literacy were more likely than patients with adequate health literacy to have poor glycemic control and reported more retinopathies (Schillinger et al, 2002).

In its report Healthy People 2010, the U.S. Department of Health and Human Services included improved consumer health literacy as Objective 11-2, and identified health literacy as an important component of health communication, medical product safety and oral health. The 2003 Coalition for Allied Health Leadership team completed a national survey of allied health professionals and educators to assess awareness and needs concerning health literacy. Approximately one-third of all respondents were unaware of the issues surrounding health literacy, or that health literacy resources were available; denied knowledge of an impact of health literacy on patient care for their specific profession or had no institutional policy or goals to address health literacy. The article states that inadequate health literacy adversely affects health care outcomes and the quality of life of 90 million Americans. The cost to the health care system is $73 billion annually (Health Literacy Survey, 2004).

"Literacy" provides the skills that enable individuals to understand and communicate health information and concerns. As mentioned above, educators do not associate literacy

Box 3-1. Health Literacy in an Older Man.

A 64-year-old man, with a history of noncompliance, was evaluated for a routine checkup. According to the resident, he hadn't taken his medications for diabetes or a heart problem for several weeks. Before leaving he received instructions about his medications, their importance and the proper doses. He disclosed he would see his doctor for follow-up, but couldn't remember the person's name. He was given a handwritten discharge summary.

He was seen five months later at a community clinic. He said he was taking his medications, but couldn't remember their names or dosages. The regimen was reviewed a second time; dates for blood tests were provided. He was scheduled for a recheck in two weeks.

When he returned, a medical student made a diagnosis that no one had considered: illiteracy. Many of his glucose values had been written for future dates and he was unable to read his list of medications. The man lived alone, dropped out of school in the second grade and had never learned to read.

Despite avoiding jargon and use of simple language, his medical team–comprised of many doctors, nurses and social workers–had not guessed he couldn't read.

This patient's problem is not uncommon. Fourteen percent of the adults in the U.S. have substandard prose ability: "ability to use printed and written information to function in society, to achieve one's goals and potential." According to The National Assessment of Adult Literacy (NAAL), these substandard skills "are no more than the most simple and concrete literacy skills: ranging from those completely illiterate to those who can identify short phrases.

Other facts: based on NAAL data, 12% of U.S. adults have "document illiteracy." That is, they lack the ability to read and understand transportation schedules and food and drug labels. These people cannot read a television program to find what time a program will be aired. Twenty percent have below basic "quantitative literacy," the ability to perform fundamental quantitative tasks such as comparing ticket prices for two events. Older people (i.e., >64 years) fared the poorest on the NAAL; 23% had below average prose literacy, 27% below basic document literacy and 34% below basic quantitative skills.

Survey results indicate more than one-third of English-speaking patients and more than half of primarily Spanish-speaking patients at U.S. hospitals have low literacy. Often, these people present in the emergency room rather than a clinic because someone there will always write the information down so they don't have to do it themselves.

Patients with low literacy skills are often ashamed of their problem, with two-thirds never telling their spouses.

One clinician thinks that literacy screening should become a new vital sign. But that approach is controversial; no one wants to be embarrassed especially in front of his or her doctor. And there is little time to collect more information now in clinical practice. However, much has been written on the topic.

The patient described at the beginning of this case, with help, enrolled in an adult reading course, but it's still not clear if he takes all his medications as prescribed.

The Bibliography for **Box 3-1** can be found at www.markmorris.org.

with reading alone, but often consider literacy to represent a constellation of skills including reading, writing, basic mathematical calculations and speech and speech comprehension skills (Kirsch, 2001; Healthy People 2010) (**Table 3-2**).

Problems Associated with Inadequate Health Literacy

Individuals with inadequate health literacy (as currently measured) report less knowledge about their medical conditions and treatment, worse health status, less understanding and use of preventive services and a higher rate of hospitalization than those with marginal or adequate health literacy (Parker et al, 2003).

Inadequate health literacy is a hidden problem. People with limited health literacy skills may be embarrassed to discuss or even mention problems they encounter with the health care system (Baker et al, 1996; Parikh et al, 1996).

Health care personnel assume patients are telling everything, which is clearly not the case (**Box 3-1**). Studies show that a large percentage of patients are noncompliant and that health care professionals significantly underestimate how common noncompliance is (Hall et al, 1988).

Two recent studies demonstrated a higher rate of hospitalization and use of emergency services among patients with limited literacy. This higher use has been associated with higher health care costs (IOM, 2004). The Institute for HealthCare Advancement estimates that the average annual health care costs of people with very low health literacy may be four times greater than that of the general population (Sarasohn-Kahn, 2002). In a small Arizona study, patients with reading levels at or below third grade had mean Medicaid charges $7,500 higher than those who read above the third grade (Weiss and Palmer, 2004).

Inadequate health literacy is particularly common among older adults and low-income patients. More than 66% of U.S. adults age 60 and older have inadequate or marginal literacy skills and about 45% of all functionally illiterate adults live in poverty (AMA Foundation, 2000).

A study of 2,659 outpatients at two hospitals found that 42% did not understand instructions to "take medication on an empty stomach." The same study found a 52% increase in the risk of hospitalization among patients with inadequate literacy compared with patients with adequate literacy (Williams et al, 1995). In the largest study of health literacy to date, one-third of English-speaking patients at two public hospitals were unable to read basic health materials. Twenty-six percent were unable to understand information on an appointment slip and 60% did not understand a standard informed consent docu-

Box 3-2. Health Literacy and Language Barriers.

Almost 50 million Americans (~19% of U.S. residents) speak a language other than English at home. A total of more than 22 million have limited English proficiency, speaking less than "very well" by their own admission. The decade leading up to 2000 experienced a 47% (more than 15 million people) increase in the number of people who spoke a language other than English at home.

Many patients who need medical interpreters have no access to them. Results of one study showed that no interpreter was used in 46% of emergency department cases involving people with limited English proficiency. Furthermore, few clinicians receive instructions with how to work with interpreters.

Language barriers and deficits can cause great harm. Patients are often nonadherent to medications, less likely to return for follow-up visits and have higher rates of hospitalization and drug complications. Two cases follow:

Case 1: A two-year-old girl was diagnosed with an inner ear infection and was prescribed an antibiotic. Her mother understood that her daughter should receive the prescribed medication twice daily. After carefully studying the label on the bottle and deciding it didn't tell how to administer the medication, the mother filled a teaspoon and poured the antibiotic into her daughter's painful ear.

Case 2: A young Spanish-speaking man stumbled into his girlfriend's house and said he was "intoxicado." The Spanish-speaking paramedics took the work to mean "intoxicated." The patient's intended meaning was "nauseous." After 36 hours of being worked up for a drug overdose, the patient was reevaluated and found to have an intracerebellar hematoma with brainstem compression and a subdural hematoma. The young man became a quadriplegic.

Family members, friends and untrained members of the support staff are often used in these encounters, but commit more errors than those with more training. Much work needs to be done in this area given the changing dynamics of the U.S. population.

The Bibliography for **Box 3-2** can be found at www.markmorris.org.

ment (Williams et al, 1995).

Racial and ethnic differences can contribute to communication breakdowns (**Box 3-2**). As many as 20% of Spanish-speaking Latinos say they do not seek medical advice due to language barriers (IOM, 2002). A 2001 survey of 6,722 adults found that minority populations are more likely to have difficulties communicating with their health care providers compared with whites (Collins, 2001).

Even highly skilled individuals may find the health care system too complicated to understand, especially when poor health, anxiety, effects of medication, etc. make them more vulnerable. Directions, signs and official documents, including informed consent forms, social services forms, public health information, medical instructions and health education materials often use jargon and technical language that make them too difficult to use (Rudd et al, 2000).

Patients with inadequate health literacy and chronic illness have less knowledge of illness management than those with high health literacy (Kalichman and Rompa, 2000). Public hospital patients with inadequate health literacy had higher rates of hospitalization than those with adequate health literacy (Baker et al, 1996). Adults with limited health literacy have less knowledge of disease management and of health-promoting behaviors, report poorer health status and are less likely to use preventive services (IOM, 2004).

Adverse drug events are another aspect of inadequate health literacy. One report found that 10% of adverse drug events were linked to errors in the use of the drug as a result of communication failure (Leape et al, 1993).

Where do Patients Receive Health Care Information?

Socioeconomic status, education level and primary language all affect whether consumers will seek out health information, where they will look, what type of information they prefer and how they will interpret that information (IOM, 2004). There is no single reliable answer.

Between 62 and 69% of adults at all literacy levels reported obtaining information from family and friends. Between 94 and 97% of adults at all skill levels reported using radio and television to obtain information. Individuals with lower literacy levels were less likely than those with higher skills to use newspapers and magazines for health information (69.5 vs. 90%).

The National Cancer Institute conducted the Health Information Trends Survey (HINTS), one of the nation's first national surveys of health information sources in 2003 and 2005. HINTS databases are designed to provide information regarding pattern of information use and opportunities to inform Americans about cancer.

In a Gallup survey, the proportion of people who reported getting "a great deal" or "moderate" amount of health or medical information from these sources follows: doctors (70%), television (64%), books (56%), newspapers (52%), magazines (51%), nurses (49%) and the Internet (37%). The proportion of people who reported a great deal or moderate amount of trust and confidence in the health or medical information from the sources follows: doctors (93%), nurses (83%), books (82%), newspapers (64%), magazines (62%), the Internet (62%) and television (59%) (Gallup Organization, 2002).

People have more ways than ever to get information, including telephone, fax, e-mail, the Internet, television, radio, print media, family and friends, etc. More sources will be available in the future, including automated monitoring of vital signs and markers, increased use of wireless technology, among others. But how do people access information today and how accurate is that information? The National Cancer Institute sought to answer some of these questions through HINTS. Some results follow (Hesse, 2004):

- Where would you go for cancer information? Provider (50%), Internet (34%), Library (5%), Family (4%), Other (4%), Print media (3%).
- Where did you go for cancer information? Internet (49%), Print media (27%), Provider (11%), Library (6%), Other (4%), Family (3%).
- Trust information by gender? There were no gender differences. Doctors came in first, followed by television. No differences existed among family/friends, newspapers, magazines, radio, television and the Internet.
- Trust information by education? Those with no high school diploma tended to trust their doctors and television far more than family, friends, newspapers, magazines, radio and the Internet.
- When asked to agree or not with the statement "Everything causes cancer:" 51% strongly agreed or agreed; only 18% strongly disagreed.
- When asked to agree or not with the statement "There's not much people can do to lower their chances of getting cancer:" 72% strongly disagreed or somewhat disagreed.
- When asked to agree or not with the statement "There are so many different recommendations about preventing cancer, it's hard to know which ones to follow:" 77% strongly agreed or somewhat agreed.

Family and Friends

Personal stories may have the power to influence health behavior, especially in those with inadequate literary skills. One study found that many individuals with inadequate literacy more often obtained information about cancer from family and others who have had experience with a late-stage diagnosis rather than from reading about the disease (Friedell et al, 1997).

The Internet

The Internet is estimated to reach more than 70 million people living in the U.S. with health information. About 90% of 15- to 24-year-olds have been online; 75% of these have used the Internet at least once to obtain health information (Rideout, 2004). Inadequate English literacy and disparities in computer access decrease the likelihood that the information will be available to, and understood by, all health consumers (Houston and Allison, 2002). The quality and reliability of online content can be problematic. A meta-analysis of consumer health information on the Internet found that 70% of the studies analyzed concluded quality was a problem (Eysenbach et al, 2002).

Health Care Professionals

A number of studies demonstrate that patients remember and understand as little as half of what they are told by their physicians. In addition, because they have knowledge deficits, patients with inadequate health literacy may be less equipped to overcome discrepancies in understanding and memory when they are at home and experience difficulties reading or interpreting instructions (IOM, 2004).

Limited education, training, continuing education and practice opportunities to develop skills for improving health literacy exist for allied health professionals and educators at the national level (IOM, 2004).

Some evidence of a failure of communication exists with patients who have inadequate health literacy as currently measured. Patients with chronic diseases and inadequate health literacy have poor knowledge of their condition and its management, often despite having received standard self-management education (Williams et al, 1998, 1998a). Patients with inadequate health literacy have more difficulty accurately reporting their medication regimens and describing the reasons for which their medications were prescribed (Schillinger et al, 2003) and may have poorer compliance (Kalichman et al, 1999).

Communication between a health care provider and patient during outpatient visits may be hampered by several related factors. These include the relative infrequency and brevity of visits, language barriers, differences between providers' and patients' agendas and communication styles and other cultural barriers, lack of trust between the patient and provider, overriding or competing clinical problems and the complexity and variability of patients' reporting symptoms and trends in their health status (IOM, 2004).

The average patient asks only two questions during an entire medical visit lasting an average of 15 minutes, according to the Bayer Institute of Health Care Communications. Studies show that most patients are relatively uninformed about their condition or the most appropriate treatment despite the fact that most patients state they want more information. Results of one study revealed that doctors imparted information to patients for an average of a little more than a minute during interviews that lasted an average of more than 20 minutes. When asked how much time they spent on patient education, the physicians overestimated by a factor of nine. The study also found that in 65% of the cases, physicians thought patients wanted less information than they actually did (Terry, 1994).

An Institute of Medicine (IOM) report clarifies the links between miscommunication and medical and health errors and adverse events (2002). A variety of problems can result if culture and language are not accounted for including failure to obtain accurate medical histories, failure to obtain informed consent, inadequate health knowledge and understanding of health conditions, inadequate treatment adherence (compliance), medication errors, decreased use of preventive and other health care services and poor patient satisfaction. Customized and tailored care based on patient needs and values and accommodating differences in patient preferences are integral to individualized care (IOM, 2001).

The concept that no one size fits all is fundamental to the understanding of health literacy. Complex problems are rarely resolved by simple solutions. However, scientific investigations of interventions to minimize the impact of health literacy and promote the development of health literacy skills are in its infancy (IOM, 2004). Evidence-based approaches show promise for contributing to better outcomes (Chapter 2).

Health literacy must be understood and addressed in the context of culture and language (IOM, 2004). Competing sources

of health information (including the national media, the Internet, product marketing, health education and consumer protection) intensify the need for improved health literacy.

Improving Health Literacy

Health literacy is fundamental to quality care (IOM, 2004). Without improvements, the effect of many advances to improve health outcomes will be diminished. Consequently, the IOM of the National Academies (U.S.) has identified improving health literacy as one of two crosscutting issues in health care requiring attention (IOM, 2003). The IOM reports that enabling patients to understand their condition and its treatment, to make the best decisions for their care and to take the right medications at the right time in the intended dose; that is, to act in their own interest remains a neglected, final pathway to high-quality health care (IOM, 2004).

A 1998 report from the U.S. Department of Health and Human Services provided evidence from accumulated studies that health, morbidity and mortality are related to income and educational factors (Pamuk et al, 1998). Life expectancy and death rates from cancer and heart disease, incidence of diabetes and hypertension and use of health services were related to family income. Death rates from chronic diseases, communicable diseases and injuries were inversely related to education (i.e., those with lower educational achievement were more likely to die of a chronic disease than those with higher educational achievement). In essence, the lower one's income or educational achievement, the worse one's health (IOM, 2004).

Approaches that appear to successfully improve health literacy include:

1. Provision of simplified/more attractive written materials
2. Technology-based communication techniques
3. Personal communication and education
4. Combined tailored approaches
5. Partnerships (collaborative measures between patient and the health care team).

In all of these, using plain language (common words, defining unusual words, writing the way people talk); simple, specific and direct sentences; active, inflective voice; sequencing ideas clearly and logically; being attentive to and respectful of culture enhance the patient's ability to understand and retain information. It is also imperative to be cognizant of overt and covert messages and to improve skills, materials and processes. This includes changing outdated approaches and encouraging professionals to improve verbal and written communication skills, including work with the adult education sector, etc. (Rudd, 2002).

Professionals are also encouraged to write legibly or type, and use simplified language with more white space, improved format and pictograms (See below.) or other graphic devices. Pictograms may be especially useful for communicating information to consumers who speak English as a second language and to those with lower reading ability levels (IOM, 2004).

The telephone can be a great means of delivering interventions such as health-related counseling and reminders, if the caller has competent verbal communication skills. Tailored print communications can improve health outcomes, but research also shows that they are less effective at influencing individuals who are not serious about making a behavioral change (Revere and Dunbar, 2001; IOM, 2002).

Arcane language and jargon that are common to health care workers are usually indecipherable to patients. Adults who have difficulty reading or understanding written materials are often embarrassed and devise ways to hide their inability to understand. If health care professionals invested more time to ask their patients to explain exactly what they understand about their diagnoses, instructions and bottle labels, the caregivers would find many gaps in knowledge, difficulties in understanding and misinterpretations (IOM, 2004). These problems are exacerbated by language and cultural variation, by technological complexity in health care and by intricate administrative documents and requirements.

Female primary care physicians tend to engage in longer visits and have more "patient-centered" consultations than their male counterparts (Roter et al, 2002). Female physicians engage in significantly more active partnership behaviors, positive talk, psychosocial counseling, psychosocial question asking and emotionally focused talk. Medical visits with female physicians are, on average, two minutes (10%) longer than those with male physicians.

Distinguishing between noncompliance and inadequate literacy may be difficult unless health care providers regularly ask patients questions such as, "Was I clear?" "Is there anything you'd like for me to go over again?" These types of questions put the burden of responsibility on the speaker rather than on the listener. Researchers and the American Medical Association advocate the importance of teachback. For example, asking "Just so we both agree, why don't you tell me what you would do if XYZ happens?" or to demonstrate how the patient would do something, like monitor blood glucose concentration.

In veterinary medicine, this simple approach of having pet owners relate back their understanding (without feeling like they've been put on the spot) can have dramatically positive ramifications for pet care. Speaking clearly and being an attentive listener can express that you care. Empathy goes a long way in building trust and establishing a relationship so that communication is successful. Focus on using basic words and making the message clear.

A meta-analysis of 41 research studies showed that giving patients more information is associated with increased patient satisfaction, better compliance and better recall and understanding of medical conditions (Rankin and Stallings, 1996).

Technology-Based Communication

It's very hard to cover all the complex information needed to make decisions in spoken and written words. Covering some information with tools such as CD-ROMs before patients meet with their doctors has increased satisfaction in at least one study in human medicine.

According to the Memorial Sloan-Kettering Cancer Center, "New technology (i.e., a CD-ROM educational tool) can save nurses' time by eliminating the need for repetitive

teaching, and enrich patient teaching by allowing the nurse more time to address individual concerns" (Ginty and Sullivan, 2001). A second study conducted at the same center discussed the benefits that were realized after nurses used an educational CD-ROM to supplement their teaching to pre- and postoperative cancer patients. According to the center, "The nurse is responsible for doing preoperative teaching, much of which is standard and the same for every patient. Nevertheless, it must be repeated for each patient." The CD-ROM covering standard pre- and postoperative topics was very effective; 78% of patients who completed a follow-up quiz had one or no answers wrong. Nurses estimated that the program significantly decreased the time it took them to do standard preoperative teaching, allowing them to focus on patient-specific questions and concerns. The study concluded that "patients stated the animation, narration and photographs on the CD-ROM reinforced their understanding and decreased anxiety" (Vaziri and Gallagher, 2001).

Professional and public awareness of the health literacy issue must be increased, beginning with education of medical students and physicians and improved patient-physician skills (Schillinger et al, 2004). Such training of veterinary students, veterinarians and all health care team members would no doubt be of great benefit to pets and pet owners as well.

Pictographs

Pictographs (e.g., like simple drawings on road signs) have been used in non-literate societies to help people remember spoken instructions. Pictographs are designed to help people understand information quickly. One small study tested the hypothesis that pictographs can improve recall of spoken medical instructions. Twenty-one junior college students listened to lists of 38 actions for managing fever and 50 actions for managing sore mouths. One of the action lists was accompanied by pictographs during listening and recall whereas the other was not. Subjects did not see any written words during the intervention and therefore, relied entirely on memory of what they heard. Mean correct recall was 85% with pictographs and 14% without ($p < 0.0001$) (Houts et al, 1998).

Impact of Health Literacy on Compliance

Health literacy has only recently reached the national agenda in human medicine and for the most part, hasn't at all in veterinary medicine. Logically, many of the 90 million Americans with inadequate health literacy own pets. It would be imprudent to assume that they understand preventive protocols, diagnoses and treatments for their pets any better than they do for themselves.

There is very little information about the exact relationship between compliance and health literacy in human medicine and none in veterinary medicine. Studies show, however, that a large percentage of patients are noncompliant and that health care professionals significantly underestimate the scope of noncompliance (Hall et al, 1988). Likewise, compliance is a major problem in veterinary medicine (See below.) (AAHA, 2003).

Conclusion

Health literacy is fundamental to quality care (IOM, 2004). A former surgeon general recently stated that "health literacy can save lives, save money and improve health and well being of millions of Americans…health literacy is the currency of success for everything I am doing as Surgeon General" (Carmona, 2003).

People's prior knowledge, beliefs and experiences influence the way they interpret and use health information. Furthermore, America's increasing cultural diversity challenges health communication activities. Until now, we've known little about how people seek health information or how to bridge the substantial discrepancies between the information they want and need and what they receive (Croyle, 2004). Several books are available to provide information about improving health literacy and compliance (**Table 3-3**).

Health literacy must be actively addressed by the medical profession, and likewise, the veterinary profession should take an aggressive approach to enhance veterinary health literacy.

CLIENT COMPLIANCE

Introduction and Background

Around 400 BCE, Hippocrates supposedly observed that some of his patients failed to comply with medical instructions, thus prolonging their recovery. He subsequently counseled his students that some patients would be less than honest about taking medication. In the early 1900s, tuberculosis patients who failed to follow medical instructions were called "defaulters" (Jaret, 2001). Patients were subsequently described as "faithless," "untrustworthy" and "unreliable" over the following half century when they failed to follow their physician's orders (Steiner and Ernst, 2000). Unfortunately, noncompliance with medical instructions remains a huge problem more than 2,400 years after Hippocrates' warning.

Improving communication is an important aspect of improving compliance. The Food and Drug Administration (FDA) supports higher-quality health information for the public. An FDA study in 1999 found that 56% of people who saw a consumer-directed print advertisement for a prescription drug said they read the brief summary "not at all" or "a little." In a follow-up study in 2002, that number increased to 73%. During the same three-year span, those saying they read "almost all" or "all" decreased from 26 to 16%. Based on these data, the FDA wants manufacturers to present key risk information in consumer-directed print advertisements in more consumer-friendly ways, including use of clearer, less cluttered formats for presenting risk information. The FDA also encourages manufacturers to focus their risk disclosures on the most important and the most common risks and to do so in language easily understood by the average consumer (FDA, 2004).

Preventive and therapeutic noncompliance is a major issue in human health care and, as we'll show, in veterinary medicine. The number one problem in treating illness today is patients' failure to take prescription medications correctly, regardless of patient age (AmericanHeart.org, 2004). Failure to take medica-

tions as directed costs the U.S. economy $100 to $300 billion annually (Fortune, 2004). In the U.S. today, the annual consequences of noncompliance include (epill.com):

- An estimated 125,000 deaths.
- 23% of nursing home admissions (380,000 patients/$31.3 billion) are the result of patients failing to take prescription medications accurately.
- 10% of hospital admissions (3.5 million patients/$15.2 billion) are the result of patients failing to take prescription medications correctly.
- Reduced productivity (absenteeism, impaired work performance [20 million workdays/$1.5 billion]).
- Lengthened hospital stays (4.2 days) due to medication noncompliance.

The American Heart Association presents the following facts on its website to further define the scope of noncompliance (AHA, 2004): Almost 49% of Americans use prescription drugs and 30% use nonprescription medications.

- Almost 29% stop taking their medicine before it runs out.
- 22% take less of the medication than is prescribed on the label.
- 12% don't fill their prescriptions at all.
- 12% don't take medication after they buy the prescription.
- At any given time, up to 59% of patients on five or more medications are taking them improperly, regardless of age.
- Adverse drug reactions may be the fourth to sixth leading cause of death. Serious adverse drug reactions occur in 6.7% of hospitalized patients.

The above data deal with health care compliance in the U.S. Similar data exist for other developed countries. The World Health Organization has published an excellent review about the difficulties of compliance: *Adherence to Long-Term Therapies: Evidence for Action* (WHO, 2003). Compliance data from developing countries is even lower.

The information that follows summarizes much of the existing knowledge about compliance in small animal veterinary practice. Promoting awareness of poor compliance rates and acknowledging our ability and obligation to improve them are the first steps in improving adherence to recommended services and products and their associated outcomes for dogs and cats.

Definitions

Compliance has been traditionally defined as "the extent to which the patient (client in veterinary medicine) follows medical instructions" (Sabate, 2001). Unfortunately, this definition promotes a paternalistic relationship and suggests patients (or clients) should be passive participants in health care. Furthermore, this concept of compliance omits many nonmedical interventions that promote health including diet, exercise, routine dental care and avoiding or minimizing behaviors that increase the risk of illness. A better definition is the extent to which a person's (or pet owner's) behavior-taking (administering) medication, following a diet and/or executing lifestyle changes-corresponds with agreed recommendations from a health care provider (WHO, 2003). Another definition used in veterinary medicine: the pets in your practice are receiving the care that you believe is best for them (AAHA, 2003). Compliance is thus a behavior and a measure (Hasford, 1999). Veterinary clients are/will become surrogates for their pets in this regard.

Compliance will be used throughout this article because the term is firmly entrenched in the medical and dental literature and is gaining in awareness in veterinary medicine. As mentioned above, compliance, as defined in human medicine, suggests a paternalistic relationship and connotes blame (as do other terms such as control, adhere, prescribe, regimen, what's best for you and will power), whether it be of patients, clients or health care providers, and is associated with the outmoded concept that the client is the sole source of noncompliance. The concept of adherence may be a better way of capturing the dynamic and complex changes required over long periods to

maintain optimal health for people or pets with chronic diseases (WHO, 2004). Adherence requires that the patient (client in veterinary medicine) agree to treatment recommendations. Concordance takes the relationship further because it fosters the concept of agreement between clients and health care providers about whether, when and how medications should be taken. Adherence is used synonymously with compliance in this chapter.

Based on the 2003 AAHA Compliance Study, veterinarians strongly believe that compliance is all or mostly the client's responsibility. Forty-one percent of veterinarians said clients were responsible for noncompliance, whereas 19% said it was the veterinarians; 36% indicated that clients and veterinarians shared the responsibility (AAHA, 2003).

Compliance Research in Veterinary Medicine

The first compliance articles began to appear in the human medical literature in the 1950s. Since then, thousands of articles have been published and dozens of businesses and websites have been created to promote the concept of compliance. By comparison, only a handful of articles have appeared in the veterinary literature. A sampling of the relevant literature follows (**Boxes 3-3** through **3-5**).

In one study, 48% of the dogs visiting 36 veterinary clinics were placed on the recommended heartworm preventive program. These dogs received 78% of the medication required to fully comply with the clinics' recommendations (Cummings, 1995). In another study involving cats with stable chronic renal failure, compliance was not achieved in more than 40% of cats, although cats receiving dietary therapy (i.e., foods restricted in phosphorus and protein) were generally healthier and lived for three times longer, on average. Limited food intake by cats, owner resistance or both were cited as reasons for noncompliance (Elliott et al, 2000).

At least three studies measured compliance with short-term antibacterial therapy in dogs. In one study, investigators assessed compliance among 95 dog owners using a telephone survey. Forty-four percent reported 100% compliance with the treatment regimen and 88% reported a compliance level of 80% or more. Compliance was significantly higher when dog owners felt that the veterinarian spent enough consultation time. Compliance results were higher for dogs treated for gastrointestinal (GI) infections compared with those treated for other diseases (Grave and Tanem, 1999). In another study, electronic monitoring (e.g., Which may mean as little as the client opened a bottle with an electronic chip, whether the client gave the medication or whether the pet regurgitated the medication are variables.) showed owners administered an average of 84% (range 7 to 104%) of an antibiotic given for five to seven days. Return medication counts and client self-reports overestimated therapeutic compliance compared to electronic monitoring. The majority of owners (71%) claimed perfect compliance with the prescribed regimen (Barter et al, 1996). The third study reported that there was no difference in compliance for regimens that included twice or three times per day administration of an antibiotic (84%). However, only 34% gave doses within the designated optimal time period. Compliance tended to be better with the twice-daily regimen although the differences were insignificant (Barter et al, 1996a). It should be noted, however, that these percentages were self-reported.

In dental compliance studies, owners of dogs were given extensive instructions about brushing their dog's teeth. Six months later, 53% were still providing the minimum care necessary to prevent periodontal disease (Miller and Harvey, 1994). Another study compared three dental homecare regimens, including daily toothbrushing and two different dental foods, with a control group in 88 client-owned cats for six months after a professional cleaning. A large-sized kibble with dental properties was most efficacious in controlling calculus formation and development of gingivitis. Toothbrushing compliance was only 40% at the end of the six-month study (Theyse et al, 2002).

Box 3-3. Human Oral Health Literacy Studies.

Eight objectives in Healthy People 2010 concern the oral health of U.S. adults, including goals to reduce dental caries, gingivitis, oral cancer and tooth loss, as well as to improve use of the dental care system. The Surgeon General recognized that "the majority of people who need such information most, those in low-income groups and those with lower education levels, also are the ones who lack the information and skills (oral health literacy) to ask for and obtain specific preventive services or treatment options."

One article in this review studied the readability of 24 educational materials for dental patients. The reading levels ranged from the third to 23rd grade levels, more than 40% of which were written above the seventh to ninth grade level. Many of the materials contained grammatical errors and obscure jargon.

A second article examined the readability and distribution of 20 printed materials containing oral health educational information. Ninety-one percent of the materials were written between the 9th and 15th grade levels.

A third article assessed the difficulty of dental words and tested the readability of selected dental health education materials. Adolescents were asked to read aloud and describe the meanings of 25 commonly used dental terms. Several words were poorly understood, including "gum disease," "oral hygiene," "fluoride tablets" and "gingivitis." The four dental health education brochures studied were written from 12.4 to 17.4 reading grade levels.

Yet another study assessed the readability of 19 oral cancer educational pieces. Five pieces tested at the sixth and seventh reading grade levels, nine at the eight and ninth grade levels, and five at grades 10 through 13.

Box 3-4. Compliance in Human Medicine.

Several types of noncompliance exist. Initial noncompliance occurs when a patient receives a written prescription or calls a pharmacy, but doesn't wait or return to pick up the filled prescription. Patients who fail to present a prescription are also initial noncompliers. Varying compliance is used to describe the process of taking a prescribed medication at a level less than recommended. Hypercompliance occurs when a patient takes a medication at a level above that prescribed. The term "white coat compliance" is used to describe behavior in which a patient who has been noncompliant takes medication at or above the prescribed level around a recheck appointment. Accordingly, both the physician and the patient may incorrectly believe the patient is receiving therapeutic benefit. "Drug holidays" refers to the behavior in which patients repeatedly and abruptly discontinue and resume taking their medication.

Studies have shown that the amount of information forgotten by patients is a linear function of the amount presented and is correlated with the patient's medical knowledge, anxiety level, and possibly age, but not with intelligence. Therefore, a phased approach is preferable in patient education. Both oral and written information should be provided (e.g., patient education booklets, medication cards, etc.) and special materials should be developed to instruct patients with low literacy (e.g., picture schedule). Formal evaluation of patient education is imperative.

Failure to attend appointments is often one of the first signs that a patient is not complying with his or her treatment. Given the difficulty of monitoring compliance directly, health care professionals may want to monitor patients' attendance at clinic appointments as a proxy measure.

Asking patients to complete diaries about medication use has the advantage of providing details about how and when the product was taken. However, whether diaries improve compliance hasn't been proven.

The Bibliography for **Box 3-4** can be found at www.markmorris.org.

The American Animal Hospital Association Compliance Study

The American Animal Hospital Association conducted the largest, most significant compliance study in veterinary medicine, which was funded by a substantial educational grant from Hill's Pet Nutrition, Inc. Results of the study were reported in the book *The Path to High-Quality Care: Practical Tips for Improving Compliance* in 2003. This comprehensive study showed that millions of dogs and cats did not receive the best care they could have. Although most practice teams thought compliance with recommendations was high, few practices actually measured compliance and the level of compliance in almost all cases was significantly less than what practice teams believed; 78% of veterinarians indicated that they were satisfied with the levels of compliance in their practices (AAHA, 2003). Researchers visited 52 practices and/or conducted in-depth interviews with practice teams. More than 1,000 pet owners were surveyed about the care they provided for their pets, their desires relative to the information and care provided by their veterinarian and their compliance with health care recommendations. Furthermore, data were gathered from the medical records of almost 1,400 cats and dogs. These data were used to quantify compliance and the opportunities that practices had to improve pet care by improving compliance (AAHA, 2003). The study quantified compliance in six areas:

- Heartworm testing and prevention
- Dental prophylaxis
- Therapeutic foods
- Senior screenings
- Canine and feline core vaccinations
- Preanesthetic testing.

Only dogs and cats seen by their veterinarian at least once during the past 12 months were included in the study; extrapolation accounts for 51 million dogs and 44.2 million cats falling into this category (AVMA, 2002). The AAHA compliance data do not include 10.6 million dogs and 22.7 million cats that were not seen at a veterinary practice during the previous year.

More than seven million dogs were not in compliance with their veterinarian's protocol for heartworm testing. Almost 21.5 million owners did not give their dog's heartworm preventive medication at all, failed to give medication for the number of days recommended by their veterinarian, or (and maybe most alarming) were never dispensed an adequate amount of preventive in the first place, or were never notified by the practice to purchase follow-up doses. In endemic areas, compliance for testing and preventive medication was 83 and 48%, respectively. The American Heartworm Association reported that more than 244,000 dogs tested positive for heartworms in 2001 (AAHA, 2003).

The AAHA Compliance Study found a dental prophylaxis compliance rate of 35% for dogs and cats with grade 2, 3 or 4 dental disease. Compliance was only 15% for those pets with grade 1 disease. The study concluded that almost 15.5 million dogs and cats with grade 2, 3 or 4 dental disease had not received dental prophylaxis. Based on chart review, 23% of those owners of pets with grade 2 or higher dental disease (3.6 million pets) did not receive a recommendation for treatment. Millions more cats and dogs had grade 1 disease. Interestingly, no grade was reported for 19% of the patients. The lack of a reported dental grade may indicate that no exam was given or poor medical record keeping (AAHA, 2003). The American Veterinary Dental College defines quality dental health care as completing a dental prophylactic procedure on any pet with grade 1 to 4 dental disease. Veterinary health care teams failed to adhere to these recommendations in a great many cases, which has resulted in less than the best care for many patients.

Compliance with feeding a therapeutic food for six canine conditions (i.e., kidney disease, bladder stones or crystals, food allergies, chronic GI disease, acute GI disease and obesity) and seven feline conditions (i.e., the same six canine topics plus feline lower urinary tract disease) was included in the survey.

Compliance with feeding therapeutic foods was 19% for dogs and 18% for cats. More than 11.6 million dogs and nine million cats with one of the diagnosed conditions were not fed an appropriate therapeutic food at all or were not fed the food for an appropriate period of time (AAHA, 2003). When all pets with diagnoses that could benefit from treatment with a therapeutic food were considered, overall compliance was 5 to 7%, which represented more than 52 million dogs and cats. The real potential for improvement for all foods combined could be as high as 20-fold. What was also disturbing is that 55% of pet owners who fed a therapeutic food also supplemented the recommended food with other foods or treats. The primary reason cited by clients was that they didn't know not to.

Thirty-five percent of the dogs and cats in a typical practice are considered senior (i.e., mature). Senior screenings minimally included blood work and a urinalysis. About 17.9 million dogs and 15.5 million cats considered to be senior had not received a diagnostic screening in the past year. Only 32 and 35% of the dogs and cats had diagnostic screening tests performed (AAHA, 2003).

Compliance for core vaccinations (i.e., distemper, hepatitis, leptospirosis, parainfluenza and parvovirus for dogs and viral rhinotracheitis, calicivirus and panleukopenia for cats) was 87%, which was higher than for any other condition studied. Still, 12.4 million dogs and cats were not protected against core diseases. Compliance with other vaccinations was not studied (AAHA, 2003).

Compliance with preanesthetic screening was 72% for dogs and 65% for cats. Compliance was 90% for practices that required preanesthetic blood work (AAHA, 2003).

Economic Aspects of Noncompliance

Poor compliance affects standards of care, overall pet health, client satisfaction and practice economics. Every veterinary health care team member and client is responsible for enhancing compliance. According to the AAHA Compliance Study, the total additional revenue opportunity per veterinarian per year is $639,700 to $660,700 for the conditions studied (2003). Other practice productivity data are available (Wayner and Heinke, 2006).

Improving Compliance

The AAHA Compliance Study concluded that compliance is related to three factors: recommendation (by the veterinarian), acceptance (by the client) and follow through (by the veterinary health care team). This can easily be remembered as CRAFT, where Compliance = Recommendation + Acceptance + Follow Through. The AAHA study noted that: 1) compliance was much lower than veterinarians believed and 2) clients would very often comply if the practice made an effort to help them comply (2003). Furthermore, a significant element of noncompliance is due to the fact that practice team members often do not make recommendations to clients. Thus a positive compliance cascade cannot happen.

As part of the study, pet owners were asked to agree with one of these statements:

- I want my veterinarian to tell me about all of the recommended treatment options for my pet, even if I may be unable to afford them.
- I want my veterinarian to tell me only about the recommended treatments for my pet that he or she thinks are not too expensive for me.

Ninety percent of respondents chose the first statement. Furthermore, only 7% declined dental care due to cost. Likewise, only 4% either discontinued or refused therapeutic foods and only 5% declined senior screenings due to cost. Cost was not a significant factor in the client's decision to accept or decline health care. Despite these findings, veterinarians overwhelmingly cited cost and insufficient client communication and education as the primary barriers to com-

Box 3-5. What Veterinarians can Learn from Physicians about Communication.

The *Journal of the American Veterinary Medical Association* published an outstanding review titled "What can veterinarians learn from studies of physician-patient communication about veterinarian-client-patient communication?" (Vol. 224 [5], March 1, 2004, pp 676-684). Several relevant points follow:

- A gold standard does not exist for assessing physician-patient interactions, nor for an accepted definition of the physician-patient relationship.
- Communication style should be tailored to the individual patient.
- The most common model for the physician-patient relationship is still paternalism. Relationship-centered care, characterized as a partnership, in which negotiation and shared decision-making is suggested as optimal. The physician's role is suggested as an advisor or counselor.
- Communication skills and dealing with clients have been listed as the most important skills for success.
- Effective communication can significantly improve medical outcomes, including patient health and satisfaction, adherence to medical recommendations and physician satisfaction.
- A controlling style including behaviors that maintain the physician's power, status, authority and professional distance negatively affects patient satisfaction.
- Factors suggested to improve client compliance include establishing two-way communication and trusting relationships, a compassionate health care team, collaborative planning of the treatment regimen, provision of specific verbal and written instructions about medications and timely encouragement.
- Medical researchers have studied physician-patient interactions for 30 years. Four basic conclusions have emerged: physician-patient interactions have an impact on patient health, patient satisfaction, adherence to medical recommendations and physician satisfaction.

The Bibliography for **Box 3-5** can be found at www.markmorris.org.

pliance (AAHA, 2003).

The AAHA study lists several follow through components to augment recommendations. These include: scheduling procedures and follow-up appointments when the recommendation is made, providing clear instructions for at-homecare and recheck exams (Almost 80% of pet owners indicated they wanted verbal and written instructions.), sending reminders (In the AAHA study, compliance was highest for core vaccinations, a service for which virtually every practice sends reminders. Few practices send reminders for medication or food refills. Sixty-five percent of pet owners said they would welcome multiple reminders by phone, mail, e-mail or a combination. Seventy-two percent said they would like to receive a phone call if they were overdue for a recommended treatment or preventive service.) and making follow-up phone calls. More than 82% of the pet owners surveyed indicated that they wanted to be able to discuss feeding and homecare instructions with other members of the health care team, not just the doctors. Practices that consistently followed-up with clients whose pets were fed a new food reported a much higher percentage of patients staying on the new food and a much higher compliance with recommended feeding guidelines (AAHA, 2003).

The AAHA Compliance Study identified six steps to improving compliance and patient care:

- Measure current compliance
- Involve the entire health care team (and establish protocols that are agreed upon)
- Set compliance goals
- Implement new protocols
- Measure and track results
- Celebrate success.

The AAHA Compliance Study found that a major cause of veterinary care providers' failure to make health care recommendations was their misjudgment of the clients' willingness to take action. The following represent reasons veterinarians cited for noncompliance (AAHA, 2003):

- Cost (60%)
- Communication and client education (55%)
- Client time or convenience (40%)
- Perceived value (25%)
- Process error at practice (15%).

Despite these perceptions 75% of pet owners agreed or strongly agreed that their veterinarian made recommendations that were good for the pet. Only 10% of pet owners agreed or strongly agreed that their veterinarian's recommendations were motivated by a desire to make money. Cost wasn't a major barrier to adherence in the AAHA Compliance Study. However, lack of an effective recommendation and lack of reinforcement by the veterinary health care team were cited by clients as important barriers to compliance. For example, veterinarians claimed that they discussed nutrition and pet food with pet owners during more than 90% of visits. Only 18 to 22% of pet owners recalled such discussions. Reasons cited for lack of client follow through include:

- Unclear diagnosis or need for follow-up care
- No one told me about the need for follow-up
- Follow-up appointment not made or was too difficult to make
- No reminders were sent.

As an example, client acceptance of dental recommendations doesn't depend on the degree of dental disease or the cost of the procedure. Clients cited these reasons for lack of compliance:

- Not enough education provided about the need for the service (45%)
- Follow-up visit not scheduled (15%)
- Veterinary health care team didn't tell me about it (8%)
- Pending appointment (5%)
- Unclear diagnosis (5%)
- Cat was too wild to catch (5%)
- Other (7%).

Several other sources bear consideration for improving compliance (**Table 3-3**).

Conclusion

It is obvious that adequate health literacy is a major obstacle to delivering optimal health care in human medicine. By extension, this issue is no less dramatic in veterinary medicine, and the processes for improved communications and health literacy cited in this chapter have direct relevance to pet care.

The health literacy issue is coupled to that of compliance/adherence. As defined in the AAHA Compliance Study, compliance in veterinary medicine is defined as, "the pets in your practice are receiving the care that you believe is best for them." That is; if you, the attending veterinarian, believe specific products and services are important for a particular pet's care, does your health care team effectively communicate your beliefs to the client in order for her/him to decide the next steps for the pet's care? Not all clients will take our recommendations, but research suggests that better communication improves medical care.

Health literacy, the degree to which individuals have the capacity to obtain, process and understand basic health information and services needed to make appropriate health decisions (Ratzan and Parker, 2000; Healthy People 2010) cannot be assumed. Effective communication is paramount to practicing great medicine (Silverman et al, 2005; Cornell et al, 2007).

Nutrigenomics and Nutrigenetics: Nutritional Genomics in Health and Disease

Samer Al-Murrani
Craig D. Thatcher
Michael S. Hand

"It is from the progeny of this parent cell that we all take our looks; we still share genes around, and the resemblance of the enzymes of grasses to those of whales is in fact a family resemblance."
Lewis Thomas

INTRODUCTION

A revolution in nutrition is underway. Through newly available scientific methods and technologies, dramatic advances in understanding the role of nutrition in health and disease are within reach. These new tools include:

1. Complete or partially sequenced genomes of many animal, plant and microbial species (Bell et al, 2001; Lander et al, 2001; Waterson et al, 2002; Kirkness et al, 2003; Seshadri et al, 2006).
2. Ample historical evidence suggests nutrients provide potent dietary signals via gene control that influence cellular metabolism and homeostasis, either positively or negatively (Clarke and Abraham, 1992; Muller and Kirsten, 2003; Straus, 1994).
3. Laboratory and computer technologies that allow for the analysis of the molecular response of entire biologic systems to nutrients (Muller and Kirsten, 2003).

This chapter will acquaint readers with the current status of emerging nutritional technologies and provide insight about the future potential of these tools. When applied to nutrition, these technologies are collectively referred to as "nutritional genomics."

NUTRITIONAL GENOMICS AND OTHER "OMICS"

Because nutritional genomics is a relatively new science, the following discussion includes a review of relevant, but perhaps unfamiliar, terminology. **Table 4-1** summarizes definitions and other related terms.

"Genome" refers to the full set of an individual's genes (i.e., its genotype). "Phenotype" refers to the entire physical, biochemical and physiologic makeup of an animal as determined by its genome and the animal's environment. "Genomics" describes the mapping, sequencing and analysis of all genes present in the genome of a given species (Mutch et al, 2005). Numerous genomes are available to the public at http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=genomeprj. The term "genomics" is sometimes used loosely to refer to sequence analysis, gene expression analysis and single nucleotide polymorphism analysis (the last two are discussed below).

Table 4-1. Glossary of nutritional genomics terminology.

Bioinformatics	The application of computerized statistical tools (informatics) to biologic data. In genome projects, informatics includes the development of methods to search databases quickly, analyze DNA sequence information and predict protein sequence and structure from DNA sequence data.
Dietary signature	The repeatable pattern of gene expression, protein expression and metabolite production in different tissues in response to one or more food components.
Gene expression	The process of converting the genetic code into mRNA and subsequently the translation of mRNA sequences into protein.
Genome	All the genetic material in the chromosomes of an organism; its size is generally given as its total number of base pairs; the term is derived from *gene* + chromo*some*.
Genomics	The mapping, sequencing and analysis of all genes present in the genome of a given species.
Genotype	The genetic makeup of an individual, in contrast to its physical appearance or phenotype.
Metabolome	The complete set of metabolites synthesized by a biologic system; all the substances except DNA, RNA and protein.
Metabolomics	The study of the influence of the genome on an organism's entire metabolite profile, at a given time.
Microarray technology	A laboratory technique that permits the simultaneous detection of thousands of genes in a small sample and analyzes the expression of those genes.
Nutrigenetics	The effect of genetic variation of an individual on the interaction between diet and disease.
Nutrigenomics	The effects of nutrients on the genome, proteome and metabolome.
Nutritional genomics	An umbrella term that includes nutrigenomics and nutrigenetics.
Phenotype	The visible properties of an organism that are produced by the interaction of the genotype and the environment.
Probes	Single stranded DNA sequences of varying lengths (depending on the technology platform) that represent individual genes that are immobilized onto a solid support.
Proteome	The entire complement of proteins, and their interactions, in cells, tissues, organs and physiologic fluids.
Proteomics	The study of the protein products of gene expression with the goal of identifying the proteins and understanding their role in the functioning of an organism.
Single nucleotide polymorphism	A variation of a gene's normal sequence, in which a single nucleotide in the genetic material is altered and the specific alteration occurs in more than 1% of the population. It is the most common form of polymorphism.
Systems biology	The study of entire biologic systems using transcriptomics, proteomics and metabolomics (**Figure 4-1**).
Transcription	The process whereby mRNA is synthesized from a DNA template.
Transcriptome	The sum of all the mRNA expressed by the genome of an organism.
Transcriptomics	The study of the relative amounts of mRNA expressed in cells or tissues at a given time.
Translation	The process of protein synthesis whereby the primary structure of the protein is determined by the nucleotide sequence in mRNA.

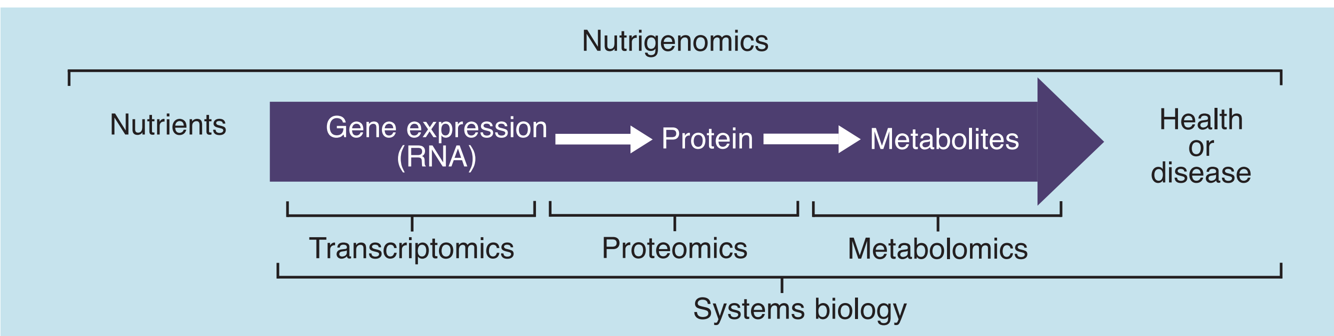

Figure 4-1. A schematic overview of the relationships between nutrigenomics, transcriptomics, proteomics, metabolomics and systems biology.

Nutritional genomics includes "nutrigenomics" and "nutrigenetics." Nutrigenetics refers to the study of how genetic variations, such as single nucleotide polymorphisms, are associated with an individual's response to nutrients or specific foods (Corella and Ordovas, 2005). That is, nutrigenetics attempts to explain how, and to what extent, nutrition-related disorders are influenced by genetic variation (Mariman, 2006). Nutrigenetics has the potential to provide for personalized dietary recommendations based on genetic makeup, by which the onset of a disorder will be prevented or delayed, thereby optimizing health. The information generated from a nutrigenetics approach can be used to identify individuals, but more importantly, groups that are most likely to benefit from a specially formulated dietary regimen.

The importance of genetic variation in the physiologic or pathophysiologic response to nutrition is already well described in principle, and examples continue to be published. A few of these examples include studies in people that link genetic variation to insulin resistance, type II diabetes mellitus and cardiovascular disease. These studies also demonstrate how an individual genotype affects appropriate dietary management for disease prevention (Mutch et al, 2005). Similar examples in animals with genetic variations that respond to special feeding regimens include obesity and diabetes mellitus (Snyder et al, 2004). It is likely that, in some cases, the increased risk for obesity in dogs may be related to breed-associated genetic variation. Another example in dogs includes large- and giant-breed puppies with genetic variation that responds to diet for the pre-

vention of developmental orthopedic disease.

Nutrigenomics relates to the study of genome-wide influences of nutrition (**Figure 4-1**). Nutrigenomics explores the effects of nutrients on the genome, proteome and metabolome (the last two are discussed below). From a nutrigenomics perspective, nutrients are dietary signals that are detected by cellular sensor systems that influence gene and protein expression and, subsequently, metabolite production. Repeatable patterns of gene expression, protein expression and metabolite production in response to particular nutrients or foods can be viewed as "dietary signatures." Nutrigenomics studies these signatures in specific cells, tissues and complete organisms to understand how nutrition influences homeostasis and resultant health or disease (Muller and Kersten, 2003). The potential outcome from nutrigenomics research is a much clearer, more complete understanding of the effects and mechanisms of diet on health. To do this, researchers use genomics tools that include transcriptomics, proteomics and metabolomics to generate data and subsequently analyze, link and mine the data using bioinformatics tools and approaches.

Transcriptomics studies the effects of nutrients on gene expression. Because messenger RNA (mRNA) results from the process of transcription, the total pool of mRNA in a cell is referred to as the transcriptome. In nutrigenomics, transcriptomics examines nutrients that influence the expression of specific genes and the transcription of the corresponding mRNA. This is one of the first steps in the regulatory process that controls the flow of information from genes. The field of transcriptomics is based on the examination of gene expression patterns quantifying the abundance of mRNA copied from a basic nucleic acid blueprint contained in the genome (Dawson, 2006). Thus, the level of mRNA in a cell or tissue at any one time is a reflection of whether a gene is activated or inactivated. Thanks to powerful new tools that have been developed over the past decade, RNA can be measured. For example, total RNA or mRNA is extracted from a cell or tissue and used to create either a complementary labeled strand of DNA called "cDNA," or, alternatively, unlabeled cDNA can be used to generate a complementary labeled strand of RNA called "cRNA." This labeled material is then hybridized with known complementary strands of DNA sequences that are attached to a solid support such as a glass or plastic slide or a nylon substrate. These fixed sequences are called "probes." Probes are often organized as an array of small dots on the solid support matrix. In some cases, arrays of probes are called microarrays or "chips" because the probes are only micrometers apart and many of them will fit on a solid platform of only 1 to 3 cm^2. It is possible to display a whole genome on a microarray. Commercial forms of microarrays are available (**Figure 4-2**). If the original cRNA sample is labeled with a fluorescent dye, the hybridized array can be scanned with a laser scanner in which the light or signal that results from the hybrid of the labeled sample and the immobilized probes is directly related to the amount of specific mRNA present in the tissue sample and represents the level of gene expression in that tissue. Thus, it is possible to determine if a specific nutritional manipulation switched a gene on or off using this technology (Debusk, 2005; Dawson, 2006). **Figure 4-3** shows a scanned image of a glass-based cDNA array.

Figure 4-2. Affymetrix GeneChip probe array used for expression profiling of experimental tissues. (Courtesy Affymetrix, reprinted with permission).

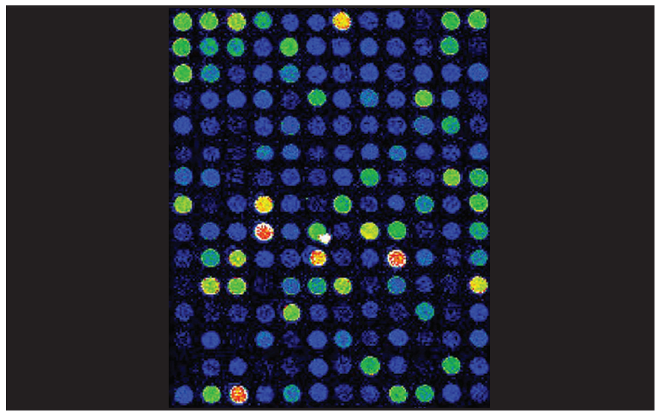

Figure 4-3. Example of the signal generated from a hybridized glass slide cDNA microarray.

However, gene transcription is only one step in the regulatory pathway that leads to functional protein formation. Thus, it is not always possible to correlate the increased or decreased presence of mRNA in tissues with specific protein changes. Even with this shortcoming, however, transcriptomics is a very powerful tool for determining and clarifying important processes in metabolic regulation because it broadly evaluates the initial regulatory steps of gene expression (Dawson, 2006).

Transcriptomics is a relatively mature technology compared with proteomics and metabolomics. Currently, it is possible to obtain an overview of the expression of essentially all genes in a single microarray or GeneChip experiment. However, it is not yet possible to measure the whole proteome or metabolome (Afman and Muller, 2006). Transcriptomic studies have already yielded exciting results, examples of which are discussed below.

"Proteome" describes the entire complement of proteins, and their interactions, in cells, tissues, organs and physiologic fluids. The number of proteins in a cell far exceeds the number of genes due to alternative gene splicing mechanisms and post-translational modifications of expressed proteins. Furthermore, because protein amounts differ widely in a cell at any given

moment, with expression levels that span many orders of magnitude, there is no single technology platform that can measure all the protein in the cell. Therefore, proteomics and the corresponding proteomic technologies are not as widely used or as standardized as the gene-based studies and technologies described above. However, because protein expression is the functional outcome of gene transcription and translation, it has long been a focus of extensive research. Using proteomics tools (the analysis of the proteome), researchers can simultaneously display and determine thousands of proteins in a study sample and identify their changes in response to nutritional inputs. Research methods in proteomics are progressing rapidly. Proteome analysis holds great promise for discoveries in nutrition research (Afman and Muller, 2006).

One of the newest "omics" is metabolomics. Metabolomics technology measures the level of all substances, other than DNA, RNA or protein, present in a sample. Metabolites include such things as intermediates of metabolism and a variety of low molecular weight molecules (e.g., lactic acid, carbon dioxide, ketones, ATP, ADP, prostaglandins, prostacyclins and thromboxanes). The metabolome represents the complete set of metabolites synthesized by a biologic system. Studying metabolites is important because of the simplistic, often incorrect belief that one gene leads to the formation of one protein, which creates one metabolite (Munoz et al, 2004). The study of a cell's complete set of metabolites is much more complex than transcriptomics and proteomics. Besides the huge variety and number of potential metabolites, many cellular metabolites have a very rapid turnover. For example, ATP has a half-life of less than 0.1 second. Also, metabolites need to be determined separately in the different compartments of a cell (e.g., cytoplasm, mitochondria, extracellular matrix) (van der Werf et al, 2001).

Unlike transcriptomics, proteomics and metabolomics are not yet routinely performed, do not have standardized procedures and continue to face challenges such as sample preparation, technological sensitivity and lack of standardized statistical methods (Mutch et al, 2005). However, the potential for nutritional applications of metabolomics is considerable and a number of research teams are addressing the current shortcomings (Afman and Muller, 2006).

"Systems biology" refers to a merging of the previously discussed "omics" technologies. Together, transcriptomics, proteomics and metabolomics allow for nutrition studies to concurrently observe and quantify a significant fraction of all regulated genes, gene expression products and metabolites. Because these layers of "omics" technologies are related (e.g., genes encode RNA, which produces enzymes that catalyze the conversion of metabolites), this combination of datasets paves the way to a complete description of how a cellular system behaves in response to external stimuli (Corthesy-Theulaz et al, 2005). Although the complexity of the systems biology approach exceeds the current bioinformatics tool's capabilities, its implications for nutrition research can be enormous.

Because these genomic technologies generate an avalanche of data, there is a need for continuing developments in bioinformatics. Bioinformatics refers to the computational technologies that support the processing, clustering, dynamics, integration and storing of the enormously complex datasets like those generated from "omics" research. The challenge is to combine all these pieces of information to ensure all data can be observed coherently. To gain full access to the potential output of the new "omics" tools, it is imperative to address the enormous challenge of unifying complex and dissimilar data. The goal is to turn all these data into knowledge.

Bioinformatics software packages can be obtained through licensing arrangements with a variety of organizations, purchased from specialty software companies or are available from open sources. Open source software usually requires programming skills on the part of the user. Regardless of source, these packages generally include programs for data analysis and visualization. Visualization describes a way of qualitatively "graphing" the results; it is an important step in extracting knowledge from data. Other software go beyond data analysis and visualization to provide the means of overlaying the data generated from "omics" experiments onto knowledge-based molecular pathways and networks and provide an overview of the interactions of the genomic, proteomic and metabolomic data together in the context of the whole cell.

THE PROMISE OF NUTRITIONAL GENOMICS: EXAMPLES OF PROGRESS AND POTENTIAL

Until recently, it was thought that changes in gene expression attributed to diet were mediated through endocrine or neural pathways. However, research has shown that macronutrients, micronutrients and their metabolites can directly regulate gene expression. For example, some of the earliest evidence demonstrating direct effects of nutrients on gene expression came from studies in zinc-deficient rats. In these models, researchers found that almost 50 genes were either up- or down-regulated in the zinc-deficient group, suggesting new mechanisms for some of the signs associated with zinc deficiency (Blanchard and Cousins, 1996). Currently, many food components, including minerals besides zinc, vitamins, carotenoids, flavonoids, monoterpenes and phenolic acids are thought to act as transcriptional activator molecules affecting gene expression (Milner, 2004).

The action mechanism of dietary carbohydrates in metabolic programming and its short- and long-term effects is a macronutrients example. Studies showed that feeding rat pups a high-carbohydrate milk formula resulted in hyperinsulinemia that persisted throughout the period of dietary intervention. There was increased hexokinase activity and increased gene expression of preproinsulin and related transcription factors and kinases in the pancreatic islets. In these experiments, the pre-

dictable metabolic and genetic adaptations that occurred in rat pups during the dietary intervention continued to be expressed into adulthood. As adults, these rats demonstrated chronic hyperinsulinemia and adult onset obesity (Srinivasan et al, 2003; Swanson, 2006).

There are also nutrigenomic studies in dogs associating specific nutrients to obesity and insulin sensitivity. Dogs fed a food designed to induce obesity and insulin resistance had a decrease in the expression of uncoupling protein 1 (UCP1) and peroxisome proliferator-activated receptor gamma (PPARγ) in their adipose tissue compared to non-obese, insulin-sensitive dogs (Leray et al, 2004). PPARγ plays a role in adipocyte differentiation, lipid storage and glucose homeostasis and induces the expression of many genes including UCP1, which plays a key role in thermogenesis.

Nutrigenomic studies in dogs have also shown that obesity-related hypertension causes marked changes in gene expression in the right atrium and left ventricle. These changes were thought to contribute to early changes in heart function, hypertrophy and remodeling (Philip-Couderc et al, 2003). Other studies focusing on gene expression in the left ventricles of dogs fed normal or high-fat foods using canine cDNA arrays identified 63 differentially expressed genes involved in metabolism, cell signaling, tissue remodeling, insulin regulation, cell proliferation and protein synthesis. The results of this study further indicated that the pattern of co-regulated genes depended on the length of time that the high-fat food was fed. These findings suggested that hypertension resulting from obesity induced by high dietary fat was associated with continuous cardiac transcriptome adaptation despite stability in both body weight and blood pressure (Philip-Couderc et al, 2004).

Proteomic studies determined that supplementing rat food with genistein, a major isoflavone from soy, increased the expression of mammary gland GTP cyclohydrolase-I, a key protein related to nitrogen oxide synthesis. There was a resultant reduction in cell proliferation and susceptibility to cancer (Rowell et al, 2005). Another study showed that inadequate provision of dietary vitamin B_{12} induced profound changes in the cerebral spinal fluid proteome in rats, linking vitamin B_{12} with neurologic health (Gianazza et al, 2003).

An example of a potential indirect effect via metabolites is that of dietary fiber on transcription. One study reported increased adipocyte leptin expression in cell cultures treated with physiologic amounts of short-chain fatty acids (Xiong et al, 2004). Short-chain fatty acids from colonic microbial fermentation of dietary fibers may help protect against overeating and obesity by decreasing appetite through leptin expression (Swanson, 2006).

Through traditional methods, key nutritional factors (essential nutrients and bioactive food components) have long been established as potential modulators of health and disease (Watson, 1998; Dove, 2001; DeBoer, 2004). Understanding the ways in which foods and their components affect gene expression will further enhance use of key nutritional factors to modulate health and disease.

Box 4-1. The Value of Sequencing the Canine and Feline Genomes.

Because of the cost of sequencing mammalian genomes to completion (approximately $50 million U.S.), these projects have been restricted to a few species considered to be of greatest value to biomedical research. Knowledge of human genome function in health and disease will benefit from comparison of its structure with genomes of certain other species. The dog is a particularly good example because of its somewhat unique population structure. The physical and behavioral characteristics of approximately 300 breeds are maintained by restricting gene flow between breeds. Many modern breeds have been inbred for desired characteristics. This has led to a species with enormous phenotypic diversity but with significant homogenization of the gene pool within breeds. Many of the approximately 450 known genetic disorders in dogs resemble human conditions, and their causes may be more traceable in large dog pedigrees than in small, outbred human families. The combination of genetic homogeneity and phenotypic diversity also provides an opportunity to understand the genetic basis of many complex developmental processes in mammals. Thus, to a large part, funding of the sequencing of the canine genome and the genome of certain other mammalian species is based on their value in further understanding human health and disease.

The Bibliography for **Box 4-1** can be found at www.markmorris.org .

THE CANINE AND FELINE GENOMES: CURRENT STATUS

The primary reason for funding the sequencing of the canine and feline genomes was to provide a basis for future comparative work in human biology including development, aging, cancer, heritable diseases and immune diseases. Dogs and cats have numerous heritable diseases, many of which are homologous to human inborn errors. Furthermore, the susceptibility of cats to viruses that cause immunodeficiencies and neoplasias (feline immunodeficiency virus and feline leukemia virus, respectively) make them important models for human AIDS and leukemia research.

Canine Genome

A sequenced genome could provide the basis for valuable information to determine the molecular differences between health and disease in dogs. The dog was the first non-rodent mammalian animal chosen for genome sequencing by the National Institutes of Health (**Box 4-1**) (Swanson, 2006). The sequence was derived for a male standard poodle; investigators estimated the genome to contain approximately 2.4 billion bases (Gb), which is about the same as the mouse genome but smaller than the human genome (approximately 2.9 Gb). With private and

Box 4-2. What is Genome "Coverage?"

A genome whose DNA base pairs have been completely sequenced one time has one-fold or "1x" coverage. At 2x coverage, each nucleotide in the genome would have been sequenced twice. The more times a genome is sequenced, the less likely it is to have gaps and mistakes. Therefore, a genome that has 6x coverage would have been sequenced enough times so that each base pair was read six times, which would provide a high level of confidence that the genome was accurate.

public funding, the Canine Genome Mapping Community and the Whitehead Genome Sequencing Center at MIT recently completed a more extensive genome sequencing of a female boxer (Lindblad-Toh et al, 2005). The boxer breed was chosen because it is one of the breeds with the least amount of variability in its genome and therefore likely to provide the most reliable reference genome sequence. This study also estimated the canine genome to span about 2.4 Gb. Using evidence-based methods, the canine genome is predicted to contain sequences for approximately 19,300 genes compared to about 22,000 that are currently thought to exist in the human genome (Lindblad-Toh et al, 2005). Because these predictions are based on computer programs that use different algorithms, the reported numbers of genes per genome are expected to vary for some time.

The information obtained by sequencing the canine genome will likely have its greatest initial impact on the study of the more than 450 genetic diseases that have been identified in dogs (Zhu et al, 2003). Although genetic diseases are problematic in many canine breeds, by far most diseases affecting dogs are more complex. For many canine diseases, besides genetic factors, disease expression is also affected by pathogen exposure, age, gender, activity level and diet (Swanson, 2006).

Feline Genome

The feline genome is more similar to that of people than dogs (approximately 3.3 Gb) (Menotti-Raymond et al, 2003; Murphy et al, 2007). The existing low coverage (2x) whole genome sequence of the cat has been useful for some comparative genome studies. However, gaps in the sequence represent a major obstacle to more important in depth studies. As mentioned above, the cat is a valuable model for understanding important diseases in people. Furthermore, the feline genome has the fewest rearrangements relative to all other mammals studied (Murphy et al, 2005). This finding suggests that the feline and human genomes represent the only index ancestral genome arrangements, which is very important as a reference for genome annotation and evolutionary studies in all mammals. These considerations have led to support for a complete high coverage (6 to 7x) whole genome sequence of the cat, which is underway. This level of coverage will make the feline genome information equivalent to that from other mammalian genomes including those of people, mice, rats and dogs. **Box 4-2** explains "genome coverage."

Cats are reported to have at least 260 genetic diseases (Zhu et al, 2003). This new information should pave the way for numerous advances in nutrigenetics and nutrigenomics of cats, our most popular companion animal.

SUMMARY

The complete sequencing of the human genome has brought much attention to the value of understanding how the interplay between genes and environmental factors, such as nutrition, relate to health and disease. To enable such studies, novel technologies have been developed to monitor the activity of multiple genes simultaneously at the level of RNA by transcriptomics, the level of the proteins by proteomics and ultimately the level of metabolites by metabolomics. In addition, these technologies have boosted interest in studying the role of genetic variation to explain individual and group susceptibility for nutrition-related disorders. These new areas of science are referred to as nutrigenomics and nutrigenetics, respectively. They hold promise to increase our fundamental knowledge of the interaction between biologic processes and food/nutrition. This will, in time, help improve maintenance foods to further improve the health status of the general pet population and lead to the development of personalized diets to prevent the onset of nutrition-related disorders in genetically predisposed individuals.

"Nutriment is both food and poison.
The dosage makes it either poison or remedy."
T. B. von Hohenheim

INTRODUCTION

Proper nutrition is among the more important considerations in health maintenance and key to disease management. A basic knowledge of nutrients, requirements, availability and consequences of deficiencies or excesses is important to feed dogs and cats correctly and give advice about feeding.

A nutrient is any food constituent that helps support life. Numerous essential nutrients have been discovered over the course of history. Nutrients are essential in that they are involved in all basic functions of the body including: 1) acting as structural components, 2) enhancing or participating in chemical reactions of metabolism, 3) transporting substances into, throughout or out of the body, 4) maintaining temperature and 5) supplying energy.

Nutrients are divided into six basic categories (**Figure 5-1**). Some nutrients fulfill a number of functions. For example, water and several minerals are needed for all the functions described above except supplying energy. Carbohydrates, fats and proteins may be used for energy but they can also serve as structural components. Vitamins are involved primarily with metabolic functions.

Figure 5-2 shows how an individual nutrient can affect the health of an animal. The minimum dietary requirement has been established for most nutrients. Clinical signs of deficiency may result if a food doesn't provide this nutrient level. Similarly, the maximum tolerable levels of certain nutrients are known and toxicity may result if a food exceeds these levels. The area between deficiency and excess represents the range of safe and adequate nutrient intake. The extent of this area will change depending on the individual nutrient and overall composition of the food. What is less well known is how exposure to marginal deficiencies and excesses affects an animal over time.

The most common method of determining the nutrient content of food is the proximate analysis, which provides the percentage moisture, protein, fat, ash and crude fiber. Digestible (soluble) carbohydrate or nitrogen-free extract (NFE) can then be calculated. **Figure 5-3** shows how the determination is conducted. Many commercial laboratories conduct proximate analyses of foods.

This chapter is organized into five sections: 1) water, 2) energy, 3) carbohydrates and fiber (including prebiotic fibers, probiotics and synbiotics), 4) protein and amino acids and 5) lipids. Chapter 6 covers vitamins and minerals. The nutrients in this chapter and those in the next will be covered in the order shown in **Figure 5-1**, beginning at the base of the pyramid. Energy, a non-nutrient, but nonetheless essential for life will be covered after water.

WATER

Definition and Function

Chemically, water is the combination of hydrogen and oxygen, which are joined in the ratio of two hydrogen atoms to one oxygen (H_2O). Water is vital to life and is considered the most

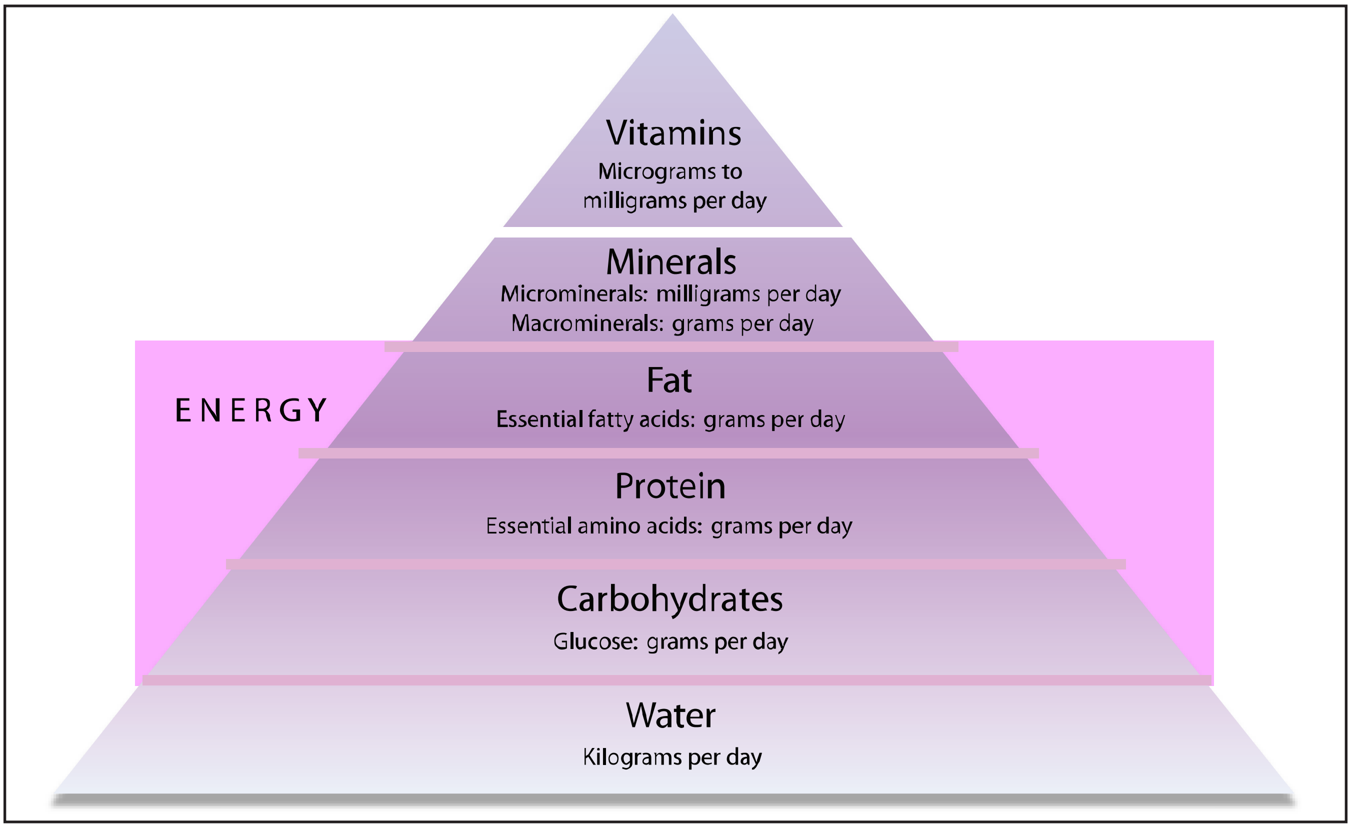

Figure 5-1. The six basic nutrients. Carbohydrates, fats and proteins may be used for energy but also serve as structural components.

important nutrient. Water performs the following important functions in animals:

1. Water is the solvent in which substances are dissolved and transported around the body. A large number of chemical compounds can be put into aqueous solution.
2. Water is necessary for the chemical reactions that involve hydrolysis (e.g., enzymatic digestion of carbohydrates, proteins and fats).
3. Water helps regulate body temperature. Water has a high specific heat (specific heat = amount of heat necessary to raise 1 g of water 1°C. Specific heat of water = 1). Large changes in heat production can take place within an animal with very little change in body temperature. This property also allows for heat to be circulated. Water has a high latent heat of vaporization. Water helps regulate body temperature when it is evaporated from the skin and respiratory tract. Large amounts of heat are required to evaporate small amounts of water; therefore, much heat can be lost with little loss of water.
4. Water provides shape and resilience to the body. Significant negative water balance can result in clinical dehydration. One manifestation of dehydration is loss of skin elasticity. As a major constituent of body fluids, water helps lubricate the joints and eyes, provides protective cushioning for the nervous system and aids in gas exchange in respiration by keeping the alveoli of the lungs moist and expanded.

Water is one of the largest constituents of the animal body,

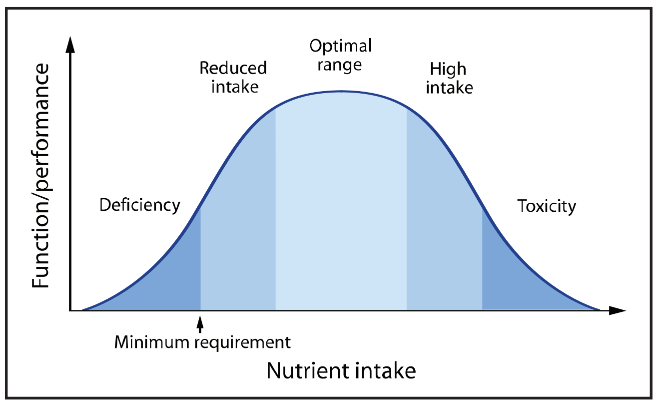

Figure 5-2. Total biologic dose-response curve. This response curve spans intakes ranging from deficiency to adequacy to toxicity. The intakes at which these three phases reside, and the width of the range between deficiency and toxicity vary widely among nutrients. (Adapted from Underwood EJ, Mertz W. Introduction. In: Mertz W, ed. Trace Elements in Human and Animal Nutrition, 5th ed. San Diego, CA: Academic Press Inc, 1987; 1.)

varying from 40 to more than 80% of the total. The percentage of water in an animal's body varies with species, condition and age. Generally, lean body mass contains 70 to 80% water and 20 to 25% protein, whereas adipose tissue contains 10 to 15% water and 75 to 80% fat. Younger, leaner animal contain more body water. Conversely, fatter animals have lower body water content.

As animals mature, they require proportionately less water on a weight basis because they consume less food per unit of body weight; thus, there is less urinary water loss. In addition, adult animals have less surface area per unit of body weight resulting in less evaporation from skin.

Water Quality

Salinity, nitrates and nitrites, toxic organic and inorganic chemicals and microbial contamination can affect water quality. Routine measurement of water quality is the concentration of all constituents dissolved in water, referred to as "total dissolved solids" (TDS). Salinity (salt content of water) is synonymous with TDS as an indication of the total ionic concentration in fresh water. Water containing less than 5,000 parts per million (ppm or mg/l) TDS is generally considered acceptable for consumption, whereas water containing more than 7,000 ppm is considered unsuitable for livestock or poultry (NRC, 1974). Although livestock and poultry TDS values are assumed to apply to dogs and cats, water containing less than 500 ppm TDS is considered acceptable for human drinking water and is a better recommendation for dogs and cats (US EPA, 1976).

Standard water quality testing (e.g., nitrates, sulfates, bacterial contamination) typically can be addressed through local public health departments because the source of water consumed by dogs and cats is often the same as that consumed by people. Serious concerns about water quality (toxic inorganic chemicals or pesticides) need to be addressed through testing at commercial analytical laboratories capable of screening water for pesticide residues and other chemicals.

Mineral Content

Water "hardness," or the sum of calcium and magnesium salts in relation to calcium carbonate, has little effect on dog or cat well being. High levels of magnesium in hard water have been implicated as a cause of urolithiasis in cats; however, the amount of magnesium consumed in drinking water is insignificant compared with the amount consumed in food (i.e., usually a 10,000-fold difference) (Kirk et al, 1995). Cats prone to urolithiasis may benefit from consumption of distilled water rather than hard water that has been softened with a sodium chloride water softener.

Nitrates

Nitrates are widely dispersed in the environment and can be a health hazard for all animals when significant amounts are present in drinking water. Although the concentration of nitrate ions (NO_3) commonly found in drinking water is well tolerated by dogs and cats, nitrite (NO_2, the reduced form of nitrate) is readily absorbed and can be toxic. At toxic levels, nitrites oxidize iron in hemoglobin to form methemoglobin, reducing the oxygen-carrying capacity of blood.

Frequently, nitrates in the water supply indicate bacterial contamination. Bacterial reduction of nitrate to nitrite is promoted as the pH increases in the intestinal tract. Bacteria in contaminated water sources can convert nitrate to nitrite. The safe upper limits for nitrate and nitrite determined for livestock drinking water are 1,320 ppm and 33 ppm, respectively. For human drinking water, the safe upper limit is based on the total amount of nitrogen derived from the combination of nitrate (30.4% nitrogen) and nitrite (22.6% nitrogen) and is 10 ppm of nitrogen. No safe upper limits have been established for dogs or cats. The livestock limits should be used until studies are conducted to determine the upper limits for dogs and cats.

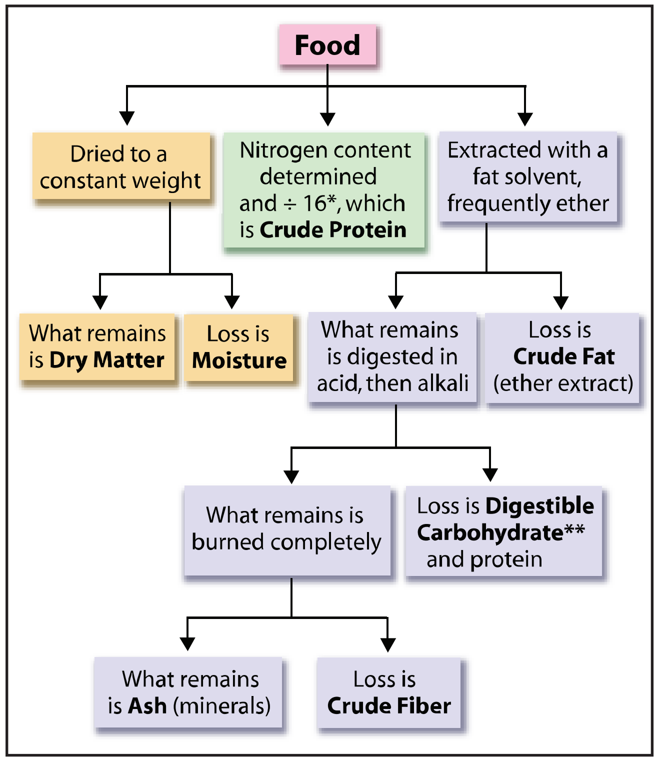

Figure 5-3. Proximate analysis of foods.
*Proteins contain 16 ± 2% nitrogen. Crude protein = nitrogen x 6.25 or nitrogen ÷ 0.16. Protein levels determined by this method will be erroneously high if the food contains non-protein nitrogen such as urea or ammonia.
**Frequently called nitrogen-free extract (NFE). NFE is determined as the difference between 100% and the amount of everything else in the food (i.e., 100% – % moisture – % crude protein – % fat – % crude fiber – % ash.) Any errors in these analyses also will appear in the NFE value.

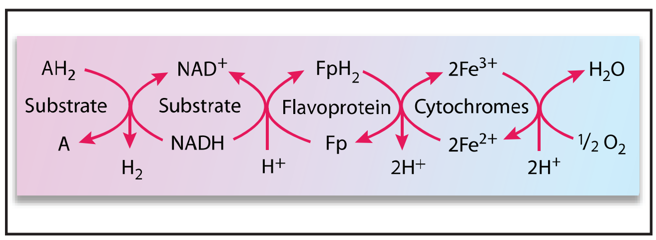

Figure 5-4. Electron transport chain and metabolic water production. Key: NAD = nicotinamide-adenine dinucleotide, NADH = the reduced form of NAD, Fe = iron, H_2O = water, O_2 = oxygen, H/H_2 = hydrogen, A = metabolite, Fp = flavoprotein.

Box 5-1. The Effect of Fasting on Water Intake: Diagnostic Implications.

Fasting eliminates water available from food, alters the amount an animal drinks and decreases total water intake. **Figure 1** shows the effect of fasting on drinking water intake, water intake from food and total water intake for dogs previously consuming moist or dry food. Total water intake decreased dramatically in both groups; however, the change in the amount consumed as drinking water was quite different. **Figure 1, Panel A** shows the response of dogs previously fed a moist food. Because most water intake for these dogs previously was from the food, only a small amount was supplied by drinking water. During fasting, water supplied by food was no longer available, thus the amount drunk increased. **Figure 1, Panel B** shows the response of dogs previously eating a dry food. Because these dogs obtained little water from the food, a large amount was supplied from drinking water. During fasting, less water was needed and the amount of drinking water consumed decreased.

The influence of the water content of the previous food on the amount of water consumed as drinking water may become important diagnostically. An owner who reports that a dog is not eating but is drinking twice as much water may be describing the normal response of a dog that has stopped eating a moist food, rather than a dog that is truly polydipsic. Conversely, dogs that had been eating dry food may appear to nearly stop drinking during periods of anorexia. These effects emphasize the importance of accurately assessing the food and feeding method.

The Bibliography for **Box 5-1** can be found can be found at www.markmorris.org.

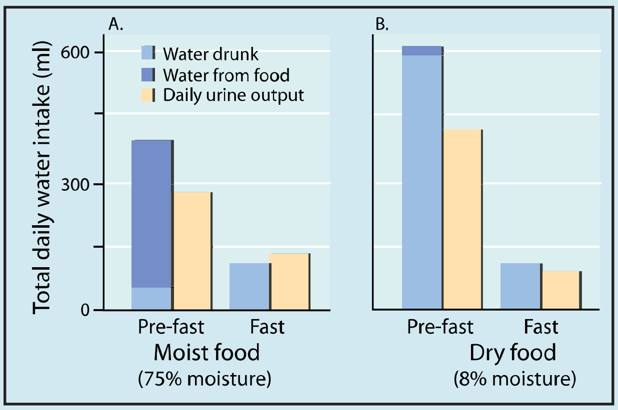

Figure 1. Effect of fasting on the amount of water consumed in the food and drunk by beagles previously consuming moist or dry foods.

Bacteria

The accepted criterion for the sanitary quality of water for people has been the absence of coliform bacteria. Although all coliform bacteria are not pathogens, many possess the potential; their presence indicates water is able to support infectious bacteria or viruses. Results of other qualitative tests made on water samples can also predict the presence of bacteria. Bacteria proportionally accompany chemical compounds such as nitrites, nitrates and phosphates. Generally, if levels of these compounds are high, the bacterial level will also be high.

Water Requirements

Water requirements are related to maintaining water balance. Body water lost by urination, defecation, evaporation and perspiration is replaced by one of two sources: 1) water derived from metabolism of nutrients and 2) water consumed as a liquid or as a portion of the food.

Oxygen is the final acceptor of hydrogen ions cleaved from energy-supplying nutrients (carbohydrates, fats and proteins) during the generation of adenosine triphosphate (ATP) (**Figure 5-4**). This combination of hydrogen and oxygen is called metabolic water. Metabolic water can account for 5 to 10% of the total water requirement. An average of 13 ml of water is produced per 100 kilocalories (kcal) of metabolizable energy (ME) ingested (Anderson, 1982). Oxidation of 1 g of glucose, fat and protein results in the production of 0.556, 1.071 and 0.396 g of metabolic water, respectively (Schmidt-Nielsen, 1964). Three to 4 g of water are released per g of glycogen used (Gosolfi, 1983).

Dogs and cats meet most of their water requirement through water ingested as food or drink. Animals consuming commercial moist foods drink less liquid than those fed dry foods because of the higher water content of moist foods (>75% water). This finding may have important diagnostic implications (**Box 5-1**). Generally, the daily water requirement of dogs and cats, expressed in ml/day, is roughly equivalent to the daily energy requirement (DER) in kcal/day (for dogs 1.6 x resting energy requirement [RER]; for cats 1.2 x RER) (Harrison et al, 1960; Haskins, 1984). The amount of water consumed by mature, healthy, nonreproducing dogs and cats at a comfortable environmental temperature is about 2.5 times the amount of dry matter (DM) consumed as food.

Domestic cats, descendants of desert animals, normally form more concentrated urine than dogs. Thus, water requirements for cats may be less than that for dogs. The need for water can be met by supplying clean, fresh water to pets at all times (**Box 5-2**).

Factors Affecting Water Requirements

Although the daily water requirements of dogs and cats are well defined, practical estimates of daily water intake are less clearly understood. In addition to metabolic needs, animals of all sizes consume water to meet a variety of needs, including physical and social. Factors such as body size (surface area), lactation, ambient temperature, type and amount of food ingested, general state of health, stress, water losses through excretion or evaporation and individual animal differences influence the absolute requirement for water.

Water Deficiency and Excess

Deficits of more than a few percent of total body water are incompatible with health, and large water deficits (i.e., 15 to 20% of body weight) lead to death. Water deprivation can lead to death within days, whereas animals may survive for weeks

without food. Under normal circumstances, thirst ensures that water intake meets or exceeds the requirement. Inadequate water intake reduces food intake, which reduces production in dogs and cats (growth, lactation, reproduction and physical activity). Decreased water intake may result from reduced availability, water temperature extremes or poor quality. Water intoxication (over consumption) is extremely rare in normal, healthy dogs and cats but can be induced in animals offered water free choice after prolonged dehydration.

ENERGY

Definition

Living organisms need energy to fuel all bodily functions. The ultimate source of all energy is the sun, which enables plants to make energy-containing nutrients from carbon dioxide and water through photosynthesis (**Figure 5-5**). A key function of dietary intake is to provide energy. Animals eat plants or other animals that have eaten plants. Although energy itself is not a nutrient, fats, carbohydrates and amino acids contain energy in the form of chemical bonds and are the energy-containing nutrients in food. Once eaten, these nutrients are digested, absorbed and transported to body cells where they are used to generate energy.

Burning nutrients and measuring the amount of released heat can determine their energy content. The body obtains energy by oxidizing nutrients to carbon dioxide and water, but does not use heat for fuel directly, although heat is used for body temperature regulation. Instead, the body captures nutrient energy in energy-containing compounds through a series of enzymatic biochemical reactions. The most important energy-containing compound is ATP.

In nutrition, the joule is the internationally recognized unit of measure for energy (Kleiber, 1972; Blaxter, 1989). The joule expresses the DER of an animal by its power needs or watts. One watt equals one joule per second. In the United States, a more commonly used energy measure is the calorie, which expresses energy in terms of heat. A calorie is the amount of heat required to raise the temperature of 1 g of water from 14.5°C to 15.5°C. A kcal is 1,000 calories and a kilojoule (kJ) is 1,000 joules. Kcal and kJ can be interconverted using the formula 1 kcal = 4.184 kJ.

Function

The biochemical reactions that take place in the body either use or release energy. Anabolic reactions require energy and, conversely, catabolic reactions release energy. ATP and other energy-trapping compounds pick up part of the energy released from one process and transfer it to the other process. For example, in the oxidation of nutrients (glucose, fatty acids and amino acids), the chemical reactions in the biochemical pathways of glycolysis, β-oxidation, deamination, tricarboxylic acid (TCA) cycle and oxidative phosphorylation simultaneously generate and consume ATP. However, the net effect of these reactions is generation of ATP. It has been estimated that the net yields for ATP are approximately 90, 75 and 55% for fat, carbohydrate and protein oxidation, respectively (Flatt, 2001). Biochemical reactions that occur in glycogen synthesis, fatty acid synthesis, protein synthesis, gluconeogenesis, protein turnover, Cori cycle, sodium-potassium ion pump, ureagenesis and muscular contractions all require ATP.

In summary, animals use energy for pumping ions, molecular synthesis and to activate contractile proteins (**Figure 5-5**). These three processes essentially describe the total use of energy by animals. Without energy supplied by food, these reactions would rapidly cease and death would occur.

Box 5-2. Measuring Water Intake in Dogs and Cats.

Daily water intake in dogs and cats can be measured easily with common household tools. The following steps should allow pet owners to obtain a reasonable estimate of daily water intake.

1. Determine daily water intake requirements (in ml) by calculating the resting energy requirement of the animal and multiplying by 1.6 for dogs and 1.2 for cats.
2. Using a fluid cup measure (1 cup = 227 ml), measure the amount of water to offer the animal throughout the day in a single container.
3. Fill the water bowl with an appropriate amount of water from the single container throughout the day, ensuring fresh water is available at all times.
4. Eliminate the animal's access to other water sources (e.g., toilet bowls, sinks, etc.).
5. If more water is needed beyond the calculated amount, carefully measure more water into the container and account for the additional amount when making intake calculations.
6. Measure the water remaining at the end of the day (sum of that remaining in the water bowl and container) and determine the amount of water consumed by subtracting the remaining water from the total amount measured during the day.

Importance of Energy in the Diet of Dogs and Cats

The energy content of a food ultimately determines the quantity of food that is eaten each day and therefore affects the amount of all other nutrients that an animal ingests. Animals should be fed enough food to meet their energy requirements and the non-energy nutrients in the food should be balanced relative to energy density to ensure adequate nutrient intake. Animals eating an energy-dense food consume less of the food to meet energy needs; therefore, the concentration of other critical nutrients must be higher to ensure sufficient intake. Conversely, animals must consume more of a low-energy food to meet energy needs. Therefore, the concentration of non-energy nutrients should be lower to avoid excessive intake and maintain nutrient balance. If the energy density of the food is too low, food intake may be restricted by the physical limitations of the gastrointestinal (GI) tract. Such a food is referred

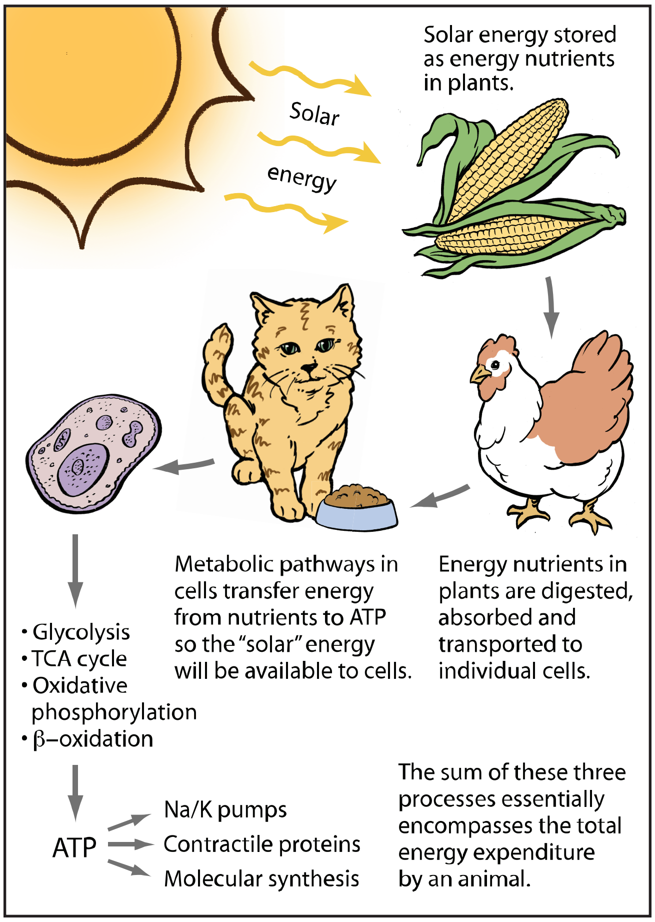

Figure 5-5. Schematic of how animals obtain and use energy. Plants use solar energy to produce energy-containing nutrients (i.e., proteins, fats and carbohydrates) via photosynthesis. Animals eat the energy-containing plant nutrients and other animals. Once eaten, energy-containing nutrients are digested, absorbed and metabolized by body cells to release energy that fuels the processes that sustain life.

to as being "bulk limited." Low-energy, bulk-limited foods designed for weight loss can be formulated to provide adequate intake of non-energy nutrients (Chapter 27).

Energy Metabolism

Digestion, Absorption and Excretion

Digestion and absorption of the energy-supplying nutrients (protein, carbohydrate and fat) are discussed in other sections of this chapter. The total amount of potential energy in food is termed gross energy (GE). Burning the food and measuring the heat produced in a bomb calorimeter determine GE in food. Animals are unable to use 100% of the GE in foods because some of the food energy is lost in the form of solid, liquid and gaseous excretions as well as radiant heat.

Nutritionists have partitioned dietary energy based on the losses that occur (**Figure 5-6**). Digestible energy (DE) refers to the GE content of food minus energy lost in feces (FE). Typically, ME is defined as DE minus energy lost in urine and as intestinal gaseous products of digestion (i.e., eructation and flatulence). However, because methane production is considered to be negligible in dogs and cats (McKay and Eastwood, 1984), ME can be defined in terms of DE and urinary energy losses.

Animals continuously produce heat as a result of basal metabolism and physical work. Heat production increases after a meal. This increase in heat due to food ingestion is called the heat increment of food (HI). HI consists of the heat of intestinal microbial fermentation and heat produced in intermediary metabolism as a result of using nutrients. A study in people showed that 5 to 10% of the energy consumed was lost as heat. The HI during the postprandial period was 60% greater for the protein-consuming group when compared to the isocaloric carbohydrate-consuming group. This increase in HI was attributed to the increased protein turnover observed by the protein-consuming group. The metabolic cost for protein turnover was approximately 36 and 68% for carbohydrate and protein feeding, respectively (Robinson et al, 2000). The energy of HI is normally wasted except when the environmental temperature is below an animal's critical temperature (i.e., shivering). In this situation, the HI is used to keep the body warm.

Subtracting HI from the ME gives the net energy (NE) of food. NE can also be partitioned into the amount used for maintenance (NE_m) and the amount used for production (NE_p: growth, pregnancy, lactation, exercise). NE values of foods and ingredients are typically used when discussing livestock nutrition (beef cattle, dairy cattle, swine), whereas DE and ME are more typically used in canine and feline nutrition. Although not commonly measured and used, the NE principles of partitioning energy for maintenance and production separately hold true for dogs and cats.

Energy Use

The initial biochemical reactions by which energy is derived from carbohydrates, fats and amino acids are different. However, all three nutrients eventually go through a final common pathway for energy generation (i.e., TCA cycle). Glucose derived from dietary carbohydrates is first oxidized through the glycolysis pathway to yield pyruvate and then acetyl-CoA. Acetyl-CoA is oxidized in the TCA cycle producing carbon dioxide, and electrons, which are captured by important heme-containing compounds called cytochromes (**Figure 5-7**). Electrons produced in the TCA cycle are shuttled by nicotinamide-adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD) to the electron transport chain where the cytochromes participate in electron transfer through valence changes in their heme iron (**Figure 5-4**). NAD and FAD are synthesized from the vitamins niacin and riboflavin, respectively. The electrons are passed between successive oxidation/reduction reactions to the end of the chain where oxygen accepts the final electrons and is converted to water. ATP is formed as the electrons are passed down the chain (oxidative phosphorylation). A net of 36 ATP is generated for each molecule of glucose that is oxidized to carbon dioxide and water.

Fatty acids and glycerol from dietary fats are initially oxidized to acetyl-CoA by the β-oxidation pathway (**Figure 5-8**).

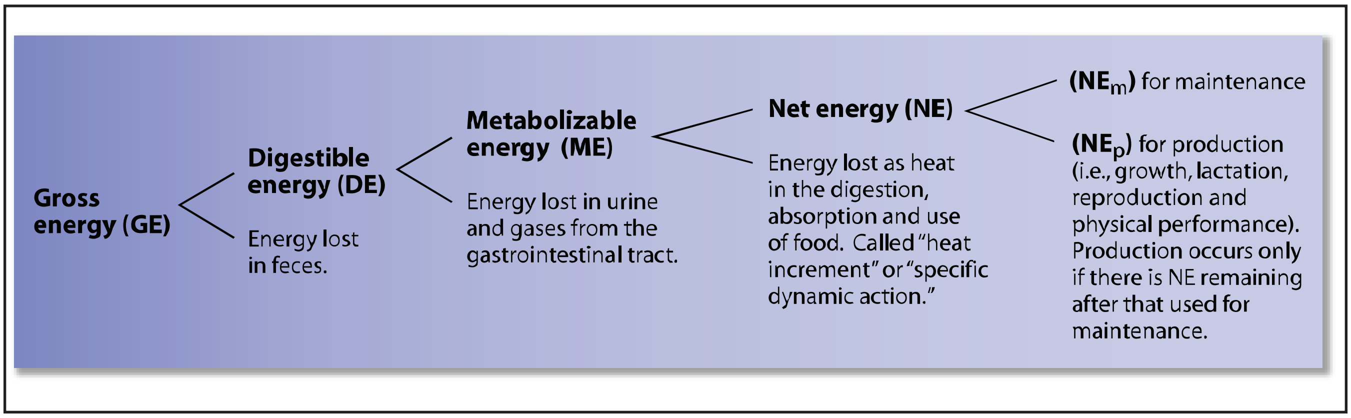

Figure 5-6. Schematic of how total gross energy of a food is partitioned into digestible energy, metabolizable energy and net energy. Net energy can be further partitioned into energy used for maintenance (NE_m) and production (NE_p).

Acetyl-CoA is then oxidized in the TCA cycle and ATP is generated via oxidative phosphorylation in the electron transport chain. The number of ATP generated from fatty acid oxidation depends on the length of the carbon chain and degree of unsaturation. For example, myristic acid (C14:0) yields 112 ATP, palmitic acid (C16:0) 129 ATP, palmitoleic acid (C16:1) 127 ATP, stearic acid (C18:0) 146 ATP and oleic acid (C18:1) 144 ATP.

Amino acids obtained from the diet and generated by endogenous protein breakdown are (re)used for protein synthesis or oxidized as an energy source. Protein synthesis requires a substantial expenditure of energy. When amino acids are oxidized, there are additional energy costs associated with gluconeogenesis and ureagenesis (Flatt, 2001). As a result the efficiency to derive energy from protein is considerably less than that from fat or carbohydrate. The amino acids used for energy are deaminated or transaminated to yield a carbohydrate moiety and ammonia; the ammonia is then converted to urea. The carbon skeleton enters the TCA cycle and ATP is formed in the electron transport chain. The number of ATP generated from oxidation of amino acids to water, carbon dioxide and urea varies, but ranges from six ATP from glycine to 42 ATP from tryptophan.

Energy Storage

ATP is the usable form of energy for body cells, but not a good energy storage molecule because it is used quickly after formation. Glycogen and triglycerides are better storage forms of energy. Production and use of ATP are equally balanced through a series of control mechanisms that monitor the amount of ATP available. After a meal containing adequate energy, the total body metabolism is generally anabolic; the body uses energy for synthetic reactions and tissue accretion (e.g., growth, reproduction). After the body has enough energy to meet demands, the pathways of glycolysis, β-oxidation, transamination, deamination and the TCA cycle are slowed. The pathways of glycogen and fat synthesis are simultaneously accelerated and excess dietary energy is stored as glycogen and body fat. These energy stores can then be used to generate ATP later when needed. Generally, in fasting animals, when the body needs energy, it uses glycogen first, fat stores second and finally, as a last resort, amino acids from body protein (Chapter 25). In fed animals, food energy is primarily used for meeting body energy needs, thus preserving body tissues by preventing catabolism. Further discussions of use and control of body energy stores during exercise can be found in Chapter 18.

Differences in the amount of energy consumed and that expended by the body can clearly result in changes in body weight, growth rate and body composition (especially body fat). Excess energy intake and storage relative to energy expenditure is a common problem in pet dogs and cats (e.g., obesity). Obese pets are at increased risk for developing a variety of health problems (Chapter 27). Excess energy intake in growing large- and giant-breed puppies may be related to developmental skeletal abnormalities (Chapter 33). Conversely, inadequate energy intake relative to expenditure may occur in animals with cancer and heart disease and resulting in cachexia (Chapters 30 and 36) and in vigorously exercising dogs such as sled dogs (Chapter 18).

Energy Analyses

The most accurate determination of the DE or ME content of food (**Figure 5-6**) is obtained through feeding studies (Yamka et al, 2007; McDonald et al, 1995; AAFCO, 2007). ME determinations involve the direct measurement of energy intake and energy lost in feces and urine obtained from digestion or metabolism studies. Energy lost as expired gases (e.g., methane) is negligible (McKay and Eastwood, 1984). As a result, energy lost as gases is typically ignored when calculating ME for dogs and cats. The Association of American Feed Control Officials (AAFCO) has published accepted protocols for the determination of ME of dogs and cat foods (2007) (**Box 5-3**). Because of the laborious nature of determining the actual ME content of dog foods, calculated ME values are used extensively for diet formulation and food labeling (Yamka et al, 2007).

Currently, AAFCO (2007) and the National Research Council (2003) recommend a predictive equation largely based on fixed energy values and digestibility coefficients for dietary components (i.e., crude protein, crude fat and carbohydrate) for estimating the ME content of dog foods. Although this predic-

RER occur in animals with normal body condition or older animals that lose weight.

WEIGHT GAIN

Weight gain occurs in growth; the energy requirements during growth have been discussed previously. Weight gain that occurs in nongrowing animals results in changes in energy requirements needed to maintain the increase in body weight (**Boxes 5-5** and **5-6**). Research in people shows that REE increases linearly with increases in body weight and gains in lean body mass (Saltzman and Roberts, 1995). Theoretical calculations of increased energy expenditure due to weight gain and actual measurements agree closely and can be described by the regression equation REE (kcal/day) = 55.6 + 16.9 x weight change (kg) (Saltzman and Roberts, 1995).

The composition of the weight gain averaged 63% body fat and 37% lean tissue in a summary of six studies involving 89 adult people (Saltzman and Roberts, 1995). The additional energy needed to support weight gain is mainly due to the amount of lean body mass that is gained and the energy required to support the increased protein turnover in the newly deposited protein.

There are no estimates supported by research using dogs and cats to correlate composition of weight gain in adults with changes in energy requirements. Therefore, in practice, dogs and cats that need to gain weight are usually fed more food, or a food with a higher energy density, until the desired weight has been achieved. The new target body weight is then used to calculate DER, and the pet is fed the amount of food necessary to maintain the new desired body weight. This method is effective, but it is difficult to predict how much of a food increase is truly needed or to estimate how long it will take for the animal to gain the needed weight. Suggested energy calculations for weight gain are summarized in **Table 5-2.**

CARBOHYDRATES INCLUDING FIBER

Simple Carbohydrates and Starches

Definition

Carbohydrates are composed of carbon, hydrogen and oxygen in the general formula $(CH_2O)_n$ (**Figure 5-11**). Carbohydrates encompass: 1) simple sugars such as monosaccharides (e.g., glucose) and disaccharides (e.g., sucrose), 2) oligosaccharides (three to nine sugar units; e.g., raffinose, stachyose) and 3) polysaccharides (more than nine sugar units). Examples of polysaccharides include starches (amylose, amylopectin, glycogen), hemicellulose, cellulose, pectins, gums, etc.

In a nutritional sense, polysaccharides, or as they are more commonly known, complex carbohydrates, can be further defined based on digestibility (**Table 5-4**). Complex carbohydrates that are digested by the animal's endogenous digestive enzymes are designated starches, whereas those polysaccharides that are resistant to enzymatic digestion and thus are fermented by intestinal microbes are labeled fibers. Starches and fibers differ chemically in that sugars in starches are linked with α-glycosidic bonds, whereas sugars in fibers are linked by β-glycosidic bonds. This small difference is important; mammalian enzymes can break α-bonds but only microbial enzymes can break β-bonds (**Figure 5-11**).

Structure

Simple sugars are divided into subgroups depending on the number of carbon atoms they contain. Three-carbon sugars (saccharides) are: 1) trioses ($C_3H_6O_3$) such as glyceraldehyde, 2) four-carbon sugars are tetroses ($C_4H_8O_4$), 3) five-carbon sugars are pentoses ($C_5H_{10}O_5$) such as ribose and xylose, 4) six-carbon sugars are hexoses ($C_6H_{12}O_6$) such as glucose, galactose and fructose and 5) seven-carbon sugars are called heptoses ($C_7H_{14}O_7$). Only one disaccharide has been found in mammals (i.e., lactose), whereas the most common plant disaccharide is sucrose. Many oligosaccharides are commonly found in plants. The trisaccharide raffinose and the tetrasaccharide stachyose are the two most common oligosaccharides found in plants (e.g., soybeans and other legume seeds, sugar beets, root crops and sugar beet molasses). Longer chain oligosaccharides can be found in a variety of plants used as food.

Starch is made up of glucose units in straight chains with α1,4 bonds (amylose) and with α1,6 bonds that form branches (**Figure 5-11**). Small intestinal digestive enzymes can break the α1,4 and α1,6 bonds. Starches in plants are called amylopectins whereas animal starch is called glycogen. Plant starches exist as semicrystalline granules that vary in size, shape and amount of other compounds (proteins) associated with the granule.

The granular structure of starch affects the ease with which it is digested (**Table 5-5**). Most starches in cooked and extruded pet foods are easily and rapidly digested. Raw or uncooked starch is typically digested more slowly than cooked starch. Some plant starches resist enzymatic digestion in the small intestine (Englyst and Cummings, 1987) and have been named resistant starch (RS). RS, by definition, is not enzymatically digested in the small intestine, thus it becomes available for microbial fermentation in the colon.

The amounts of rapidly digestible, slowly digestible and RS in foods are highly variable and depend on the starch source, type and extent of processing (BNF, 1990). **Table 5-5** shows a nutritional classification of the types of starch found in foods.

Function

The body uses simple carbohydrates and starches in foods as a source of glucose. As such, they have several major functions. First, they provide energy (ATP) via glycolysis and the TCA cycle. Second, when metabolized for energy to carbon dioxide and water, they are a source of heat for the body. Third, as they proceed through metabolic pathways, certain products can be used as building blocks for other nutrients, such as nonessential amino acids, glycoproteins, glycolipids, lactose, vitamin C, etc. Finally, simple carbohydrates and starches in excess of the body's immediate energy needs are stored as glycogen or converted to fat.

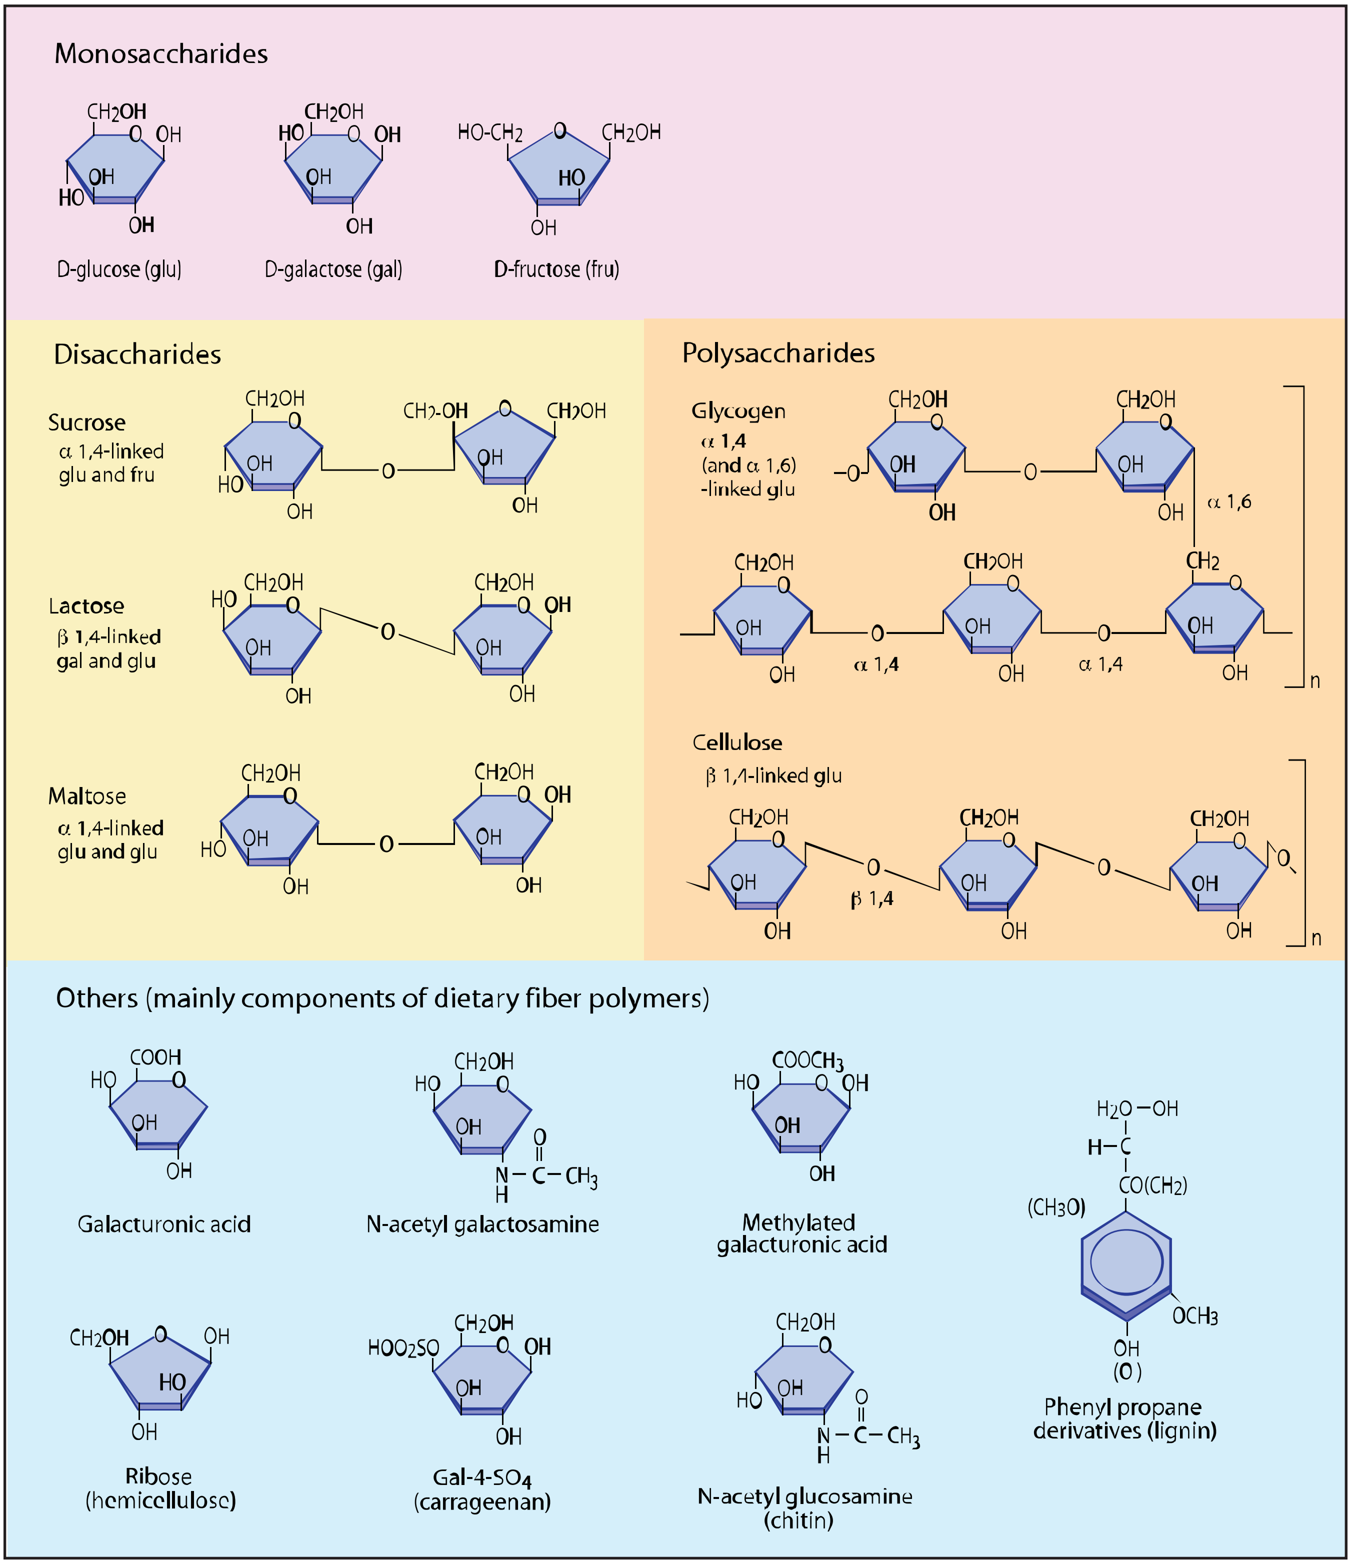

Figure 5-11. Components and classification of dietary carbohydrates. Dietary carbohydrates are usually classified as monosaccharides, disaccharides (sugars that yield two monosaccharides on hydrolysis) and polysaccharides (carbohydrates that yield nine or more monosaccharides when hydrolyzed). Other carbohydrates are primarily components of dietary fiber.

Table 5-4. Classification and digestion of complex carbohydrates.*

Complex carbohydrate type	Function	Digestion site	Digestion products
Starch, glycogen	Storage polysaccharide in plants and animals	Small intestine (enzymatic)	Mono- and disaccharides (glucose, maltose)
Hemicellulose, cellulose	Structural parts of plant cell walls	Large intestine (microbial fermentation)	Volatile fatty acids (acetate, propionate, butyrate)
Lignins, cutins, waxes	Associated cell wall substances	Not digested or fermented	Excreted in feces
Gums, mucilages, pectins	Naturally occurring polysaccharides in plants	Large intestine (microbial fermentation)	Carbon dioxide, methane, hydrogen, volatile fatty acids

*Adapted from the British Nutrition Foundation. Complex Carbohydrates in Foods. New York, NY: Van Nostrand Reinhold, 1990.

IMPORTANCE OF CARBOHYDRATES

The primary purpose for adding carbohydrates and starches to pet foods is to supply energy. Generally, assuming an average digestibility (84%), carbohydrates supply about 3.5 kcal/g. Although there is no minimum dietary requirement for simple carbohydrates or starches per se, certain organs and tissues (e.g., brain and red blood cells) require glucose for energy. Glucose can be obtained from precursor nutrients such as glucogenic amino acids or glycerol from fats via gluconeogenic pathways. The body always maintains a glucose supply to key tissues; thus, if adequate dietary carbohydrates are unavailable, amino acids will be shunted away from muscle growth, fetal growth and milk production to be used for glucose synthesis.

When energy needs are high and tissue accretion is occurring (e.g., during growth, gestation and lactation), adequate dietary carbohydrates or glucose precursors are necessary to maintain metabolic processes (Romsos et al, 1981; Kienzle et al, 1985; Meyer and Kienzle, 1991; Blaza et al, 1989). In these situations, carbohydrates become conditionally essential; therefore, foods fed to growing animals and those with high-energy needs should contain at least 20% carbohydrates.

In addition to nutritional reasons for adding carbohydrates to pet foods, carbohydrates also are important in pet food processing. Chapter 8 provides detailed information.

Metabolism

DIGESTION

Digestion of simple carbohydrates and starches occurs throughout the digestive tract and involves mechanical, enzymatic and microbial processes. Mechanical breakdown occurs primarily in the oral cavity. Because dogs and cats lack salivary α-amylase, enzymatic digestion of starch is not initiated in the mouth. In the stomach, food is mixed with gastric juices (i.e., hydrochloric acid and proteolytic enzymes). Although the stomach plays an important role in protein digestion, little carbohydrate digestion occurs here. Simple carbohydrates and starches are digested and absorbed in the small intestine. Enzymes secreted from the pancreas digest the majority of starches and sugars in the lumen of the small intestine, whereas enzymes at the small intestinal mucosal brush border are important in the final stages of carbohydrate digestion and absorption.

Starch is initially cleaved by the enzyme α-amylase, which creates branched oligosaccharides, the disaccharide maltose and the trisaccharide maltotriose. The brush border enzymes maltase, sucrase and isomaltase cleave the larger glucose chains into single glucose molecules that are then absorbed. Sucrase also splits the disaccharide sucrose into glucose and fructose units. Lactase, another brush border enzyme, splits lactose, the sugar found in milk, into glucose and galactose. Lactase activity is usually high in young, suckling animals but often declines in adults. Conversely, amylase, maltase and isomaltase display a reverse temporal pattern; concentrations of these enzymes are low in suckling animals and higher in adults (Meyer and Kienzle, 1991; Kienzle, 1988). For example, in puppies, amylase and sucrase activities increase by 21 days after birth and increase further by Day 63 postpartum. This pattern suggests that growing dogs have an increasing ability to digest carbohydrates from foods (Buddington et al, 2003).

Starch is made up of glucose units in straight chains (amylose) and with branches (amylopectin) linked with α-bonds (**Figure 5-11**). Starches are contained within granules in plants in a highly crystalline formation. As foods containing starches are heated or cooked with water, the starch crystals are melted and hydrated, a process called gelatinization (Camire et al, 1990). The extent to which starch granules are disrupted and the extent of gelatinization depend on many factors including grinding, moisture, cooking time and temperature. For most starches, digestibility increases with the degree of gelatinization. Extrusion cooking, a process used in dry pet food production, increases overall digestibility of starches in grains by gelatinizing starch. The canning process also results in gelatinization of starch.

Several reports indicate that dogs and cats readily digest starches in commercial pet foods (Meyer and Kienzle, 1991; Gross et al, 1998; Walker et al, 1994; Schunemann et al, 1989). In studies, dogs were fed foods in which 30 to 57% of the food came from extruded corn, barley, rice or oats. The starch from all grains was nearly 100% digested in the small intestine; essentially no starch passed into the colon (Walker et al, 1994).

Other studies compared the digestibility of isolated raw cornstarch, tapioca and potato starches and cooked rice starch (Meyer and Kienzle, 1991; Schunemann et al, 1989). In these studies, isolated starches contributed 40% of the DM of the food. By the time the starch reached the colon, uncooked corn-

starch was digested to the same degree as cooked rice starch (>94% digested); however, uncooked potato (0%) and tapioca starches (<70%) were poorly digested in the small intestine. The uncooked tapioca starch subsequently resulted in increased bacterial fermentation rates as evidenced by high volatile fatty acid concentrations in the feces. Large amounts of easily fermentable carbohydrates (e.g., tapioca starch) in the colon increase the risk of excessive fermentation causing gas and flatulence and upsetting the balance of microflora.

In feeding trials with cats, investigators demonstrated that cooked cornstarch was nearly 100% digested when consumed by cats at 4.7 g/kg body weight per day (Meyer and Kienzle, 1991; Kienzle, 1993, 1993a). Raw cornstarch was only 60 to 70% digested and raw potato starch was 40% or less digested when consumed at 8.8 and 8.9 g/kg body weight per day. Most commercial cat foods contain approximately 30 to 35% DM carbohydrate. This level provides approximately 5 to 8 g of starch/kg body weight per day, which should pose no digestive or metabolic problems for cats (Meyer and Kienzle, 1991).

ABSORPTION

Glucose and galactose are absorbed through an active transport mechanism using specific carrier proteins and a sodium gradient. Fructose is absorbed by a separate carrier system that appears not to be sodium dependent. Absorption occurs across the small intestinal mucosa through villi. The enterocytes covering the villi contain the carbohydrate-digesting enzymes, transport proteins and other enzymes used to synthesize triglycerides and chylomicrons. Enterocytes can use absorbed sugars for energy or the sugars can be released into portal blood for transport to the liver and beyond.

Deficiency of digestive enzymes or failure of the energy-dependent transport system may cause carbohydrate intolerance or malabsorption. Many disaccharidase deficiencies result from intestinal mucosal damage induced by infections and other diseases. The resulting colonization of the lower small intestine by colonic bacteria may result in bacterial proteolysis of carbohydrate-digesting enzymes.

Unabsorbed carbohydrates in the intestinal lumen create high osmotic pressure, reduce water and mineral absorption and may result in small bowel diarrhea. In addition, excessive fermentation of unabsorbed carbohydrates leads to bacterial overgrowth, production of gas (carbon dioxide, hydrogen and methane) and short-chain fatty acids. Excessive carbohydrate fermentation can lead to flatulence, abdominal distention and diarrhea. Carbohydrate intolerance may be diagnosed by finding increased concentrations of hydrogen in the breath (breath hydrogen analysis) as a result of bacterial fermentation (Bissett et al, 1997).

USAGE

Glucose and other sugars derived from food arrive at the liver via the portal blood. The liver plays a central role in synthesizing, storing, converting and releasing glucose for use by other organs. Insulin and glucagon finely control the concentration of blood glucose. The glycemic index ranks dietary carbohydrates based on their effect on blood glucose. Carbohydrates that result in a low postprandial blood glucose response have a lower glycemic index and vice versa. Animals with impaired glucose tolerance should consume foods that have a relatively low glycemic index. Altering carbohydrate sources or adding fiber can modulate the glycemic index.

The central nervous system and erythrocytes require glucose for their energy needs, whereas other tissues can use other substrates (e.g., muscle uses fatty acids). Glucose is metabolized via glycolysis followed by the TCA cycle (**Figure 5-7**). Complete oxidation of glucose to carbon dioxide, water, ATP and heat requires oxygen and is termed aerobic metabolism. The final transfer of energy from carbohydrate to ATP occurs via the electron transport chain (**Figure 5-4**). If there is a shortage of oxygen in tissues, such as occurs with intense exercise, some ATP can be derived from glucose via anaerobic metabolism in which glucose is partially metabolized to pyruvate (via glycolysis) and then converted to lactic acid.

Glucose consumed in excess of immediate needs may be stored as glycogen. The enzyme glycogen synthetase synthesizes glycogen from glucose units. This enzyme is particularly active in liver and muscles. Endurance athletes have used carbohydrate loading (i.e., eating large amounts of carbohydrate several days before competition) to maximize muscle glycogen stores. Carbohydrate loading in canine athletes has been practiced, but has not been widely researched (Chapter 18). After glycogen stores are filled, additional dietary carbohydrates are converted to long-chain fatty acids and stored as adipose tissue.

In the hours following digestion and absorption of a carbohydrate-containing meal, the liver and other body tissues switch from glycogen storage to glycogenolysis under the influence of an increased glucagon to insulin ratio. This ratio also stimulates lipolysis, thus overall body metabolism switches toward lipid use for energy. Glucose is synthesized from carbon skeletons of amino acids, glycerol and lactic acid (gluconeogenesis) to maintain plasma glucose concentration. This function is critical to provide an adequate supply of glucose to the brain (**Figure 5-7**). The liver and kidneys, but not muscles, are the sites of gluconeogenesis; therefore, muscle cannot supply glucose to the bloodstream.

STORAGE

The body stores sugar as glycogen, a glucose polysaccharide. Its highest concentration is in the liver, but muscle tissue, because of its greater mass, stores the most glycogen.

Ribose, although not a true carbohydrate store readily available for oxidation, is found as part of nucleic acids, ATP and guanosine triphosphate (GTP). The body also has stores of sugar-protein complexes (glycoproteins, mucus and proteoglycans) and sugar-lipid complexes (glycolipids).

EXCRETION

Excreted products resulting from normal carbohydrate metabolism include carbon dioxide in the breath, heat radiating from the body and water. In cases of malabsorption of simple sugars and starches, increased intestinal fermentation may lead

to more hydrogen in expired breath and flatus and short-chain fatty acids in stools. Animals with deranged carbohydrate metabolism (diabetes mellitus, ketosis, glycogen storage diseases and fructose, galactose and pyruvate enzyme deficiencies) may have elevated urinary or plasma levels of the metabolic intermediates related to the specific disease (glucose, ketones, lactic acid, oxalate, etc.). Chapter 29 discusses treatment of the most common disease of abnormal carbohydrate metabolism, diabetes mellitus.

Carbohydrates of Special Importance

XYLOSE

Xylose is a five-carbon sugar used in clinical veterinary medicine to assess intestinal absorptive capacity, alterations in GI emptying, bacterial overgrowth and exocrine pancreatic insufficiency (Chapters 54, 60 and 66). When xylose is administered orally, approximately 48% is expected to be absorbed into the bloodstream and excreted in urine (Williams and Guilford, 1996). Altered xylose absorption can be diagnostic for certain diseases. The xylose absorption test is typically only recommended for use in dogs; there is too much individual variability in results from cats (Williams and Guilford, 1996).

LACTULOSE

Lactulose is a synthetic disaccharide containing galactose and fructose connected by a β1,4 bond. Lactulose is formed when lactose (galactose and glucose) is subjected to isomerization in aqueous alkaline solutions. Lactulose is not hydrolyzed by mammalian enzymes, but can be digested by microbial enzymes; thus, it is fermented in the colon. Lactulose enhances the growth of specific types of bacteria (*Lactobacillus bifidus*), has laxative effects and acidifies the colon to aid in ammonia trapping. Fermentation of excessive amounts of lactulose may worsen flatulence and cause diarrhea. Clinically, lactulose is often given to help manage hepatic encephalopathy (Chapter 68). (It is also occasionally administered before breath hydrogen collection and used with a xylose absorption test to differentiate among small intestinal disease, bacterial overgrowth and exocrine pancreatic insufficiency (Chapters 55, 60 and 66).

GLYCOSAMINOGLYCANS

Glycosaminoglycans are complex polysaccharides associated with proteins. They form integral parts of the interstitial fluid, cartilage, skin and tendons. The primary glycosaminoglycans are chondroitin sulfate and hyaluronic acid. Chondroitin sulfate is a polymer of two alternating sugar units, glucuronic acid and N-acetylgalactosamine. Hyaluronic acid is a linear polymer of two sugars: glucuronic acid and N-acetylglucosamine. Chondroitin sulfate and other glycosaminoglycans are available as dietary supplements with alleged benefits for arthritic conditions, degenerative joint diseases and geriatric patients in general. In one study using a combination of oral chondroitin sulfate and glucosamine in human patients with osteoarthritis of the knee joint, there was no pain relief in the overall patient population, but there was some benefit for patients with moderate to severe pain (Clegg et al, 2006).

RESISTANT STARCH

RS (**Table 5-5**) is a fraction of starch found in foods that potentially resists digestion in the small intestine (Englyst and Cummings, 1987). RS is classified according to the rapidity with which glucose is released from a starch source and is a fraction of the total amount of starch that remains after a sample is incubated for 100 minutes with the enzymes pancreatin and amyloglucosidase. Four types of RS have been identified (Brown, 1996):

RS_1 = starch physically trapped within the starch granule that is released during processing and chewing.

RS_2 = starch granular structures (e.g., those found in raw potato, bananas and tapioca).

RS_3 = recrystallized starch formed after cooking, when the starch cools or is dried.

RS_4 = chemically modified starch resistant to enzymatic hydrolysis.

RS_1 and RS_2 represent the residues of starches that are digested very slowly and incompletely in the small intestine. RS_3 is highly resistant to digestion by intestinal enzymes and is fermented by colonic bacteria.

Physiologically, RS are thought to have various functions related to their dietary fiber-like properties including reducing the glycemic index of food, decreasing the glucose and insulin responses to food and improving bowel health (Brown et al, 2001). In particular, RS can be used as a source of fiber for gluten-free or hypoallergenic foods.

OLIGOSACCHARIDES

Oligosaccharides are polymers that contain up to nine sugars. Oligosaccharides that contain fructose are termed fructooligosaccharides (FOS). Although FOS are the most extensively studied oligosaccharides, other oligosaccharides include mannanoligosaccharides (MOS), galactooligosaccharides (GOS), xylooligosaccharides (XOS), isomaltooligosaccharides (IMOS), soybean oligosaccharides (SOS), pectic oligosaccharides, chitooligosaccharide, lactusucrose and lactulose or other polysaccharide/oligosaccharide-containing sources such as inulin. Oligosaccharides resist digestion by enzymes in the small intestine and enter the colon intact. In the colon, certain bacteria (bifidobacteria and *Lactobacillus* spp.) readily ferment oligosaccharides, which enhances the bacterial growth rate (Roberfroid et al, 1998, 1993; Gibson and Roberfroid, 1995; Hidaka et al, 1986; Bunce et al, 1995, Flickinger et al, 2000; Grieshop et al, 2004). Increased numbers of these bacterial species may benefit the overall health of people and other animals, including pigs, rabbits and rats (Bunce et al, 1995; Willard et al, 1994; Howard et al, 1995).

Bifidobacteria produce short-chain fatty acids that decrease the intestinal pH and inhibit the growth of pathogenic bacteria. FOS reduce fasting blood glucose levels, cholesterol and low-density lipoproteins (LDL) in people with diabetes mellitus (Yamishita et al, 1984). The benefits of oligosaccharides such as FOS, MOS and GOS in dogs, pigs, rabbits and rats include improved intestinal flora (i.e., reduced numbers of pathogens), reduced mortality, improved feed efficiency,

improved weight gain, increased nitrogen digestion and retention, reduced body fat, improved stool quality and reduced fecal odor (Grieshop et al, 2004; Flickinger et al, 2003, 2000; Bunce et al, 1995; Willard et al, 1994; Delzenne et al, 1993; Morissee et al, 1992).

Analyses

The total carbohydrate content of pet foods and ingredients is not typically determined directly by analysis but indirectly by difference. NFE is the carbohydrate fraction of a proximate analysis. NFE is determined by adding the percentages of water, crude protein, crude fat, ash and crude fiber and subtracting from 100%. NFE is primarily made up of readily digestible carbohydrates (e.g., sugars and starches) (**Figure 5-3**).

Techniques such as gas-liquid chromatography and high-performance liquid chromatography can be used to separate and analyze different monosaccharides. In addition, colorimetric enzymatic assays specific for each sugar are available. The starch content of foods can be determined by heating the sample to gelatinize the starch followed by incubation with starch-digesting enzymes (amyloglucosidase and pancreatin). The amount of glucose liberated by enzymatic hydrolysis is analyzed and converted to starch content (Herrera-Saldana and Huber, 1989).

Requirements, Deficiencies and Excesses

Dogs and cats do not have an absolute dietary requirement for carbohydrates in the same way that essential amino acids or fatty acids must be provided. They do, however, have a requirement for adequate glucose or glucose precursors to provide essential fuel for the central nervous system. When energy needs are high and anabolic processes are proceeding at an active rate (e.g., during growth, gestation and lactation), it is best to supply a food containing readily digestible carbohydrates and starches. Without dietary carbohydrates, there is added strain on lipid and protein metabolic pathways to supply glucose precursors (NRC, 2006). Lipolysis must be increased to provide energy and glycerol units for gluconeogenesis. Similarly, glucogenic amino acids from dietary protein must be used for glucose formation; therefore, these amino acids are not available to meet body protein synthesis requirements.

From a practical standpoint, whether carbohydrate is essential in the food or not is of little importance because most commercially prepared pet foods contain carbohydrates well in excess of glucose requirements. Grains such as corn, rice, wheat, barley and oats provide the bulk of starch in commercial pet foods and are well digested and absorbed due to the cooking and extrusion processes used to make pet foods.

CANINE CARBOHYDRATE REQUIREMENTS

Gestation and lactation increase the need for glucose to support fetal growth and lactose synthesis in milk. In one study, pregnant bitches were fed a high-fat but carbohydrate-free (0% of energy from carbohydrate) food with 26% of ME from protein. They developed hypoglycemia the week before whelping and had reduced plasma concentrations of lactate and alanine, a reduced number of live births, lethargy and reduced mothering ability compared with bitches fed a food containing 44% of ME as starch (Romsos et al, 1981). In another study using 51% of ME as protein, pregnant bitches fed either a starch-free or starch-containing diet performed similarly (Blaza et al, 1989).

Extensive research in dogs indicates that a starch-free food containing at least 33% of ME from protein is necessary to supply needed glucose precursors (Kienzle et al, 1985). Fetal abnormalities, embryo resorption, ketosis and reduced milk production are other possible adverse effects of providing inadequate carbohydrate during gestation and lactation (NRC, 2006).

Overall, a minimum of 23% carbohydrate is recommended in foods for gestating and lactating bitches. Excess starch in the food typically does not cause health problems in dogs. Dry extruded dog foods typically contain 30 to 60% carbohydrate, mostly starch, and cause no adverse effects. Excesses of simple sugars in commercial pet foods are also not a practical concern because sugar levels are usually low. On the other hand, carbohydrate intolerances may occur in some animals as a result of primary or secondary disaccharidase deficiencies. For animals with obesity or diabetes mellitus, foods with low glycemic indices are indicated for controlling the postprandial increase in blood glucose.

FELINE CARBOHYDRATE REQUIREMENTS

Normal cats can maintain adequate blood glucose levels when fed low-carbohydrate, high-protein foods (Kittlehut et al, 1978). Cats have some unique metabolic differences that limit their ability to efficiently use large amounts of absorbed dietary carbohydrate. For example, cats have low activities of the intestinal disaccharidases sucrase and lactase (Kienzle, 1993b); furthermore, the sugar transportation system in the feline intestine does not adapt to various levels of dietary carbohydrates. Cats

Table 5-5. Nutritional classification of starch.*

Type of starch	Example of occurrence	Probable digestion in the small intestine
Rapidly digestible starch	Freshly cooked starchy food	Rapid and complete
Slowly digestible starch	Most raw cereals	Slow and complete
Resistant starch		
Physically inaccessible starch	Partly milled grain and seeds	Resistant
Resistant starch granules	Raw potato and banana	Resistant
Recrystallized starch	Cooled, cooked potato, bread and cornflakes	Resistant

*Adapted from the British Nutrition Foundation. Complex Carbohydrates in Foods. New York, NY: Von Nostrand Reinhold, 1990.

Table 5-6. Sources of dietary carbohydrates.

Carbohydrate	Sources
Amylopectin (plant starch)	Starchy plants; grains; used as thickener in processed foods
Amylose (plant starch)	Starchy plants; grains
Carrageenan	Red seaweed; used in candies and some processed foods
Cellulose	Substituent of plant cell walls; major component of wheat bran
Corn syrup	Used in processed foods
Dextrins	Used in processed foods
D-Fructose	Fruits; traces in most plant foods; honey; maple sugar
D-Galactose	Component of lactose; produced during digestion
D-Glucose (dextrose)	Fruits; traces in most plant foods; honey; maple sugar
Glycogen (animal starch)	Liver; muscle
Hemicellulose	Substituent of plant cell walls
High-fructose corn syrup	Used in processed foods
Lactose (milk sugar)	Milk; dairy products
Lignin	Substituent of plant cell walls
Maltose	Sprouted grain; produced during digestion of starches
Pectins	Fruits
Raffinose, stachyose, verbacose	Plant "antifreeze"
Sucrose	Cane sugar; beet sugar; fruits; maple sugar

produce only 5% of the pancreatic amylase that dogs produce (Kienzle, 1993). Unlike dogs, cats lack hepatic glucokinase activity, which limits their ability to metabolize large amounts of simple carbohydrates (Kienzle, 1993b; McDonald et al, 1984). Glucokinase is responsible for phosphorylating glucose to G-6-P in the pathway of glucose oxidation. Feline liver is also thought to lack fructokinase (McDonald et al, 1984).

The metabolic differences between cats and dogs support the classification of cats as strict carnivores, adapted to a low-carbohydrate diet, and dogs as omnivores. If large amounts of carbohydrates are fed to cats (e.g., more than 40% of the food's DM), signs of maldigestion occur (e.g., diarrhea, bloating and gas) (Meyer and Kienzle, 1991) and adverse metabolic effects can occur (e.g., hyperglycemia and excretion of significant amounts of glucose in urine). Despite the limitations of digestive capacity and metabolism, the starch levels found in commercial cat foods (up to 35% of the food's DM) are well tolerated. There are also differences among carbohydrate sources and their effects on blood glucose due to the glycemic index of the specific carbohydrate source. Of the cereal grains, in cats, rice has the greatest effect on postprandial blood glucose levels compared to corn, barley and sorghum (Bouchard and Sunvold, 2000).

Sources

Starches are the primary carbohydrates found in corn, wheat, rice, barley, oats and potatoes (**Table 5-6**). Meat is a poor carbohydrate source. Commercial extruded pet foods use starches in grains to provide structure, texture and form to extruded kibbles. In addition, the extrusion process gelatinizes starch, which makes it easily and rapidly digested in the small intestine of dogs and cats. Most starches from grains are easily digested in the small intestine, when fed uncooked (raw) or cooked to dogs and cats (Meyer and Kienzle, 1991; Gross et al, 1998; Walker et al, 1994). Potato starch is an exception. Raw potato starch is contained in granules that have a crystalline structure that resists digestion by people, dogs and cats (Meyer and Kienzle, 1991; Englyst and Cummings, 1987a). Freshly cooked potato starch, however, is highly digestible. A study showed that rapidly digestible starch increased from 24 to 65% when extruded (Murray, 2001). However, starch begins to recrystallize when cooled or dried. In vitro digestion studies and studies in people show that up to 13% of the recrystallized potato starch resists digestion by pancreatic amylase and thus will be fermented in the colon (Englyst and Cummings, 1987a; Cummings and Englyst, 1995).

RS in cereal grains (rice, barley, wheat, sorghum and corn) and potato flour converted to rapidly digestible forms with low or high temperature extrusion (Murray et al, 2001; Spears and Fahey, 2004). Bacteria normally present in the small intestine of dogs and cats are able to use these starches; up to 39% of their organic matter disappears after five hours of fermentation (Murray et al, 2001). An in vitro study showed that the RS concentrations of selected feed ingredients corresponded inversely to their ileal digestibility. For example legumes (various beans and peas) with an average of 25% RS had an ileal starch digestibility of 21%, whereas cereal grains had an average of 15% RS and flours with 3% RS had ileal starch digestibilities of 60 and 65% respectively (Bednar, 2001). However, the RS fraction is fermented in the large intestine, contributing to its functional properties as a fiber. Fermentation of RS in the colon produces butyrate, which is important for the health of colonocytes. Some legumes (e.g., soybeans) contain significant quantities of raffinose and stachyose, which can be digested by gut microflora but not by canine and feline digestive enzymes. These sugars allegedly cause digestive abnormalities (e.g., flatulence) due to the gaseous waste products produced by bacterial fermentation.

Sugar is sometimes added to enhance palatability of foods for dogs. Commercial semi-moist cat foods use mono- and disaccharides as functional ingredients to achieve texture and moistness and to prevent spoilage. Pet food with gravies and sauces may contain dextrins, corn syrup and other starches for texture and appearance. Sucrose does not enhance palatability of foods for cats because cats have few sucrose-sensitive taste buds (NRC, 2006; Boudreau and White, 1978). A dog's ability to taste sweetness is different from a person's because of differences in the number and type of sweetness receptors on taste buds (Boudreau and White, 1978; Boudreau, 1989). Therefore, the sweetness rankings of different sugars developed for people are not applicable to cats and dogs. Unlike in people and other primates, dietary sugars do not present a risk for dental caries in dogs and cats (Chapter 47).

Fiber

Definition

Fiber refers to a multitude of compounds categorized as com-

plex carbohydrates (**Table 5-4**). Fibers differ from starches in that fibers resist enzymatic digestion in the small intestine. As a result, microbes in the colon usually ferment fibers. Fibers include cellulose, hemicellulose, pectin, gums and RS (See previous discussion.) and are unique because of the types of sugars they contain and the resultant chemical bonds.

Chemical Structure

Unlike starches, cellulose is a polymer of glucose units bonded by β1,4-linkages (rather than α linkages) that are only broken by microbial enzymes (**Figure 5-11**). Cellulose is the most abundant polysaccharide in plants, forming the structure of plant cell walls. In plants, hydrogen bonds closely hold straight cellulose chains to one another forming orderly and compact aggregates called fibrils. Cellulose fibrils contain regions that are highly crystalline and other regions that are more random and amorphous. Cellulose is usually associated with hemicellulose and lignin within plant cell walls. Water-soluble chemical derivatives of cellulose, including carboxymethylcellulose, methylcellulose and hydroxypropylcellulose, are used as stabilizers, thickeners and emulsifiers in pet and human foods such as ice cream, gravies, soups and beverages. Cellulose is also added to weight-reduction foods for people and pets to dilute calories and provide bulk. Cellulose is not very water soluble but can have significant water-holding capacity and is slowly fermented by microbes in the colon.

Hemicelluloses are composed primarily of glucose, galactose, mannose, xylose, arabinose and uronic acids joined together in different combinations and various linkages. Hemicelluloses are closely associated with the cellulose in the cell walls of plants. Most hemicelluloses are not water soluble because of their various structures and composition.

Pectin is a linear chain of galacturonic acid linked by α1,4-glycosidic bonds found in cell walls and intercellular regions of plants. The linear galacturonic chain of most pectins is interrupted by other sugars (e.g., galactose, arabinose and rhamnose) to form branches and kinks. Pectins are found in high levels in fruits and vegetables such as apples, strawberries, raspberries, carrots, broccoli, potatoes, sugar beet pulp and the skins of citrus fruits. Commercially, pectin is extracted from either apple or citrus waste after the manufacture of juice. Pectins are water soluble, form viscous gels and are rapidly fermented by intestinal bacteria.

Gum is a general term for the diverse group of viscous and sticky polysaccharides found in the seeds and exudates of plants. The sugars that make up gums are diverse, and the precise structural information for some gums is unknown. Gum arabic, guar gum, gellan gum, konjac gum, carrageenan gum, psyllium gum, xanthan gum, carob gum, gum ghatti and gum tragacanth are just a few of the gums used as thickening agents, water binders, stabilizers, emulsifiers and gelling agents in jams, pie fillings, confectionery products, sauces, salad dressings, canned meat products and moist pet foods. Depending on their source and processing, gums have variable viscosity and solubility in water and thus have variable fermentation rates. Intestinal bacteria moderately to rapidly ferment most gums.

Lignin is not a carbohydrate in the strictest chemical definition; however, it is often considered a fiber because it makes up the structural part of plant cell walls and is not digested by mammalian intestinal enzymes. Lignin is not a single chemical compound but a series of compounds made from derivatives of phenylpropane associated in complex cross-linked structures. Lignin is highly resistant to enzymatic (intestinal and bacterial) digestion and chemical degradation. Strong chemical bonds between lignin and plant cell wall fibers, proteins and other compounds make lignins unavailable during digestion.

Other plant polysaccharides can also be considered as fibers. These include fructans (inulin), galactans, mannans, mucilages and β-glucans with β1,3- and β1,2-glucose bonds. Amounts of these fibers in foods are usually quite low.

Figure 5-12. Physiochemical and analytical properties of dietary fiber components.

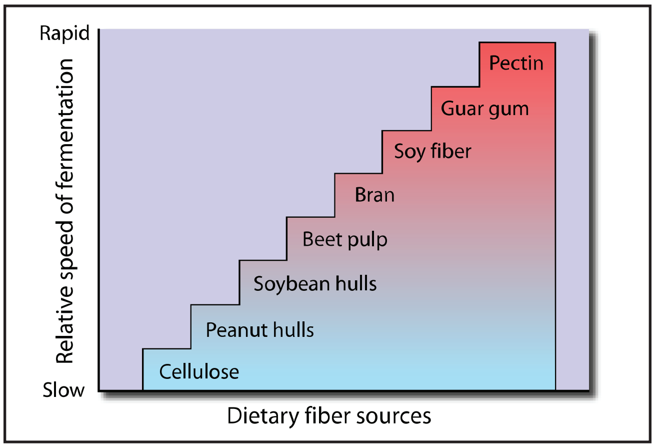

Figure 5-13. Relative degree of fermentation of various dietary fiber sources in the gastrointestinal tract of dogs and cats. At the extremes are pectin and gums, which are rapidly fermentable, and cellulose, which is slowly fermentable. Other fiber sources such as soy hulls and beet pulp are intermediate and termed moderately fermentable.

Other Classifications of Fiber

In addition to classifying fibers by their structure as described above, fibers have been classified by their rate of fermentation, digestible and indigestible fractions, solubility in water, water-holding capacity and viscosity (**Figure 5-12**). The different ways of classifying fibers allow the important physiologic functions and diverse effects of fiber in animals to be highlighted and understood.

Fiber sources can be described as rapidly to slowly fermentable (**Figure 5-13**). Rapidly fermented fibers produce more short-chain fatty acids and gases in a shorter period of time compared to fiber sources that ferment more slowly (Sunvold et al, 1994, 1994a). Slowly fermentable fiber sources used in pet foods contain primarily celluloses and hemicelluloses including purified cellulose and peanut hulls. Citrus and apple pectins and most gums are rapidly fermented. Fiber sources that contain mixtures of pectins, hemicelluloses and celluloses (e.g., rice bran, oat bran, wheat bran, soy fibers, soy hulls and beet pulp) are moderately fermentable. The rate and extent of fiber fermentation are important distinguishing characteristics when discussing physiologic functions of fiber. As the fermentation rate of fiber increases, GI transit time decreases, fecal bulk decreases and fecal bile acid excretion increases.

Fiber is also classified according to solubility, or the ability of a fiber to disperse in water. Most rapidly fermentable fibers such as pectins and gums are "soluble." Lignin and the slowly fermentable fibers such as cellulose and most hemicelluloses are "insoluble." All fibers hold water to some degree; however, the soluble fibers have a greater water-holding capacity and may form gels and viscous solutions within the GI tract. A new classification of fiber relates to the ability of certain microorganisms in the gut to use fiber as food. Fibers are classified as "prebiotic fibers," which are defined as "nondigestible food ingredients that selectively stimulate a limited number of bacteria in the colon to improve host health" (Gibson and Roberfroid, 1995). (See below.) The definition implies that prebiotic fibers are resistant to hydrolysis by mammalian enzymes, are able to support the growth of beneficial bacteria and do not support the growth of potential pathogens, although some prebiotic fibers do support growth of putative pathogens to a limited degree.

Fiber concentration, ionic concentration, pH, particle size and the hydrophobic and hydrophilic properties of polysaccharide structures affect the viscosity of fibers in water. An increase in viscosity in the GI tract can slow nutrient absorption, reduce postprandial glycemia, slow gastric emptying, delay mouth to cecum transit and reduce interactions of food particles with digestive enzymes and epithelial surfaces. The fermentation rate of a fiber interacts with its water-holding capacity and viscosity to affect the degree of fecal bulking (volume). For moderately and slowly fermentable fibers, the degree of fecal bulking is related to water-holding capacity. Slowly fermented fibers (e.g., cellulose) are the most effective stool bulking agents because they retain their structure longer and are thus able to bind water. For rapidly fermentable fibers, the increased bound water reduces fecal bulk. In fact, most fermentable fibers have laxative effects and may produce diarrhea if fed at high levels. An increase in fecal bulk has been advocated for the treatment and prevention of irritable bowel syndrome, constipation and other GI disorders (Chapters 48 to 65).

Function

The primary function and benefit of adequate dietary fiber are to increase bulk and water in the intestinal contents (Leib, 1990; Twedt, 1993; Gurr and Asp, 1994). Fiber appears to shorten intestinal transit rate in dogs with normal or slow transit time and prolong it in dogs with rapid transit rate (Burrows et al, 1982). Together, these factors help promote and regulate normal bowel function. In addition, the typical end products of microbial fermentation of fiber (acetate, propionate and butyrate) are important in maintaining colonic health. Fiber decreases luminal pH through production of short-chain fatty acids and increases the population of anaerobic flora. The antibacterial properties of short-chain fatty acids may decrease pathogenic intestinal bacteria, increase resistance of the gut to colonization by pathogenic bacteria and may be important in prevention of and recovery from intestinal disorders and cancer (Twedt, 1993; Gurr and Asp, 1994; Burrows et al, 1982; Salter et al, 1993). Dietary fibers classified as prebiotics also increase beneficial bacteria that protect the GI tract against colonization by pathogens. Prebiotic fibers may also reduce fecal odor by modifying fecal concentrations of metabolites and, via their carbohydrate residues, improve immune function by influencing gut-associated immune cells. (See below.)

Colonocytes preferentially use butyrate, an end product of fiber fermentation, as their energy source rather than glucose or amino acids (Roediger, 1982). In addition, short-chain fatty acids facilitate absorption of sodium, chloride and water in the colon. The gut microflora produce an array of com-

lulose, cellulose and lignin; however, the pectins are lost. Acid detergent fiber (ADF) is determined by boiling the analytical sample in an acidic detergent solution. The fraction remaining contains cellulose and lignin. The result of subtracting the amounts of ADF and NDF in a particular food or ingredient approximates the hemicellulose content. Like the limitations of crude fiber determinations, NDF and ADF do not measure the more soluble fiber fractions of pectins and gums; therefore, they are not widely used to determine fiber in pet foods.

Requirements

Fiber is not considered essential in the diets of cats and dogs, although it is often included in commercial foods. Overall, dogs and cats do not derive much energy from absorbing the typical end products of bacterial fermentation; however, short-chain fatty acids are important in maintaining colonic health. Therefore, a small amount of fiber (<5%) that contains both rapidly and slowly fermentable fibers is recommended in foods for healthy pets (Chapters 13 and 20). Today, much interest exists in human and veterinary nutrition about the role of "pharmacologic doses" of certain nutrients (e.g., fiber) in preventing chronic diseases (**Box 5-7**).

Fiber also aids in managing diseases such as obesity, diabetes mellitus, diarrhea, colitis and constipation. The types and amounts of dietary fiber required to assist in the management of these diseases can be found in Chapters 27, 29, 56, 62 and 64.

Deficiencies

Total deficiency of fiber in typical pet foods is not a practical problem because many ingredients contain some fiber. Homemade foods, veterinary therapeutic foods made with more refined ingredients and purified diets used in research studies can be extremely low in fiber. Some dietary fiber that produces short-chain fatty acids is usually recommended.

Excess/Toxicity

Excess fiber may have undesirable effects. For instance, certain fiber types decrease mineral absorption. The effects on mineral absorption vary by type of fiber and the mineral. More rapidly fermentable fibers (e.g., pectins and guar gum) appear to decrease availability of some minerals, whereas fibers that contain more cellulose have little effect on mineral absorption.

Excess fiber can dilute the energy and nutrient content of the food to such an extent that an animal may have difficulty eating enough of the food to meet its needs. Controlled levels of fiber are advantageous in weight-reducing foods for dogs and cats; however, such foods are fortified so that only total energy intake is low and other nutrients are present in adequate amounts to meet daily requirements.

Sources

The maximum crude fiber content of pet foods must be listed in the guaranteed analysis section of pet food labels in the United States. Most dog and cat foods have DM crude fiber contents of less than 5%. The fiber in most pet foods comes from a variety of ingredients. Grains such as whole corn and brown rice are sources of fiber in dry extruded foods. Some pet foods contain specific ingredients added to provide fiber. Fiber sources commonly used in pet foods today include the hulls from rice, soybeans, peanuts and oats, dried beet pulp, various vegetable gums, corn bran, wheat bran, rice bran, oat bran and more purified fiber sources such as oligosaccharides, cellulose and soy fiber. AAFCO publishes official definitions of fiber ingredients (2007). **Table 5-9** lists common fiber ingredients with fiber content and general classifications of solubility and fermentability.

Table 5-9. Characteristics of selected fiber ingredients.

Fiber ingredient	Crude fiber (%)*	Total dietary fiber (%)*	Solubility in water	Fermentability rate
Apple pectin	0	95	Soluble	Rapid
Beet pulp	20	66	Insoluble	Moderate
Cellulose	80	98	Insoluble	Slow
Citrus pulp	12	77	Soluble	Rapid
Corn bran	19	90	Insoluble	Moderate
Guar gum	0	81	Soluble	Rapid
Gum arabic	0	91	Soluble	Rapid
Pea fiber	30	92	Insoluble	Moderate
Peanut hulls	57	76	Insoluble	Slow
Rice bran	44	13	Insoluble	Moderate
Soy fiber	20	83	Soluble	Rapid
Soy hulls	34	69	Insoluble	Moderate/slow
Sunflower hulls	54	80	Insoluble	Slow
Wheat bran	10	43	Insoluble	Moderate
Wheat middlings	7	46	Insoluble	Moderate

PROTEIN/AMINO ACIDS

Definition

Proteins are large, complex molecules composed of hundreds to thousands of amino acids. Amino acids are composed of carbon, hydrogen, oxygen, nitrogen and sometimes sulfur and phosphorus. Four chemical groups covalently bonded to a carbon atom form the general structure of amino acids. The four groups include a hydrogen atom, a carboxyl group (COOH), an α-amino group (NH_2) and another chemical group specific for each amino acid (**Table 5-10**). Although hundreds of amino acids exist in nature, only 20 are commonly found as protein components. The amino acids found in mammalian proteins are the L-isomer of α-amino acids, which means the side chain unique to each amino acid is linked to the α-carbon atom in the L (levorotatory) position.

Structure

Proteins are linear polymers of amino acids in which the amino group of one amino acid and the carboxyl group of another amino acid are coupled together (peptide bond) (**Figure 5-15**). Amino acids arranged in chains are referred to as peptides. Two bonded amino acids form a dipeptide, three a tripeptide and more than three a polypeptide.

Proteins can be described as having a primary, secondary, tertiary or quaternary structure. The primary structure of proteins refers to the sequence (order) of amino acids along the polypeptide chain. The secondary structure of proteins refers to the

configuration of the polypeptide chains resulting from hydrogen bonds between adjacent amino acids. Alpha-helices, β-pleated sheets or random coils are formed by these hydrogen bonds. The tertiary structure describes how further interactions of the amino acids cause folding and bending of the polypeptide chain giving the protein its biologic activity. Proteins have a quaternary structure if they contain more than one polypeptide chain. Hydrogen, electrostatic and ionic bonds form between the polypeptide chains and stabilize the aggregates. The primary structure of proteins is responsible for the secondary, tertiary and quaternary structures that are formed.

Other compounds bound to peptides may also classify proteins. Simple proteins are made up of only amino acids. Simple proteins are subclassified into fibrous or globular proteins according to shape, solubility and chemical composition. Fibrous proteins include collagens, elastins and keratins, which are the major structural proteins in the body. Collagens are the main proteins of connective tissues and make up about 30% of the total proteins in the body. Elastin is the protein found in tendons and arteries. Keratins are the main proteins in hair. All enzymes, hormones and antibodies that are proteins have a globular structure. Subgroups of globular proteins include the albumins, histones, globulins and protamines.

Conjugated proteins contain amino acids and carbohydrates (glycoproteins), lipids (lipoproteins) or minerals (phosphoproteins, chromoproteins). Glycoproteins are commonly found as components of cell membranes and function to modulate enzymes, receptors and immune function and to recognize cells (antigen and blood types). Glycoproteins are also components of mucous secretions that act as lubricants in many parts of the body, myelin that surrounds nervous tissue and as part of lipoproteins. Lipoproteins transport lipids in the bloodstream in a water-miscible form to tissues. Lipoproteins are typically classified into four main categories according to their density: 1) chylomicrons, 2) very low-density lipoproteins (VLDL), 3) LDL and 4) high-density lipoproteins (HDL) (Chapter 28). Proteins that contain minerals include hemoglobin (iron), cytochromes (copper) and caseins (phosphorus).

Some proteins in the body contain special amino acids that are derived from common amino acids. Collagen contains hydroxyproline and hydroxylysine, which are derivatives of proline and lysine, respectively. Triiodothyronine and tetraiodothyronine (thyroxine) are derived from tyrosine and function as hormones and part of the protein thyroglobulin. Gamma-carboxyglutamic acid is derived from glutamic acid and is key for the function of calcium binding in thrombin, which functions in blood clotting. Other amino acids such as taurine (a β-amino acid) and γ-aminobutyric acid function in specific roles in the body, but are not found as part of proteins.

Purines (adenine and guanine) and pyrimidines (cytosine, thymine, uracil) are other nitrogen-containing molecules that form nucleic acids. Nucleic acids (RNA and DNA) carry the genetic information that codes for the primary structure of proteins (the amino acid sequence).

Function

Proteins are the principal structural constituents of body organs and tissues including: 1) collagen and elastin found in cartilage, tendons and ligaments, 2) the contractile proteins actin and myosin in muscles, 3) keratin proteins in skin, hair and nails and 4) blood proteins including hemoglobin, transferrin, albumin and globulin. Proteins also function as enzymes, hormones (e.g., insulin) and antibodies. Amino acids can serve as a source of energy after the nitrogen-containing amino group is removed by deamination or transamination.

Importance of Amino Acids

Several amino acids are classified as essential or indispensable (10 for dogs and 11 for cats). These amino acids cannot be synthesized by the body in sufficient quantities and therefore must be supplied by food. The carbon skeletons of these essential amino acids are the critical component that the body cannot synthesize. Many of the remaining amino acids are nonessential or dispensable; they can be synthesized in the body from carbon and nitrogen building blocks and need not be present in the food if adequate nitrogen and energy are available. Some amino acids are conditionally essential. These amino acids ordinarily are not required in the food except during certain physiologic or pathologic conditions when they may not be synthesized in adequate quantities.

Although nonessential amino acids can be made from precursor carbon skeletons, they are just as critical to the makeup of proteins and are just as essential for metabolic reactions in the body as essential amino acids. Protein is also necessary to provide the body with a source of nitrogen for synthesis of other nitrogen-containing compounds including purines, pyrimidines, nucleotides, nucleic acids, creatinine, nitric oxide and some neurotransmitters.

Metabolism

Digestion and Absorption

Dietary proteins must be digested to be absorbed from the GI tract. Protein digestion begins in the stomach with the action of the enzyme pepsin in the presence of hydrochloric acid. The main end products of gastric protein digestion are mixtures of large polypeptides; however, little or no absorption of these molecules occurs. In the small intestine, the pancreas and cells lining the small intestine secrete other enzymes (endopeptidases and exopeptidases). These enzymes break the bonds between the amino acids of large polypeptides resulting in free amino acids, dipeptides and tripeptides that can be absorbed across the intestinal wall (Mathews, 1991). Some proteins are less readily digested than others. The rapidity of digestion is influenced by many factors, including protein structure, processing effects, other nutrients in the meal and the presence of enzyme inhibitory factors.

Absorption of amino acids is a sodium-dependent, active-transport process that requires energy (ATP). This process is mediated by four different carrier systems that transport neutral amino acids, basic amino acids, dicarboxylic amino acids and imino acids. These separate carrier systems help ensure trans-

Table 5-10. Amino acids.

Name	Structural formula	Abbreviations 3-letter	Abbreviations 1-letter	Side chain	Essentiality
Alanine		Ala	A	Aliphatic	Nonessential
Arginine		Arg	R	Basic	Essential
Asparagine		Asn	N	Acidic	Nonessential
Aspartate		Asp	D	Acidic	Nonessential
Cysteine		Cys	C	Sulfur containing	Nonessential, but can provide for up to 50% of methionine requirements
Glutamate		Glu	E	Acidic	Nonessential
Glutamine		Gln	Q	Acidic	Conditionally essential
Glycine		Gly	G	Aliphatic	Nonessential
Histidine		His	H	Basic and aromatic	Essential
Isoleucine		Ile	I	Aliphatic branched chain	Essential
Leucine		Leu	L	Aliphatic branched chain	Essential

port of a well balanced mixture of amino acids from the intestinal lumen to the portal vein.

Amino acids and proteins not absorbed in the small intestine can be fermented in the hindgut and produce fecal odor compounds. These compounds are produced by bacterial enzymes during the degradation of endogenous and undigested food proteins. The fecal odor compounds include ammonia, aliphatic amines, indoles, phenols and volatile sulfur-containing compounds. These compounds not only affect fecal odors but can also seriously affect the GI health of animals (Hussein and Sunvold, 2000). The amount of dietary amino acids that reach the large intestine can alter fecal compounds. The amount of amino acids reaching the large intestine can be affected by high food DM intake, high protein foods and foods that contain low quality proteins. An increase in protein and amino acid flow to the large intestine can result in more substrate for the resident bacteria and an increase in fecal odor components (Yamka et al, 2006; Hussein and Sunvold, 2000).

Many studies investigating altering fecal odor compounds have focused on the use of prebiotics. Researchers found that feeding adult dogs FOS (0.5% of the DM) decreased putrescine, cadaverine, tyramine and total amines (Hussein and Sunvold, 2000). This study demonstrated that fecal odor could be manipulated by prebiotics; however, few studies have focused on fecal components related to protein source. Another study found that dogs consuming poultry by-product meal produced more fecal odor compounds than dogs fed soy-based foods (Yamka et al, 2006). The reduction of fecal odor compounds in soy-fed dogs was likely the result of hindgut fermentation of soluble fiber and oligosaccharides present in soy.

Apparent vs. True Digestibility

Estimations of crude protein and amino acid availabilities of most feed ingredients can be provided by determining apparent ileal protein and amino acid digestibilites. Apparent digestibilities are determined by comparing the amounts of amino acids present in the feed and digesta without determining endogenous nitrogen losses. For determining true ileal amino acid digestibilities, undigested dietary amino acids present in the ileal digesta should be differentiated from endogenous amino acids. Recent studies suggest that endogenous nitrogen losses are higher than previously estimated and that differences in apparent digestibilities between feedstuffs are attributed to differences in endogenous gut nitrogen losses rather than differences in true digestibilities (Nyachoti et al, 1997). Factors such as body weight, dietary fiber content, DM intake and the presence of anti-nutritive factors in the diet influence secretions and/or reabsorption of endogenous gut protein (Nyachoti et al, 1997).

Several methods exist for estimating the contribution of endogenous protein and amino acids at the distal ileum; three are used most commonly. The first method is a direct method for measuring endogenous protein. This method requires that animals be fed a protein-free diet. It is assumed that the recovery of endogenous protein and amino acids at the distal ileum is the same for animals fed protein-free and protein-containing diets (Nissen, 1992; Burns et al, 1982; Kendall et al, 1982). The second method is the regression method. The regression method determines endogenous protein and amino acid recoveries in digesta with the aid of regression to zero protein intake using a series of test source protein levels. However, with the regression method, no relationship is assumed between protein

Table 5-11. Glucogenic and ketogenic amino acids.

Exclusively ketogenic	Leucine, lysine
Exclusively glucogenic	Alanine, serine, glycine, cysteine, aspartate, asparagine, glutamate, glutamine, arginine, histidine, valine, threonine, methionine, proline
Ketogenic and glucogenic	Isoleucine, phenylalanine, tyrosine, tryptophan

Table 5-12. Factors for converting nitrogen to crude protein.

Food protein	Nitrogen (g/kg)	Conversion factor
Barley, oats, wheat	171.5	5.83
Corn, eggs, meat	160.0	6.25
Milk	156.8	6.38
Soybeans	175.1	5.71

intake and the recovery of endogenous protein and amino acids (Nissen, 1992). The third method for determining the recovery of endogenous protein is the ^{15}N-isotope dilution technique. The endogenous protein is labeled, secreted into the GI tract via a continuous infusion of ^{15}N-leucine. This method directly measures the contribution of endogenous to total protein recovered at the distal ileum in animals fed protein-containing foods (Grala et al, 1998; Nissen, 1992).

True, rather than apparent, ileal amino acid digestibilities should be used when formulating diets, but this requires further development of methods for routine estimation of endogenous nitrogen losses. Improvements in protein usage should be sought via reducing endogenous nitrogen losses and improving true ileal amino acid digestibilites (Nyachoti et al, 1997).

Protein Usage

Absorbed amino acids and small di- and tripeptides are reassembled into "new" proteins by the liver and other tissues of the body. Amino acids from food are transported from the liver to other tissues by serum albumin or as free amino acids. The fate of amino acids after absorption falls into three general categories: 1) tissue protein synthesis, especially in muscles and liver, 2) synthesis of enzymes, albumin, hormones and other nitrogen-containing compounds and 3) deamination and use of the remaining carbon skeletons for energy.

A high rate of protein synthesis occurs in production of red and white blood cells, epithelial cells of the skin and those lining the GI tract (i.e., intestinal mucosa, which produces exocrine secretions, such as digestive enzymes and mucus) and the pancreas. In addition, all body proteins are continuously broken down and resynthesized, a process known as protein turnover. Some proteins (muscle proteins and some plasma proteins such as albumin) have a relatively long lifetime (days to weeks). Other proteins (cytokines and enzymes) have relatively short lives (minutes to hours).

Muscle protein composes nearly 50% of total body protein, but only accounts for 30% of new protein synthesized, whereas visceral and organ proteins compose a smaller portion of total body protein but account for 50% of new proteins synthesized. Because protein turnover is the sum total of the continuous degradation and synthesis cycles of specific proteins, a measure of protein turnover is only a "snapshot" in time of protein metabolism. In addition, rates of protein synthesis and degradation for any particular protein can change under different physiologic conditions.

The body is able to synthesize new proteins and enzymes provided all the necessary amino acids are available. The source of amino acids is not important. Cells use amino acids from a variety of sources including those derived from food proteins, single amino acids added to the food and amino acids synthesized by the body. In addition, cells synthesizing new protein cannot distinguish between amino acids from grains (e.g., corn and rice) and those from meats (e.g., chicken and beef). The only criterion is that all the amino acids needed to synthesize a particular protein be present in sufficient quantities when necessary. Protein synthesis will be limited when certain amino acids are not present or available in the quantities needed.

During protein turnover, a fraction of amino acids enter catabolic pathways that lead to their permanent loss. The amount of nitrogen lost every day as a result of the body's continuous breakdown process is called obligatory nitrogen loss. Dietary protein must be consumed each day to replace amino acids lost to catabolism. Trauma, infection, severe sepsis and burns increase protein turnover and nitrogen losses, whereas nitrogen losses are reduced during long-term fasting and starvation. Nitrogen is normally lost from the body in feces (nitrogen, proteins, cells), in urine and through skin desquamation and loss of hair.

Nitrogen balance is the net difference between nitrogen consumed and lost; however, the determination is fraught with technical difficulties. Most commonly, nitrogen losses are underestimated through incomplete collection of feces, urine, hair and sloughed cutaneous cells; whereas, nitrogen intake is routinely overestimated. Thus, nitrogen balance should only be regarded as a crude estimate of body protein status and not be used to distinguish among subtleties in protein and nitrogen metabolism.

Protein Storage

Although, in effect, there is some storage of excess amino acids, they are not stored to the same degree that extra fat and carbohydrates are stored. Structural proteins in all tissues, especially in muscles and liver and serum albumin, can be considered as amino acid stores. Muscle protein represents the largest reserve from which amino acids may be drawn in times of need. Too much loss of body protein impairs muscle function. Liver and muscle protein and serum albumin synthesis increase after consumption of a protein-containing meal. After protein synthesis is maximized, excess amino acids are deaminated and transaminated to yield amino groups and carbon skeletons. The carbon skeletons can be used for many purposes including glucose precursors, which can be stored as glycogen or converted to fatty acids and acetyl-CoA, which can be used for fuel immediately. In the hours after consumption of a meal containing protein, body protein synthesis

gradually declines as the amino acids from the meal are used. Because protein turnover and obligatory nitrogen losses continue to occur, muscles must convert from net uptake to net release of amino acids as fasting becomes dominant. Although glycogen and lipids are the preferred short-term and long-term energy stores, protein catabolism can supply carbon skeletons needed to maintain glucose pools and supply the body with energy (ATP). Protein degradation continues until the next meal, after which protein synthesis exceeds protein breakdown.

The carbon skeletons of catabolized amino acids can be completely oxidized to carbon dioxide or converted by the liver to glucose or ketone bodies. Thus, amino acids can be glucogenic or ketogenic. Glucogenic amino acids can be converted to glucose through pyruvate or any of the TCA cycle intermediates. Ketogenic amino acids are those that can be converted to acetyl-CoA or ketone bodies but cannot be metabolized to glucose. Some catabolized amino acids yield two different carbon skeletons, one ketogenic and the other glucogenic (**Table 5-11**).

Protein Excretion

Amino acid catabolism produces waste nitrogen, if it is not used for purine or pyrimidine synthesis. Catabolism of amino acids typically leads to formation of ammonia, which is toxic to body cells. Ammonia must be converted to a less toxic form that can be transported in blood and excreted. Ammonia formation occurs in all tissues, but is especially prevalent in the liver and kidneys during gluconeogenesis. More than 90% of the nitrogen resulting from protein degradation is converted to urea in the liver and kidneys and then excreted in urine. A smaller fraction of nitrogen is lost as ammonia, creatinine and nitrate. Hepatic and renal detoxification of ammonia via the urea cycle is a critical function. The amino acids ornithine, citrulline and arginine are key intermediates. Other amino acids (e.g., glutamate, aspartate, alanine and the amide group of glutamine) carry excess amino groups from other tissues to the liver and kidneys for conversion to urea. Catabolism of other nitrogen-containing metabolites also contributes to the waste nitrogen pool.

CLINICAL PROBLEMS ASSOCIATED WITH NITROGEN DISPOSAL

Hyperammonemia may result if any of the enzymes involved in the urea cycle are lacking or have impaired activity. Part of the therapy for any disease (e.g., liver disease) in which urea cycle function is reduced is to decrease plasma concentrations of ammonia. Reducing total protein intake, reducing intake of nonessential amino acids and substituting keto analogues of some amino acids may help reduce the ammonia load. Other measures (e.g., dialysis, transfusion, administration of drugs and other compounds that trap nitrogenous metabolites) can be used to prevent an ammonia encephalopathy crisis (Chapter 68).

Reduced renal function may also impair nitrogen disposal (i.e., urea may not be excreted efficiently). Reducing waste products of protein catabolism through dietary manipulation aids therapy for chronic renal failure (Chapter 37).

Catabolism of purines (adenine and guanine from nucleotides, ATP and GTP, RNA and DNA) may also create nitrogen disposal problems. Uric acid is the end product of purine catabolism in people, nonhuman primates, birds and Dalmatian dogs; all other mammals produce allantoin. Uric acid and allantoin are excreted in urine and feces. Accumulation of uric acid in serum can lead to gout (uric acid crystals in joints) and uric acid uroliths. Hyperuricemia can be treated with drugs (allopurinol) and with dietary intervention. Reducing total protein intake and reducing or eliminating dietary ingredients containing high levels of purines (organ meats, glandular meats, fish such as mackerel and sardines) have been successful in some dogs with urolithiasis (Chapter 39).

Protein-losing enteropathy (PLE) and protein-losing nephropathy (PLN) are two syndromes in which excessive amounts of protein are lost from the body. PLE is a group of diseases characterized by excessive loss of serum protein into the intestinal tract. Causes of PLE include lymphatic disorders (lymphangiectasia, neoplasia, congestive heart failure) and diseases associated with increased mucosal permeability or mucosal ulceration (intestinal neoplasia, granulomatous enteritis, lymphocytic-plasmacytic enteritis, intestinal parasitism, etc.).

PLN is characterized by excessive loss of serum protein into urine. Causes of PLN include glomerulonephritis and amyloidosis that develop secondary to chronic inflammatory conditions such as neoplasia, heartworm disease, ehrlichiosis, systemic mycosis, brucellosis, osteomyelitis and immune-mediated disease.

Analyses of Protein

Chemical Analyses of Protein

Protein concentration in foods (crude protein content) is typically calculated from the nitrogen content by the Kjeldahl method or Dumas combustion procedure. The Kjeldahl method involves digesting the food sample with sulfuric acid, which converts all nitrogen in amino acids to ammonia. The ammonia is distilled, collected and quantified using a colorimetric titration procedure. The Dumas combustion procedure requires no hazardous materials and involves measuring the nitrogen gas after combustion and total destruction of the sample. This method has been adopted as an acceptable method for measuring total nitrogen in animal foods (Etheridge et al, 1998). When using either method, two assumptions are made in calculating crude protein from nitrogen. First, that all nitrogen in the food sample is present as protein and second, that all protein contains 16% nitrogen. The crude protein content of the food is then calculated: crude protein in food (g/kg) = g nitrogen in food/kg x 6.25.

Neither assumption is always true. Not all nitrogen in food is present as protein; some nitrogen is present as free amino acids, amides, glycosides, alkaloids and ammonium salts. Other nitrogen is complexed with lipids. Different protein ingredients in food also have different nitrogen contents and, therefore, different conversion factors (**Table 5-12**). The use of an average conversion factor (i.e., 6.25) for all proteins in food simplifies cal-

culations and can be rationalized by keeping in mind that most pet foods are mixtures of protein-containing ingredients. In addition, animal protein requirements are typically calculated from determination of individual amino acid requirements that are converted to nitrogen requirements and then expressed as a protein requirement by multiplying nitrogen by 6.25. Although the crude protein content of pet foods gives a measure of the amount of nitrogen available to the animal, it does not provide information about protein quality or the nutritional value of the protein source(s).

Protein Quality

Protein quality refers to the efficiency by which amino acids from food are converted into tissue. That efficiency in turn depends on the protein source, concentration of essential amino acids in the food and their availability (Brown, 1989). Proteins that provide optimal proportions of all essential amino acids are referred to as high quality proteins. When a protein lacks one or more of the essential amino acids (limiting amino acid), the quality of the protein decreases and it is referred to as a poor quality protein (Orok et al, 1975). Other amino acids may not be used when a limiting amino acid is absent. Poor protein quality can also result from an excess of certain amino acids that may interfere with usage of other amino acids. (See Imbalance and Antagonism.) Digestibility can influence protein quality and can be affected by ash content, processing time and/or temperature. The amino acids of poor quality protein cannot be properly digested and used by the animal. For example, overcooking can form indigestible nutrient forms called Maillard complexes. Processing methods and heat treatment of various feedstuffs can also affect digestibility. Researchers studied the effects of processing temperature and time on nutrient quality of moist dog food (Jamikorn et al, 2000). They demonstrated that raising the processing temperature (6°C) or increasing the processing time (25 min.) may alter nutrient content and digestion.

Other factors that can affect protein availability include fiber content, tannins, pectins, oligosaccharides and phytase or trypsin inhibitors, which can be found in plant protein sources. Proteins of plant origin generally have lower digestibility than animal proteins because plant fiber and carbohydrates lower digestion, due to a reduced degradation rate of nutrients in the gut and increased bacterial activity (Murray et al, 1997; Neirinck et al, 1991; Meyer, 1984). Feeding high-fiber diets decreases apparent protein digestibility (Kendall and Holme, 1982), presumably from increased adsorption of amino acids and peptides by fiber, and obstruction of digestive enzymes by fiber components in cell walls (Knabe et al, 1989).

Dogs use poor quality proteins less efficiently (Burns et al, 1982). Poor quality proteins can lead to profound nutritive failure, accompanied by a rapid decline in weight, loss of appetite and eventual death (Palika, 1996; Rose and Rice, 1939). Dogs and cats will increase food intake to meet their protein/amino acid requirements for maintenance if the food contains low quality protein. By understanding the availability of limiting amino acids in a particular food or protein source, nutritionists can improve the protein quality of the food through protein complementation (feeding multiple protein sources) and/or amino acid supplementation. Thus, measuring protein quality becomes necessary in formulating different feedstuffs to supply digestible amino acids or crude protein.

MEASURES OF PROTEIN QUALITY

Several methods have been used to determine the quality of protein sources for animals. Some methods involve testing the protein source by feeding it to animals (in vivo methods), whereas other methods evaluate the protein's quality by chemically analyzing its amino acid composition (in vitro methods). There are a number of ways to measure protein quality in vivo. Many of these tests are based on variations of nitrogen balance experiments.

The first and crudest method is the protein efficiency ratio (PER), which measures the ability of dietary protein to be converted into tissue. The method works only with young, growing animals and may be influenced by the level of energy or fat in the diet and by the level of dietary protein. The PER is calculated as: PER = weight gain of animal ÷ protein intake of animal (Brown, 1989; Burns et al, 1982). The typical PER value for animal proteins is 2.5 (Brown, 1989).

The most frequently used measure of protein quality is biological value (BV), which is defined as the percentage of absorbed protein retained. BV gauges the efficiency with which the body is able to convert absorbed dietary amino acids into tissues. The BV is calculated as: BV = (food nitrogen - [fecal nitrogen + urinary nitrogen]) ÷ (food nitrogen + fecal nitrogen) (Brown, 1989; Burns et al, 1982; Davidson et al, 1979). There are some practical problems using BV as a measure of protein quality. It is possible for a protein source to lack high digestibility, but have a high BV if the residue is absorbed and well used by the animal (Brown, 1989).

To account for these differences in digestibility, a new method (net protein utilization) was established for determining protein quality. This method, unlike BV, includes allowances for nitrogen losses during digestion and is equal to BV multiplied by true digestibility. Use of the coefficient allows for adjustments to determine differences in true and apparent availability of dietary amino acids for the animal (Brown, 1989; Burns et al, 1982; Davidson et al, 1979).

The amino acid score (AAS) is a chemical method for comparing the amount of the first limiting amino acid in a test protein with the level of the same amino acid found in a reference protein. The AAS is calculated as: AAS = mg of amino acid/g of test protein ÷ mg of amino acid/g of reference protein. This method for measuring protein quality is very rapid and highly reproducible. Because it is derived solely from amino acid composition, AAS does not compensate for differences in digestibility that can be caused by processing (Brown, 1989; Food and Agriculture Organization of the United Nations, 1973).

The slope ratio method is a biologic equivalent of the AAS. The slope ratio method compares the growth performance produced by a test protein with that of a reference protein such as defatted whole egg (Samonds and Hegsted, 1977). The slope ratio (SR) is calculated as: SR = slope of response curve for ani-

Table 5-13. Small intestinal and total tract crude protein and small intestinal amino acid digestibility of dog foods containing animal protein sources.*

mals fed the test protein ÷ slope of response curve for animals fed the reference protein. The slope ratio method usually uses growth as the response and may be sensitive to different levels of energy (Brown, 1989).

Ileal-cannulated dogs can also be used to determine protein quality (Walker et al, 1994). Protein digestibility coefficients based on collection and analyses of digesta from the terminal ileum give a more accurate measure of protein nitrogen absorbed than those based on fecal collections. Values determined from terminal ileal digesta exclude endogenous protein secretion from the GI tract and contributions from intestinal microflora. Ileal collection eliminates the large intestine and bacterial fermentation as sources of error. Use of ileal-cannulated dogs has enabled researchers to study the effects of feeding various protein sources and carbohydrates on digestibility and protein quality. **Tables 5-13** and **5-14** summarize recent work with ileal-cannulated dogs and demonstrate the differences in quality among various protein sources. Because of the complications involved with using ileal-cannulated cats (Mawby et al, 1999), no published studies have investigated protein quality using this model. As a result, only total tract crude protein digestibility data are available for cats (**Table 5-15**).

Finally, stable isotopes have been used to study protein quality. Whole body nitrogen flux can be determined using ^{15}N-glycine and ^{13}C-leucine. These markers have been used extensively in human pediatrics (Bolster et al, 2001; Zello et al, 2003), human geriatrics (Chevalier et al, 2003; Gibson et al, 2002) and in young-adult/aging dogs (Williams et al, 2001).

Protein quality varies with the animal species; poor quality proteins for one monogastric species may not be poor quality in other monogastrics (e.g., dogs vs. cats). The sensitivity of quality depends on the rate of growth or the level of demand to synthesize proteins for needs such as lactation, trauma, athletic performance and stress. Animals that are relatively inactive, mature and under no stress may not be very sensitive to moderate differences in protein quality (Brown, 1989).

Table 5-15. Total tract crude protein (CP) digestibility of cat foods containing plant and animal protein sources.*

Protein source	Carbohydrate source	Total tract CP digestibility (%)
Fish meal[1]	Corn	78
Meat meal[2,4]	Corn	91
Soy protein	-	-
With 25% butter[3]	Cornstarch	91

Protein/Amino Acid Requirements
Factors Affecting Requirements

New proteins can be synthesized from dietary amino acids or nonessential amino acids that were previously synthesized by the body. By definition, essential amino acids used in protein synthesis must be provided by food. Therefore, animals do not have a requirement for protein per se but have an amino acid requirement. The amount of each amino acid that an animal requires varies based on factors such as growth, pregnancy, lactation and some disease states. In addition to requiring specific essential amino acids, dogs and cats have a requirement for building blocks (carbon skeletons and nitrogen) for nonessential amino acids. The building blocks for nonessential amino acids can either be derived from excess essential amino acids that are broken down and reassembled into nonessential amino acids or from other nonessential amino acids in food. Thus, a complete statement of amino acid requirements should include all the essential amino acids and an amount of amino nitrogen that can be used for synthesis of nonessential amino acids.

The amount of protein or amino acids that must be included in a pet food also depends on how much food the animal consumes. It is easy to understand why animals that are growing, pregnant or lactating require dietary protein to support new tissue growth and milk production. If an animal only consumes small quantities of food to meet its energy requirement then the food needs to have a greater protein concentration to meet the animal's protein requirement. For example, high-calorie pet foods should have more protein as a percentage of the

Table 5-16. Ideal amino acid profiles (relative to lysine) for dogs and cats.*

Amino acids	Dogs	Cats
Lysine	1.00	1.00
Methionine + cystine	0.64	1.00
Tryptophan	0.22	0.19
Threonine	0.67	0.87
Arginine	0.71	1.12
Isoleucine	0.57	0.63
Valine	0.75	0.75
Leucine	1.00	1.50
Histidine	0.29	0.38
Phenylalanine + tyrosine	1.00	1.12

*Baker DH, Czarnecki-Maulden GL. Comparative nutrition of cats and dogs. Annual Review of Nutrition 1991; 11: 239-263.

food than low-calorie foods. The opposite is also true. Larger portions of low-calorie foods are typically consumed; therefore, animals can adequately meet their daily requirements with a food that has a lower percentage of protein.

Adult animals also need dietary protein to replace the amino acids that enter pathways of amino acid catabolism and are permanently lost. Healthy adults also have a daily requirement for protein to replace nitrogen lost as urea, ammonia, creatinine, nitrate in urine and feces, sloughing of epithelial cells in skin and the GI tract, sweat, hair, nasal secretions, semen from males and secretions due to reproductive cycles in females. Dietary protein that must be consumed each day to replace the obligatory nitrogen loss is termed the maintenance protein requirement.

Adult and growing animals have maintenance requirements for protein, but only growing animals have the additional protein requirement for growth. The additional protein required by pregnant and lactating animals really supports growth. An animal's physiologic state also may result in increased or decreased protein catabolism and nitrogen losses. For example, patients with cancer, burns and trauma may have increased daily protein requirements.

Nitrogen balance is the difference between the nitrogen consumed and the amount lost each day. Growing animals, pregnant females and any animals that are replenishing or rebuilding tissue are in positive nitrogen balance. Zero nitrogen balance occurs in normal healthy adults receiving minimally adequate or more than adequate dietary protein when nitrogen output equals nitrogen intake. Negative nitrogen balance can occur during lactation, starvation or fasting when there is inadequate or no protein intake. Excessive body protein catabolism due to burns, injury, fever, infections, hormonal imbalance or psychological causes can also cause negative nitrogen balance. Amino acid imbalances and antagonisms can cause negative nitrogen balance even when adequate amounts of protein are consumed.

IMBALANCE AND ANTAGONISM

Essential amino acids must be provided in adequate amounts and in proper balance. When amino acids are used for protein synthesis, all the amino acids necessary to synthesize each protein must be present. The amino acid in shortest supply relative to demand is called the "first limiting amino acid." An imbalance occurs when one or more amino acids needed for protein synthesis are not available in the quantity needed, but at least one other amino acid is provided in excess (Harper et al, 1970). Amino acid antagonism occurs when amino acids have similar chemical structures (Harper et al, 1970). Typically, an excess of one of these amino acids increases the requirement of one or more chemically similar amino acids (antagonism). Amino acid imbalance or antagonism does not typically occur in animals consuming commercial pet foods because most foods use complementary proteins (plant and animal sources). However, even use of complementary protein sources can result in imbalances or deficiencies of other amino acids. Therefore, it becomes important to understand the optimal levels and ratios of the essential amino acids necessary for animals.

The ideal or perfect protein concept was first established in swine. This concept defines the ideal ratio of essential amino acids necessary to maximize tissue growth and diet usage. Researchers used the same concept for dogs and cats by extrapolating data from requirement studies using foods with purified amino acids (Baker and Czarnecki-Maulden, 1991). The requirement of each amino acid was determined by feeding graded levels of essential amino acids (with the same metabolizable energy) to puppies and kittens. These amino acids were then compared to the lysine requirement. Thus, the ideal protein concept creates ratios of the essential amino acids to lysine and is independent of total dietary nitrogen (crude protein of the food) and energy levels (**Table 5-16**). This ratio assures the protein in the food is "perfect" by containing optimal levels of amino acids (no imbalances or deficiencies).

Protein Requirements for Dogs and Cats

The absolute minimum dietary protein requirement can be estimated by feeding extremely high-quality protein or commonly used protein sources. If the estimate is based on feeding high-quality protein (e.g., lactalbumin), a growing dog requires approximately 18% DM protein and an adult dog about 8% DM protein (NRC, 2003). AAFCO has established that canine foods containing commonly used protein ingredients should contain at least 22% DM protein for growth, and 18% DM protein for adult maintenance (2007). It is important to note that AAFCO recommendations should be interpreted as daily allowances, not as absolute minimum requirements.

Growing kittens and adult cats have higher protein requirements than most other domestic species. The minimum protein requirement has been estimated to be about 18% DM for kittens and 16% DM for adult cats, assuming use of extremely high-quality protein sources (NRC, 2003). For commercial foods using commonly available protein sources, AAFCO has recommended that foods for kittens and adult cats contain at least 30 and 26% DM protein, respectively (2007). Again, AAFCO recommendations for protein should be interpreted as daily allowances, not as an absolute minimum requirement.

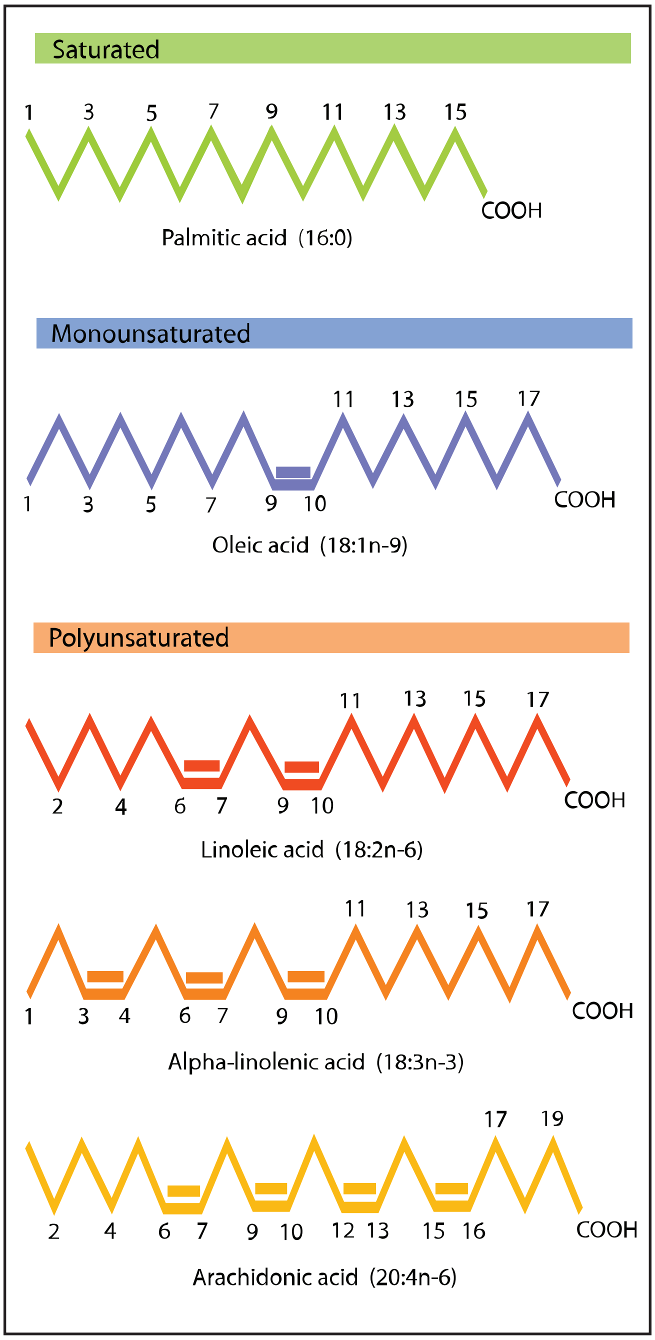

Figure 5-16. Fatty acids consist of hydrocarbon chains with a carboxylic acid group (COOH) on one terminus and a methyl group on the opposite terminus. Fatty acids with no double bonds in the hydrocarbon chain are referred to as saturated, one double bond as monounsaturated and more than one double bond, polyunsaturated. The carbon on the opposite terminus from the carboxylic acid group is designated the number one carbon and given the symbol n-1. Nomenclature specifies the number of carbons and the location and number of double bonds. For example, an 18-carbon polyunsaturated fat with three double bonds, the first of which is between carbons 6 to 7 is designated 18:3n-6 (γ-linolenic).

the main protein source of the food may be limiting. Methionine and lysine are typically used to fortify pet foods.

LIPIDS

Definition

Lipids are high energy compounds that supply nutritional and functional requirements in mammals. Generally, lipids share the physiochemical property of being insoluble (hydrophobic) in polar solvents such as water. Lipids that are solid at room temperature are commonly called fats whereas those that are liquid at room temperature are referred to as oils. In a nutrient analysis, the ether extract of a food contains primarily lipids and represents the crude fat content (**Figure 5-3**).

Structure

The structure of lipids ranges from simple to complex although any one classification scheme is difficult to impose. The basic subunits of lipids are hydrocarbon molecules linked by covalent bonds in various manners to themselves and other molecules in a vast assortment of permutations that result in the myriad of functions and structures observed in nature. **Table 5-18** and **Figures 5-16** and **5-17** will be helpful for reference throughout this chapter and the text.

Function

Dietary intake of lipids benefit the animal by supplying energy, essential fatty acids (EFA) and a positive environment for fat-soluble vitamin absorption. Dietary fats are the most concentrated forms of energy sources in pet foods, supplying 2.25 times the metabolizable energy of proteins and carbohydrates. Excess dietary lipids may be assimilated and stored as fat in adipocytes, whereas additional lipids are incorporated into functional lipid or catabolized for fuel, depending on the energy status of the animal. Triglycerides compose the majority of fat found in adipocytes, which may be synthesized de novo from nonfat precursors such as carbohydrate or protein during periods of positive energy balance.

Some lipids required for adequate physiologic function, such as certain long-chain fatty acids, cannot be synthesized de novo and are thus required in food. These fatty acids are called EFA because a lack of them in foods results in classic signs of deficiency. A small amount of lipid (1 to 2% of total food) of no specific structure is also required in foods for proper absorption of fat-soluble vitamins (A, D, E and K).

Fatty Acids

Structure

Nonesterified fatty acids (NEFA) consist of hydrocarbon chains ranging from two to 24 carbons or more, with a carboxylic acid group on one terminus and a methyl group on the opposite terminus. NEFA that contain 14 to 24 carbons are classified as long chain, eight to 12 medium chain and two to six short chain. **Figure 5-17** shows fatty acid chemistry and structure.

Lipid may be either in liquid or solid state depending on

Box 5-8. Cis and Trans Fatty Acids.

When carbons are connected by a double bond, rotation around the bond is not possible resulting in fatty acids that are either cis (with the carbons being on the same side) or trans (with the carbons being on the opposite side). Most polyunsaturated fatty acids are in the cis configuration. Fatty acids can be converted, however, to the trans configuration during excessive heating or through partial hydrogenation (i.e., the production of margarine from oil). Although trans fatty acids are metabolized for energy and incorporated into storage lipid, similar to the cis isomers, they are not further metabolized to eicosanoids. Nutritionally, trans isomers are in many ways like saturated fatty acids in that they are used for energy but cannot function as essential fatty acids.

temperature and fatty acid composition. A more unsaturated (increased number of double bonds) fatty acid makeup results in fats that have lower melting points compared with those of fats made from more saturated (decreased number or no double bonds) fatty acids. The length of the carbon chains in the fatty acids making up a fat also changes the melting point. Fats that contain fatty acids of shorter carbon chain length have lower melting points than do fats that contain longer fatty acids. Animals take advantage of these differences in physical characteristics to synthesize phospholipids containing appropriate classes of fatty acids that allow for membrane fluidity at physiologic temperatures.

Omega-3, Omega-6 and Omega-9 Fatty Acid Families

Fatty acids with the first double bond between the third and fourth carbon are in the omega-3 family, sixth and seventh carbon the omega-6 family and ninth and tenth carbon the

Box 5-9. Long-Chain vs. Medium-Chain Fatty Acid Metabolism.

Medium-chain fatty acids (mcFFA eight to 12 carbon lengths) are a minor component of natural compounds such as triglycerides from mother's milk or coconut milk. Triglycerides containing mcFFA are assigned the name medium-chain triglycerides (MCT). Even in foods "rich" with MCT, the overall contribution to the fat component of those foods is minor, compared with long-chain triglycerides. However, because MCT are subject to different metabolic regulation they may prove useful in certain disease states and have been included in some foods formulated for specific diseases (**Table 1**).

The Bibliography for **Box 5-9** can be found can be found at www.markmorris.org.

Table 1. Comparison between medium-chain triglycerides (MCT) and triglycerides.

Process	MCT	Triglycerides
Gut hydrolysis	Rapid, 5x triglycerides	Slower rate than MCT
Absorption	2x faster than triglycerides	Slower rate than MCT
Enterocyte reprocessing	Free fatty acid not reassembled in triglycerides	Free fatty acid reassembled in triglycerides
Transport	Portal vein, albumin bound	Chylomicrons, lymphatics and then general circulation
Hepatocyte		
Esterification	Not esterified to CoA	Esterified to CoA
Carnitine	Not bound to carnitine	Bound to carnitine
β-oxidation	Unregulated	Regulated

Table 5-18. Classification, structure and function of general lipids.

Classification	Structure	Function
Hydrocarbons	$-CH_3$, $-CH_2$, -CH	Building blocks
Nonesterified fatty acids	$CH_3(CH_2)n(CH_1)nCOOH$	
Saturated	Stearic, palmitic	Energy, membrane fluidity
Monounsaturated	Oleic, palmitoleic	Energy, membrane fluidity
Polyunsaturated	Omega-3, omega-6	Precursors of eicosanoids and prostaglandins
Simple lipids	Fatty acid + alcohol in ester bond	Energy storage, insulation
Triglycerides	Glycerol + three fatty acids	
Complex lipids		
Phospholipids	Diacyl glycerol 3' phosphate	Membrane lipids
Lecithin	3' phosphocholine	Emulsifying agent
Cephalin	3' phosphoserine/ethanolamine	CNS membrane
Inositol	Carbohydrate (3' phosphoinositol)	2nd messenger
Ceramide	Sphingosine + fatty acid	CNS membrane
Sphingomyelin	Ceramide + phosphocholine	Myelin
Glycolipids	Sphingomyelin + carbohydrate	CNS membrane/recognition
Cerebroside	Ceramide + monosaccharide	
Ganglioside	Ceramide + oligosaccharide	
Prostaglandins	20-carbon polyunsaturated fatty acids	Paracrine and autocrine action
Sterols and steroids	Four-ring hydrocarbon structures	Bile acids, hormones, membranes, lipoproteins, cholesterol, cholesterol esters
Fat-soluble vitamins	See vitamins	See vitamins

Box 5-10. Lipoprotein Lipase.

Lipoprotein lipase is an enzyme that hydrolyzes triglycerides into nonesterified fatty acids (NEFA) and glycerol. Lipoprotein lipase is located within the cell and is under hormonal control, specifically insulin. In its inactive state, lipoprotein lipase lies underneath the cell membranes that surround blood vessels. It is attached to the inner surface of the cell via a rope-like protein connection. Under the influence of insulin, this connection is loosened and the lipoprotein lipase is allowed to "float" to the cell surface where it can hydrolyze triglycerides in lipoproteins. Apo-CII is required as a coenzyme for lipoprotein lipase. The resulting NEFA diffuse into the cell for metabolism and glycerol is transported back to the liver for metabolism. Some lines of domestic cats have a genetic defect that results in absence of lipoprotein lipase activity.

Box 5-11. Good and Bad Cholesterol.

High-density lipoprotein (HDL) is the smallest of the lipoprotein molecules and is synthesized primarily in the liver and to a lesser degree in enterocytes. HDL is involved in reverse cholesterol transport. HDL transfers free cholesterol from cell membranes to the HDL molecule as cholesterol esters via an enzyme lecithin: cholesterol acyl transferase. The cholesterol esters may be transferred to very low-density lipoproteins (VLDL) by cholesterol ester transfer protein to eventually form low-density lipoprotein (LDL), which provides cholesterol to peripheral cells. Alternatively, the cholesterol esters may be delivered to the liver in HDL for excretion as bile salts. Because HDL is capable of transporting cholesterol from the periphery to the liver for disposal, it is said to contain "good cholesterol." LDL, on the other hand, is said to contain "bad cholesterol" because it transports cholesterol to the periphery where excess may result in arterial plaque and cardiovascular disease.

omega-9 family. The omega-3 and omega-6 fatty acid families are EFA because they cannot be synthesized de novo in mammals; lack of EFA in foods results in suboptimal physiologic activity (MacDonald et al, 1984a). Mammals are capable of de novo synthesis of saturated fatty acids and fatty acids of the omega-9 series up to 18 carbons (McGarry, 1986). Subsequently, mammals may elongate and desaturate de novo or dietary fatty acids of all classes via enzymes specific for certain carbons in the hydrocarbon chain (**Figure 5-19**). However, mammals cannot desaturate fatty acids between the n-1 carbon and the n-3, n-6 or n-9 double bond. Because of the specificity of these enzyme systems, unsaturated fatty acids cannot be converted between families (e.g., omega-6 or omega-9 to omega-3). Also, because of limitations and specificity in metabolism, monounsaturated and saturated fatty acids cannot be converted to EFA (e.g., omega-9 or stearate to omega-6).

Members of the omega-6 family include linoleic acid (18:2n-6), γ-linolenic acid (18:3n-6) and arachidonic acid (20:4n-6). Dogs, but not cats, are able to elongate and desaturate linoleic acid to form arachidonic acid (MacDonald et al, 1984b, 1984c; McLean and Monger, 1989). Thus, linoleic acid is usually listed as an EFA for dogs, whereas, both linoleic acid and arachidonic acid are EFAs for cats. The omega-6 fatty acid family is required for growth, reproduction and precursors of eicosanoid and prostaglandin synthesis.

Members of the omega-3 family include α-linolenic (18:3n-3), eicosapentaenoic (20:5n-3) (EPA) and docosahexaenoic (22:6n-3) acids (DHA). The omega-3 fatty acid family, especially 22:6n-3, is required for brain and retinal function (Neuringer et al, 1984; Arbuckle and Innis, 1992). Both fatty acid families contribute to cell membrane fluidity and skin health. Processing EFA in pet foods may affect their biologic activity (**Box 5-8**). **Table 5-19** summarizes the families, common names and biologic uses of several fatty acids found in nature.

Lipid Metabolism

GI Handling of Dietary Lipid

Lipids in foods include triglycerides, phospholipids, cholesterol, cholesteryl esters and fat-soluble vitamins. Long-chain NEFA make up a very small percentage of dietary lipids and will not be discussed here. Dogs and cats digest dietary lipids efficiently, with apparent lipid digestibility normally ranging between 80 and 95%. Increased levels of saturated and trans fatty acids reduce lipid digestibility (**Box 5-8**).

Fats and oils must undergo digestion via enzymatic and physical processes before they can be absorbed from the lumen of the gut. The following steps are involved in lipid digestion, absorption and initial metabolism (**Figure 5-19**) (Brody, 1994a):

- Gastric lipase in the stomach and duodenum degrades triglycerides of intact lipid micelles.
- Bile salts emulsify lipid micelles to form mixed micelles and coactivate pancreatic lipase.
- Pancreatic lipase and colipase hydrolyze triglycerides in mixed micelles.
- Gastric and pancreatic lipase activity results in 2-monoacylglyceride + two NEFA.
- NEFA and 2-monacylglyceride are absorbed into enterocytes.
- Triglycerides are reformed in enterocytes from long-chain NEFA and 2-monoacylglyceride.
- Apolipoproteins + triglycerides + cholesterol form chylomicrons in enterocytes and enter lymphatics.
- Chylomicrons in lymphatics enter the general circulation via the thoracic duct.
- Chylomicrons are partially metabolized and remnants attach to liver receptors.

Triglyceride-containing medium-chain fatty acids undergo similar processing until they enter the enterocyte at which point they are not re-esterified, but transported via albumin directly to the liver for metabolism (**Box-5-9**).

Short-chain fatty acids (particularly butyrate) resulting from fiber fermentation in the large intestine are an important source of fuel for colonocytes. Excess short-chain fatty acids enter the

portal circulation for metabolism by the liver.

Hepatic Handling of Dietary Lipid

The liver determines the fate of dietary lipid under the direction of hormonal signals related to energy balance. The primary fuel source for hepatocytes is provided via β-oxidation of NEFA whether dietary or endogenous in origin (**Figure 5-8**). The fate of dietary lipid from chylomicron origin can be traced as follows (**Figure 5-19**) (Brody, 1994b):

- Chylomicron remnants attach to receptors on liver cells.
- Triglycerides are hydrolyzed to glycerol and CoA esterified fatty acids.
- CoA esterified fatty acids may be either shunted to β-oxidation in mitochondria or repackaged into triglycerides and then VLDL for use by peripheral tissues (storage or fuel). Their fate depends on the energy status of the animal.
- Glycerol is converted to 3-P-glycerol (only in liver) and enters the carbohydrate metabolic pathway.

Although fat storage is easily accomplished by de novo synthesis (production of fat from carbohydrate or protein), it is more energy efficient for animals to deposit dietary fat than to synthesize it. When fat is deposited from foods, the fatty acid profile tends to reflect the type of fat consumed. When fat is synthesized, stored fat composition reflects the fat synthetic enzyme activity of the animal.

Lipoprotein Metabolism

Lipoproteins are relatively large conglomerates of protein and lipid that are necessary to transport hydrophobic lipids effectively through the aqueous medium of physiologic solutions. **Table 5-20** gives a generic relative composition of the different lipoprotein classes observed in mammals (Chapter 28). As the protein component increases, the relative density of the lipoprotein increases reflecting dilution of the buoyant density of fat. Lipoproteins are made only in the liver (VLDL, HDL) and enterocytes (chylomicrons). The protein fraction, before it is integrated with the lipid component, is termed apolipoprotein.

Lipoprotein metabolism is very complex with species variation. However, a general introduction is necessary to understand lipoprotein metabolic disorders discussed in later chap-

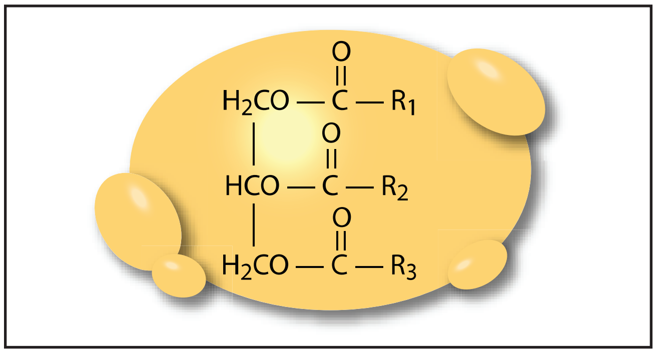

Figure 5-17. Triglycerides are the main storage forms of fatty acids, each molecule of which is composed of a three-carbon glycerol nucleus and three fatty acids (R_1, R_2, R_3).

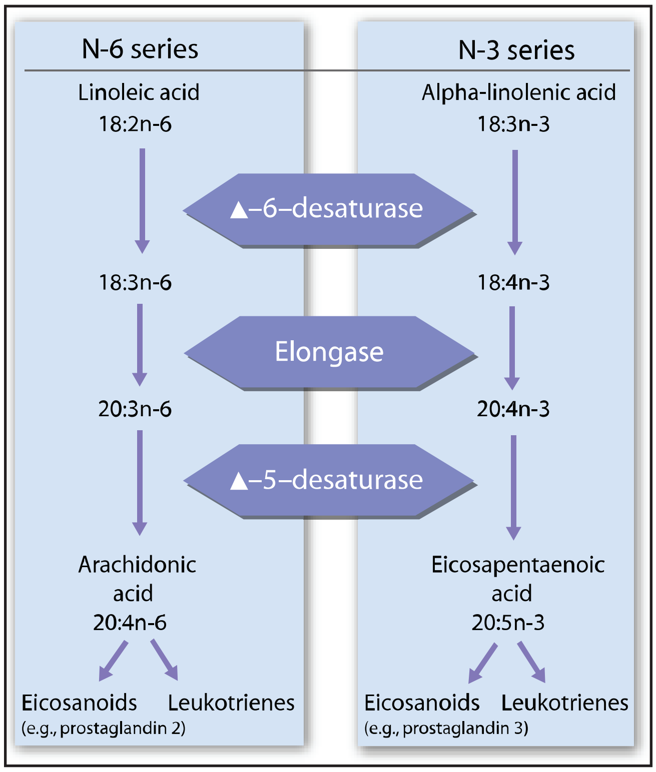

Figure 5-18. Diagram of metabolic pathways (elongation and desaturation) for essential fatty acids.

Table 5-19. Essentiality and biologic function of common fatty acids.

Structure	Common name	Essential	Biologic function
14:0	Myristic	No	Energy use and storage, acylation of proteins
16:0	Palmitic	No	Energy use and storage, acylation of proteins
16:1	Palmitoleic	No	Energy use and storage
18:0	Stearic	No	Energy use and storage, membrane fluidity
18:1n-9	Oleic	No	Energy use and storage, phospholipid structure
18:2n-6	Linoleic	Yes	Energy use and storage, arachidonic acid precursor (20:4n-6)
18:3n-3	Alpha-linolenic	Yes	Energy use and storage, eicosapentaenoic acid precursor (20:5n-3)
18:3n-6	Gamma-linolenic	Yes	Energy use and storage, arachidonic acid precursor
20:4n-6	Arachidonic	Yes (cat) No (dog)	Energy use and storage, synthesis of cytokines and eicosanoids, synthesis of steroid hormones, membrane fluidity, competitor of eicosapentaenoic acid (20:5n-3)
20:5n-3	Eicosapentaenoic	Probably	Energy use and storage, synthesis of cytokines and eicosanoids, retinal and nervous tissue development, membrane fluidity, competitor of arachidonic acid (20:4n-6)
22:6n-3	Docosahexaenoic	Probably	Energy use and storage, retinal and nervous tissue development, membrane fluidity, competitor of omega-6 fatty acids

Box 5-12. Hormone Sensitive Lipase.

Hormone sensitive lipase (HSL) catalyzes the reaction of triglycerides to nonesterified fatty acids (NEFA) and glycerol in adipocytes. Under the influence of insulin (following a meal), HSL is modified to a very low activity, which favors deposition of triglycerides in adipose tissue. Under the influence of glucagon (fasting) or epinephrine (flight or fight mechanism), HSL is highly active and the result is an efflux of NEFA and glycerol into the blood (bound to albumin) for transport to other tissues as an energy source. The NEFA that arrive back at the liver are catabolized or repackaged to triglycerides. In some pathologic conditions, triglycerides may accumulate in the liver (feline hepatic lipidosis) because the necessary repackaging materials for very low-density lipoprotein synthesis are not available in the liver.

Table 5-20. Composition of general lipoprotein classes in mammals.

Lipoprotein	Acronym	Protein:lipid (%)
Chylomicron	CM	1:99
Very low-density lipoprotein	VLDL	10:90
Low-density lipoprotein	LDL	25:75
High-density lipoprotein	HDL	50:50

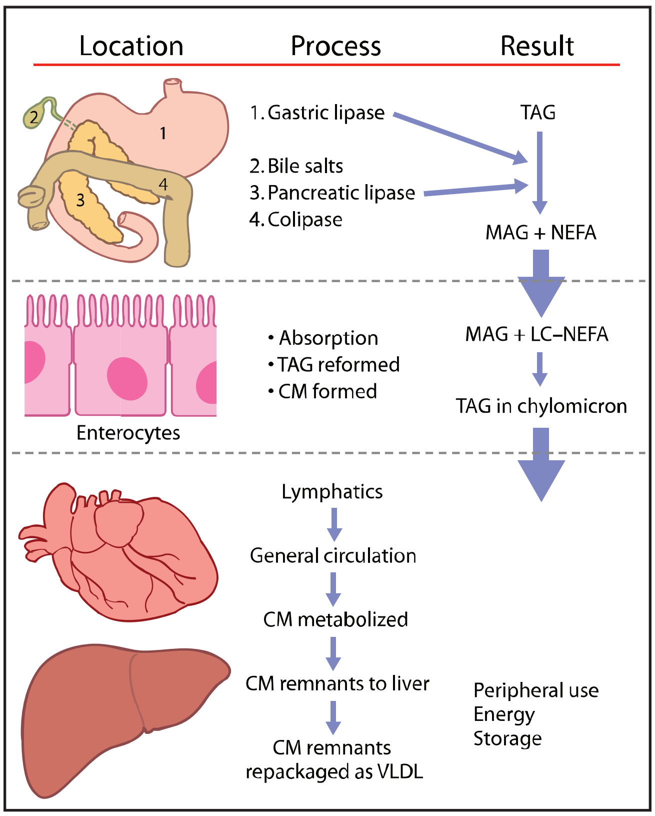

Figure 5-19. Digestion, absorption and fate of dietary triacylglycerides in mammals. See text for details. Key: TAG = triglyceride, MAG = monoacylglyceride, NEFA = nonesterified fatty acid, LC-NEFA = Long-chain NEFA, CM = chylomicron, VLDL = very low-density lipoprotein.

ters. An important point to remember is lipoprotein structure is not static and each class of lipoprotein has characteristics that may overlap with other classes. The following outline and **Figure 5-20** depict lipoprotein metabolism from the origin of lipoproteins in enterocytes or hepatocytes (Brody, 1994b):

- Chylomicrons are formed in enterocytes.
- HDL transfers apolipoprotein C-II and E (lipoprotein lipase cofactors) to chylomicrons and VLDL.
- Lipoprotein lipase in peripheral tissue hydrolyzes triglycerides in chylomicrons (**Box 5-10**).
- Chylomicron remnants bind to receptors in the liver.
- Liver hydrolyzes, reforms triglycerides and combines new apolipoproteins to form VLDL or HDL.
- VLDL triglycerides are hydrolyzed by lipoprotein lipase in the periphery to form VLDL remnants.
- VLDL remnants are taken up by the liver or converted to LDL for uptake by peripheral tissues.
- HDL made in the liver (major) and enterocytes (minor) transport excess cholesterol from the periphery to the liver for excretion in bile salts (**Box 5-11**).

Storage

Excess energy intake is stored in adipocytes as triglycerides. The triglycerides in adipocytes are formed directly from excess dietary fat or from de novo synthesis of fat in the liver under appropriate metabolic signals. The fat energy store in human adipocytes is capable of supporting life for one to two months. The key enzyme for release of energy from adipocytes is hormone sensitive lipase, which is under the control of hormonal signals (**Box 5-12**).

Lipid Function

Energy

Although providing dietary fat is an excellent way to meet an animal's energy requirement, this requirement can also be theoretically met by the protein and carbohydrate content of a food. On a per weight basis, the energy value of dietary fat is approximately 2.25 times that of protein or carbohydrate. Additionally, direct use of dietary fat for storage in adipocytes or use in functional lipid requires less energy for assimilation and storage when compared with de novo synthesis from protein or carbohydrate in food. In other words, fat stored directly from dietary fat has 10 to 15% more energy than fat made from excess dietary carbohydrate or protein because of the inherent loss of efficiency in de novo fat synthesis. This increased efficiency of fat use results in an increased energy value for dietary fat that animals may use to meet energy requirements or store as adipose tissue.

Essentiality

Fatty acids of the omega-6 family have functionally distinct effects compared with those of fatty acids of the omega-3 family. The addition of lipid-containing arachidonic acid to foods containing no arachidonic acid results in increased feed efficiency during growth and enhanced skin condition including reduced epidermal water loss. Arachidonic acid also allows processes requiring eicosanoids to occur such as reproduction

and platelet aggregation (MacDonald et al, 1984b, 1984c). Because dogs can convert linoleic acid (18:2n-6) to arachidonic acid (20:4n6), linoleic acid is usually listed as an EFA for dogs. A concentration of 1% of the food DM as linoleic acid is a safe and effective concentration for dogs (Wiese et al, 1962, 1965, 1966).

Because linoleic acid corrected many clinical signs of fatty acid deficiency in cats, it also is listed as an EFA for cats (McDonald et al, 1984a). Some of the signs of EFA deficiency in cats, however, were not ameliorated by linoleic acid but rather improvement depended on arachidonic acid supplementation. One group of investigators concluded that cats cannot convert linoleic acid to arachidonic acid in sufficient quantities for platelet aggregation and prevention of mild mineralization of the kidneys (McDonald et al, 1984b). Arachidonic acid supplementation allows normal reproduction in female cats (McDonald et al, 1984c). Male reproduction (spermatogenesis), unlike female reproduction, does not require dietary arachidonate because of the testes' ability to elongate and desaturate linoleate (McDonald et al, 1984c). These studies indicate that arachidonate is an EFA for cats. Foods for cats should contain at least 0.5% DM linoleic acid

Box 5-13. What's New in Fatty Acids: Resolvins, Protectins and Omega-3-Derived Mediators.

INTRODUCTION

Beneficial actions of polyunsaturated fatty acids were noted many years ago but the underlying mechanisms for these effects are poorly understood. It is clear that arachidonic acid is transformed into many potent bioactive compounds such as prostaglandins, leukotrienes and lipoxins. The departure of fatty acids from simply playing structural roles in cell membranes and/or as energy stores came largely from the recognition of the rapid transformation of arachidonic acid to these potent eicosanoids by both cyclooxygenase and lipoxygenase mechanisms. Many of the classic prostaglandins and leukotriene mediators are pro-inflammatory and play a decisive role in inflammation and/or in systems in which prostaglandins are key physiologic regulators. Inflammation is a vital reaction but it also plays a central role in many prevalent chronic diseases such as osteoarthritis, periodontal disease, inflammatory bowel disease, cancer, brain aging/dementia, allergic dermatitis and lower urinary tract disease.

In sharp contrast, it has become clear in recent years that counter-regulatory substances such as lipoxins are generated during resolution of acute inflammation, and that these serve as agonists for endogenous antiinflammatory mechanisms. This constitutes the first evidence that the resolution of inflammation, which was once thought to be a passive process, is actually an active process that involves up-regulating specific pro-resolution circuits. Thus, resolution of inflammation is an active endogenous process aimed at protecting the host from exacerbated inflammation.

THE OMEGA-3 FATTY ACID CONNECTION

The molecular mechanisms underlying the beneficial actions of polyunsaturated fatty acids remain an area of active research. Investigators have recently identified novel oxygenated products generated by enzymatic processes from the precursor omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). These new compounds possess potent actions in the resolution of inflammation and may also have neuroprotective properties. The term resolvin (resolution phase interaction products) has been proposed for some of these compounds because they display potent antiinflammatory and immunoregulatory properties, reducing neutrophil traffic and the magnitude of the inflammatory response. The term protectin (or neuroprotectin) has been proposed given the protective actions of some of these compounds in neural and retinal tissues.

Resolvins are derived from EPA (E series) and DHA (D series). Both the D and E classes of resolvins appear as biosynthetic products involving cell-to-cell interaction with vascular endothelial cells and are potent regulators of leukocyte infiltration. Specifically, resolvin E1 (RvE1) dramatically reduces dermal inflammation, peritonitis, colitis, periodontitis, dendritic cell migration and interleukin (IL)-12 production. Resolvins of the D series block tumor necrosis factor-alpha activity and act as potent regulators to limit leukocyte infiltration into inflamed brain, skin and peritoneum.

Among the essential fatty acids, DHA is concentrated in the central nervous system, neurons and retina where it is thought to regulate membrane fluidity and ion fluxes. The term docosanoids has been proposed to describe products generated from DHA. DHA-derived docosatrienes have neuroprotective action in retinal cells and can improve the sequelae associated with stroke and dementia. The terms protectin or neuroprotectin describe these compounds, which are rapidly generated from DHA and released locally into tissues. There is emerging evidence that resolvins and docosanoid compounds may also have immunoregulatory actions by influencing antigen-presenting cells and T-cell traffic.

CONCLUSION AND CLINICAL IMPLICATIONS

Fatty acid supplementation has been used for many years to help manage patients with a variety of inflammatory diseases. The underlying mechanisms for the beneficial effects of fatty acid supplementation have been poorly understood. Recent research has identified novel oxygenated compounds termed resolvins and protectins, which are generated from EPA and DHA. These endogenous lipid/chemical mediators are "switched-on" in the resolution phase of an inflammatory response, thus acting as "braking-signals" in inflammation and reducing leukocyte-mediated injury in several different tissues. The discovery of resolvins and protectins offers molecular mechanisms that could underlie some of the beneficial actions of dietary fatty acid supplementation observed in many clinical settings.

MINERALS

Introduction

Definition

The term "mineral" is generally used to denote all inorganic elements in a food. These inorganic elements constitute the majority of ash that remains after combustion of all organic matter. Ash analysis is of little value either for expressing mineral requirements or for indicating the useful mineral content of foods for two basic reasons: 1) body requirements are specific for certain inorganic elements (e.g., calcium, zinc, etc.) and 2) ash may not be a measure of total inorganic matter present, because some organic carbon may be bound as carbonate, and some inorganic elements (e.g., sulfur, selenium, iodine, fluorine and even sodium) may be lost during combustion.

The most important reason to determine total ash is to calculate the nitrogen-free extract by difference, as is required in the proximate analysis of foodstuffs. Specific minerals of interest can then be assayed (if not volatilized) from the ash component.

More than 18 mineral elements are believed to be essential for mammals (McDowell, 1992). By definition, macrominerals are required by the animal in the diet in percentage amounts, whereas microminerals or "trace" minerals are required at the mg/kg or parts per million (ppm). There are seven macrominerals: calcium, phosphorus, sodium, magnesium, potassium, chloride and sulfur. There are at least 11 trace elements or micronutrient minerals: iron, zinc, copper, iodine, selenium, manganese, cobalt, molybdenum, fluorine, boron and chromium. The last six are assumed to be essential for dogs and cats by analogy with other species. Calcium, phosphorus, magnesium, potassium, sodium and chloride are discussed below. Neither the Association of American Feed Control Officials (AAFCO) nor the National Research Council (NRC) lists a sulfur requirement for dogs or cats (AAFCO, 2007; NRC, 2006). Generally, there isn't a dietary need for sulfur per se, if a food is formulated to meet the sulfur-containing amino acid requirements of animals with simple stomachs.

Of the microminerals, only iron, zinc, copper, manganese, iodine and selenium will be discussed here. These trace minerals have been deemed essential for dogs and cats (although clinical cases of manganese deficiency have never been reported to occur in dogs or cats) (AAFCO, 2007). Cobalt and molybdenum are clearly important minerals in ruminant nutrition, but are not considered essential in monogastric species. Information about chromium and boron, two ultra-trace minerals, is included because of the potential importance these nutrients may have in companion animal nutrition. Other new trace elements discovered since 1970 include arsenic, lead, lithium, nickel, silicon, tin and vanadium. The essentiality of these minerals has not been elucidated in all species and under practical conditions may not be essential in the diet.

Function

Minerals are fundamental as: 1) structural components of body organs and tissues, such as calcium, phosphorus and magne-

Table 6-1. Mineral functions and effects of deficiencies and excesses.

Mineral	Function	Deficiency	Excess
Calcium	Constituent of bone and teeth, blood clotting, muscle function, nerve transmission, membrane permeability	Decreased growth, decreased appetite, decreased bone mineralization, lameness, spontaneous fractures, loose teeth, tetany, convulsions, rickets (osteomalacia in adults)	Decreased feed efficiency and feed intake, nephrosis, lameness, enlarged costochondral junctions. Increased calcium intake is a risk factor for calcium-containing urinary precipitates; however, moderate- to high-calcium levels may be protective against calcium oxalate precipitates. Calcium in meals may bind with oxalate in the gut decreasing the risk.
Phosphorus	Constituent of bone and teeth, muscle formation, fat, carbohydrate and protein metabolism, phospholipids and energy production, reproduction	Depraved appetite, pica, decreased feed efficiency, decreased growth, dull coat, decreased fertility, spontaneous fractures, rickets	Bone loss, uroliths, decreased weight gain, decreased feed intake, calcification of soft tissues, secondary hyperparathyroidism
Potassium	Muscle contraction, transmission of nerve impulses, acid-base balance, osmotic balance, enzyme cofactor (energy transfer)	Anorexia, decreased growth, lethargy, locomotive problems, hypokalemia, heart and kidney lesions, emaciation	Rare. Paresis, bradycardia
Sodium and chloride	Osmotic pressure, acid-base balance, transmission of nerve impulses, nutrient uptake, waste excretion, water metabolism	Inability to maintain water balance, decreased growth, anorexia, fatigue, exhaustion, hair loss	Occurs only if there is inadequate good-quality water available. Thirst, pruritus, constipation, seizures and death
Magnesium	Component of bone and intracellular fluids, neuromuscular transmission, active component of several enzymes, carbohydrate and lipid metabolism	Muscle weakness, hyperirritability, convulsions, anorexia, vomiting, decreased mineralization of bone, decreased body weight, calcification of aorta	Uroliths, flaccid paralysis
Iron	Enzyme constituent, activation of O_2 (oxidases and oxygenases), oxygen transport (hemoglobin, myoglobin)	Anemia, rough coat, listlessness, decreased growth	Anorexia, weight loss, decreased serum albumin concentrations, hepatic dysfunction, hemosiderosis
Zinc	Constituent or activator of 200 known enzymes (nucleic acid metabolism, protein synthesis, carbohydrate metabolism), skin and wound healing, immune response, fetal development, growth rate	Anorexia, decreased growth, alopecia, parakeratosis, impaired reproduction, vomiting, hair depigmentation, conjunctivitis	Relatively nontoxic. Reported cases of zinc toxicity from consumption of die-cast zinc nuts or pennies
Copper	Component of several enzymes (oxidases), catalyst in hemoglobin formation, cardiac function, cellular respiration, connective tissue development, pigmentation, bone formation, myelin formation, immune function	Anemia, decreased growth, hair depigmentation, bone lesions, neuromuscular disorders, reproductive failure	Hepatitis, increased liver enzyme activity
Manganese	Component and activator of enzymes (glycosyl transferases), lipid and carbohydrate metabolism, bone development (organic matrix), reproduction, cell membrane integrity (mitochondria)	Impaired reproduction, fatty liver, crooked legs, decreased growth	Relatively nontoxic
Selenium	Constituent of glutathione peroxidase and iodothyronine 5'-deiodinase, immune function, reproduction	Muscular dystrophy, reproductive failure, decreased feed intake, subcutaneous edema, renal mineralization	Vomiting, spasms, staggered gait, salivation, decreased appetite, dyspnea, oral malodor, nail loss
Iodine	Constituent of thyroxine and triiodothyronine	Goiter, fetal resorption, rough coat, enlarged thyroid glands, alopecia, apathy, myxedema, lethargy	Similar to those caused by deficiency. Decreased appetite, listlessness, rough coat, decreased immunity, decreased weight gain, goiter, fever
Boron	Regulates parathyroid hormone, influences metabolism of calcium, phosphorus, magnesium and cholecalciferol	Decreased growth, decreased hematocrit, hemoglobin and alkaline phosphatase values	Similar to those caused by deficiency
Chromium	Potentiates insulin action, therefore improves glucose tolerance	Impaired glucose tolerance, increased serum triglyceride and cholesterol concentrations	Trivalent form less toxic than hexavalent. Dermatitis, respiratory irritation, lung cancer

sium in bones and teeth, 2) constituents of body fluids and tissues such as electrolytes concerned with the maintenance of osmotic pressure, acid-base balance, muscle contraction, membrane permeability and tissue irritability (e.g., sodium, potassium, chloride, calcium and magnesium in blood, cerebrospinal fluid and gastric juice) and 3) catalysts/cofactors in enzyme and hormone systems, as integral and specific components of the structure of metalloenzymes, or as less specific activators within those systems. **Table 6-1** lists specific functions of each mineral.

Homeostasis

Specific concentrations and functional forms of minerals must be maintained within certain limits for optimal growth, health and fertility. Higher organisms possess homeostatic mechanisms that attempt to maintain concentrations of minerals at their active sites within narrow physiologic limits despite over- or under-ingestion. Such mechanisms include control of intestinal absorption or excretion, the availability of specific stores for individual elements and the use of "chemical sinks" such as metallothionein that can bind potentially toxic amounts of elements in an innocuous form (Underwood and Mertz, 1987).

The degree of homeostatic control varies from one element to another. Continued ingestion of diets or exposure to environments that are severely deficient, imbalanced or excessively high in a particular trace element, or in an interfering substance such as phytate or certain fibers, can induce changes in functioning forms, activities or concentrations of that element in body tissues and fluids so that they fall below or rise above the desired limits. Altered metabolism develops in these circumstances, which may affect physiologic function. Structural disorders may also arise in ways that differ with various elements, with the degree and duration of the dietary deficiency or toxicity and with the age, gender and species of the animal involved.

Deficiency/Adequacy/Toxicity

Traditionally, minerals were classified as "essential" or "toxic," but as more information was gathered, elements shifted from the latter to the former category (e.g., selenium). However, toxicity may occur with all elements. A "biologic dose-response curve" exists for each element (Underwood and Mertz, 1987). This curve (Figure 5-2) identifies a range of concentrations that spans three primary areas: 1) at low concentrations, physiologic function is consistently and reproducibly impaired (defined as deficiency), 2) at optimal concentrations, the nutrient is provided at levels necessary to meet the requirements of the animal and 3) at excessive concentrations, pharmaco-toxicologic effects occur. The intakes or dose levels at which these phases become evident and the width of the optimal plateau vary widely among minerals and can be markedly affected by the extent to which various other elements and compounds are present in the animal's body and in the food consumed (Box 6-1). Table 6-1 lists specific signs of mineral deficiencies and toxicities.

Several nutrients have specific therapeutic uses at high dosages (e.g., zinc is fed at growth-promoting levels in swine to prevent diarrhea). However, high doses may result in detrimental side effects after prolonged use. The pharmacologic actions of nutrients differ in several ways from their physiologic functions: 1) doses greatly exceeding the amount of a nutrient present in foods are usually needed to obtain a therapeutic response, 2) the specificity of the pharmacologic action is often different from the physiologic function and 3) chemical analogues of the nutrient that are often most effective pharmacologically may have little or no nutritional activity (RDA, 1989) (Box 5-7).

Claims of nutritional adequacy of pet foods are based on the current AAFCO nutrient allowances ("profiles"). These levels are neither minimal requirements nor necessarily optimal intake levels. It isn't possible to establish optimal levels without additional information about nutrient requirements for all lifestages and information concerning the availability of nutrients from pet food ingredients and complete diets. In some cases, insufficient margins of safety have been given to account for population variation, product diversity, processing effects and potentially low nutrient availabilities of certain pet food ingredients. In the case of trace minerals, the ratio between dietary allowance and absolute requirement can be as large as 100:1 (e.g., chromium) because of incomplete absorption, or can approach unity (e.g., iodine) when absorption is high (Underwood and Mertz, 1987). The nature of typical diets consumed strongly influences dietary allowances because numerous interactions among dietary components and different

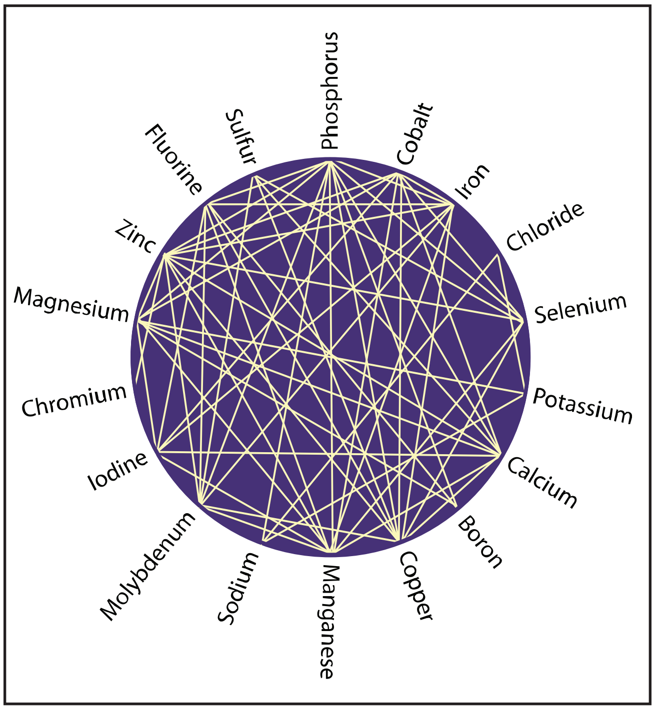

Figure 6-1. Mineral interrelationships. Minerals connected by a line clinically or experimentally interact with the other mineral. This interaction may be bidirectional (each mineral affects the use of the other) or unidirectional (one mineral affects the use of the second mineral but not vice versa). (Adapted from Puls R. Mineral Levels in Animal Health. Clearbrook, British Columbia: Diagnostic Data Sherpa International, 1990; 19.)

Box 6-1. Mineral Balance Studies.

The requirements for most nutrients are derived from experimental and clinical evidence of deficiency and the amount of nutrient needed to prevent signs of deficiency. When balance studies are used to estimate requirements, the requirement is defined as the intake at which zero balance is attained, or when intake is equal to excretion in urine and feces. However, the zero balance point will underestimate the requirement, if the measurement does not account for endogenous losses and losses in sweat.

Mineral balance studies have been criticized as inadequate and erroneous measures of body requirements. Small percentage errors in determining intakes and excretion can result in significant differences in balance calculations. One of the biggest problems in conducting balance studies is separating feces into time intervals that can be related to intake. Fecal markers aid in separation, but peristaltic reflux may still confound results. In addition, one animal's rate of passage can vary markedly. Adaptation to a different intake level may occur in a few days or weeks. Some adaptations, however, take several months or even years to occur. Thus, the adaptation period and collection period need to be sufficiently long to take into account animal adjustments to new foods, rates of passage and homeostatic adaptation.

Balance studies are probably more reliable when the mineral is excreted in the urine, rather than in the feces. This finding is true for sodium, potassium and selenium. When absorption of a nutrient is low, as is the case for a number of minerals, the amount of fecal mineral is large compared with the amount absorbed (e.g., the mineral concentration in feces is attributed to unabsorbed mineral and endogenous secretion). Failure to measure endogenous secretion may markedly underestimate the true amount of absorbed mineral. However, if radioisotopes or stable isotopes are used in conjunction with a balance study, the endogenous secretions can be distinguished from unabsorbed mineral and a measure of true absorption attained (as opposed to "apparent" absorption, which does not account for endogenous losses). Balance studies without the use of isotopes are fraught with inaccuracy and variability. Few analytical methods give a coefficient of variation as good as 5%, especially in complex matrices such as food, urine and feces. Thus, balance studies will not detect nutritionally important mineral differences when absorption efficiencies are low and radioisotopes or stable isotopes are not used.

Probably the biggest criticism of balance studies is that balance studies better reflect habitual intake than a requirement or zero balance. For example, an intake of 1 µg of selenium/kg body weight maintains a zero balance in Americans. Approximately one-tenth of that intake maintains a balance in people living in China; China is an area in which the risk of selenium deficiency is high and prevalence of Keshan disease is significant. Thus, zero balance does not necessarily indicate absence of disease. In New Zealand, selenium balance is maintained on an intake of one-third the amount required by Americans.

Analogous situations also exist worldwide for calcium balance. Widely different intakes of calcium result in zero balances in different countries. Thus, the previous dietary intake exerts a significant effect on the nutrient level that results in a zero balance and is more a reflection of the intake required to maintain an existing mineral pool size.

Balance studies should be evaluated with caution when attempting to determine requirements. A summary of their limitations follows:

- Prior long-term habitual intake influences whether positive, negative or equilibrium balance occurs at a particular intake.
- The duration of the study may not be long enough to allow for homeostatic adaptation.
- Cumulative errors occur from environmental contamination, individual variability and analytical methods. Thus, balance studies that demonstrate no treatment differences, may in fact be a result of the insensitivity and imprecision of the balance method.

The Bibliography for **Box 6-1** can be found at www.markmorris.org

chemical forms in individual foods determine biologic availability. Thus, it is important to understand the limitations of AAFCO nutrient profiles.

Mineral Interactions

A tremendous number of mineral-mineral interactions exist (**Figure 6-1**). In general, these interactions can be antagonistic (the presence of one mineral reduces the transport or biologic efficacy of the other) or synergistic (the two minerals act in a complementary fashion either by sparing or substituting for the other mineral or the two together enhance a biologic function). Most mineral interactions are antagonistic and can occur via a number of different mechanisms that include interactions (Solomons, 1988): 1) in the food during processing, before consumption, 2) in the digestive tract, where there is competition for uptake sites or intracellular-level mechanisms, 3) at the tissue level, either at storage sites or inhibition of enzyme activity, 4) at the time of transport and 5) in the excretory pathway.

The rigors of processing can affect the availability of minerals either positively or negatively via changes in solubility, pH, reduction potential and charge density and creation of complexes (Clydesdale, 1988). Charge density refers to the valence state and size of a metal. For example, the cations in the periodic table in groups 6B to 2B, with a relatively high ionic charge ($^+2$, $^+3$) and small size, form a large number of stable complex ions, whereas the large alkali metal cations, such as Na^+ and K^+, with a small charge are much less likely to form complexes with proteins or carbohydrate moieties via ionic, coordinate or covalent bonds. Furthermore, among the transition metals, which may form more than one cation, complexes formed by the $^+3$ valence state (e.g., Cr^{+3}, Co^{+3}) are more numerous and more stable than complexes formed by their respective $^+2$ ions. Charge is also involved with cell permeability and ion solubility before ions enter cells. Solubility varies tremendously depending on ion size and degree of polarity or charge.

Solubility is of obvious importance; a mineral must come in contact with the intestinal mucosa if it is to be absorbed. Charge density is less obvious but important for its effect on complex formation and membrane permeability. Solubility as it refers to mineral availability includes the solubility of an ion, salt, hydrate or complex, and to the type and strength of chemical bonds within these molecules. Inhibition of mineral absorption by a food can be overcome by the use of mineral enhancers, such as ascorbate, meat, citric acid and other ligands (e.g., ascorbate enhances iron absorption but negatively affects copper uptake; both effects are brought about by a change in pH and reduction in valence state).

Mineral-mineral interactions that occur in the digestive tract result from chemically similar minerals sharing "channels" for absorption. In this situation, simultaneous ingestion of two or more such minerals will result in competition for absorption (Solomons, 1988). In other words, when the dietary supply of a nutrient and/or the body reserves of a mineral are low, the intestine adapts to improve the efficiency of uptake and transfer. When the adaptation is nonspecific, other similar minerals have enhanced absorption. In iron deficiency, an up-regulation of iron also increases uptake of lead (Solomons, 1988). Other examples of interactions occurring in the digestive tract include the formation of insoluble mineral complexes (e.g., foods containing phytate and excessive calcium will form an insoluble calcium/phytate/zinc complex that reduces zinc availability).

Mineral-mineral interactions can also occur at the tissue storage level. High levels of dietary iron, for example, reduce hepatic copper stores. In studies, when ratios of iron to copper exceeded 20:1, hepatic copper levels were reduced to less than 50% of control values (Solomons, 1988). Likewise, trace minerals such as zinc can be mobilized when calcium is deficient because co-mobilization of both minerals takes place from the skeleton, making both available for use.

Mineral-mineral interactions can also occur at the time of transport. Transferrin is a serum transport protein for iron. Transferrin is generally less than 50% saturated with iron in its transit from site to site (Solomons, 1988). Transferrin can also transport chromium and manganese; therefore, these minerals may compete for binding sites contained in transferrin.

Finally, mineral-mineral interactions can also occur within pathways of excretion. For example, levels of circulating ionized calcium govern the release of parathyroid hormone (PTH) from the parathyroid gland. PTH status, in turn, influences renal tubular handling of filtered phosphate. Evidence also points to an interaction between calcium and magnesium at the level of renal excretion (Solomons, 1988).

Availability

Evaluation of feeds as sources of minerals depends not only on what the feed contains (i.e., the analyzed nutrient content), but also on how much of the mineral can be used by the animal. The adequacy of a food, as determined by its analytical mineral concentration, can be misleading because a number of factors can influence mineral availability. These include: 1) the chemical form (which influences solubility), 2) the amounts and proportions of other dietary components with which it interacts metabolically, 3) the age, gender and species of the animal, 4) intake of the mineral and the need (body stores) and 5) environmental factors (Underwood and Mertz, 1987) (**Box 6-2**).

Few studies have been completed in dogs and cats to evaluate the availability of minerals in foodstuffs used in commercial pet foods. Thus, there are many unknowns about the availability of nutrients in pet foods and whether a given food is truly adequate for a given lifestage. The availability of different forms of a mineral can vary widely even among inorganic mineral supplements. In general, different forms of trace minerals (iron, zinc, manganese and copper) differ in availability as follows: sulfate and chloride forms >carbonates >oxides (Aoyagi and Baker, 1993; Wedekind and Baker, 1990; McDowell, 1992a; Henry et al, 1986). The oxides of iron and copper are poorly available and should not be used as mineral supplements in pet food (McDowell, 1992a; Morris and Rogers, 1994).

In general, meat-derived foodstuffs are considered a more available source of certain minerals than plant-derived foodstuffs. The organic forms of minerals found in meats are often more available or as available as those from inorganic mineral supplements, whereas the minerals in plants are often less available (Aoyagi et al, 1993; Hortin et al, 1993). This finding applies more for iron, zinc and copper than for selenium.

Although the mechanism has not been fully delineated, one theory has been suggested to explain why organic forms of minerals are better used than inorganic forms. This theory postulates that chelates or complexes provide the mineral in a protected form (Kratzer and Vohra, 1986), analogous to the iron contained in heme, wherein the iron is complexed to a protoporphyrin ring. Because the metal is complexed or bound, it is protected from being sequestered by other dietary components (e.g., phytate, fiber and sugars) and is less likely to compete with mineral excesses.

Regardless of whether the molecular species is plant- or animal-derived, the complex must be able to be absorbed by mucosal cells or be cleaved to release the mineral in a soluble form or have stability constants that allow the mineral to be transferred to mucosal or serosal acceptors for availability (Clydesdale, 1988). Other explanations for why animal products are generally more available forms of certain minerals than plants include the "meat-factor" effect, wherein meat provides an available form of the mineral and enhances the absorption of the mineral supplied by the rest of the food (Kapsokefalou and Miller, 1993; Turnlund et al, 1983). In addition, meats, unlike plants, do not contain anti-nutritional factors, such as phytate, oxalate, goitrogens and fiber, which reduce mineral availability.

Not all fiber sources, however, negatively affect mineral availability. Research in chicks (Wedekind et al, 1995, 1996) and puppies (Wedekind et al, 1996a) indicated marked differences about how fiber sources affect mineral availability (Table 5-7). In these studies, beet pulp consistently reduced the availability of minerals (zinc, calcium, phosphorus and iron); however, cellulose, corn bran and sunflower hulls had negligible effects. Pea fiber, peanut hulls and soy hulls inhibited availability of some

Box 6-2. Organic vs. Inorganic Minerals.

There is some debate about whether organic forms of trace minerals are more available than inorganic forms. The answer depends on the specific mineral, the dietary conditions and the physiologic state of the animal. Clearly, the organic forms of certain minerals (e.g., selenium, chromium, iron) are better used than inorganic forms. (See the selenium, chromium and iron sections of this chapter.) Which form is better used is less clear for other minerals (e.g., zinc, copper). For example, there are as many studies that have failed to show increased availability with zinc/copper organic forms as there are studies demonstrating improved availability.

A number of factors influence the outcome of availability studies, including: 1) the presence of non-nutritional factors (e.g., phytate, fiber, goitrogens), 2) nutrient interactions (e.g., excesses of other minerals) and 3) physiologic state (e.g., demand for certain minerals increases with reproduction and growth compared to that of maintenance, thus in these situations, the differences in availability are magnified between organic and inorganic sources).

Results of studies in puppies showed that as calcium levels increased from 1.0 to 1.5%, zinc usage (as measured by changes in plasma zinc concentrations) decreased, irrespective of whether the source was organic (zinc propionate) or inorganic (zinc oxide). Zinc from zinc propionate was approximately 1.8 to 2 times more available than from zinc oxide.

Other investigators likewise noted increased zinc retention (as measured by zinc deposition in hair and fecal zinc excretion) for adult dogs fed a zinc-amino acid chelate compared with the same dogs fed zinc polysaccharide or zinc oxide. Increasing calcium from 1.2 to 3.2% reduced zinc retention when dogs were fed zinc polysaccharide or zinc oxide, but not the zinc-amino acid chelate.

Similarly, researchers have demonstrated in livestock and fish that growth rate and calcium and phytate levels are factors that significantly affect zinc use. Thus, these factors determine whether the use of organic zinc sources is beneficial. Together, these data suggest little or no benefit to using organic zinc in foods low in phytate and calcium (e.g., low calcium is defined as calcium levels approximating NRC recommendations for respective species). However, as phytate and/or calcium levels increase, or demand for zinc increases (e.g., rapid growth rate), there is greater zinc use from organic zinc sources (parameters used to assess zinc availability included bone zinc, immune response and/or growth rate). Furthermore, the more rapidly the animal grows, the greater the benefit demonstrated for organic zinc (e.g., fish >chicks [broiler breeds >leghorn-type] >puppies >pigs). The efficacy decreased as the animal matured, suggesting organic zinc sources in foods may be less beneficial for adult animals.

In summary, organic forms of minerals may be beneficial when dietary or physiologic conditions limit mineral availability. These conditions include: 1) mineral antagonisms caused by phytate, fiber and imbalances/excesses of other minerals and 2) increased metabolic demand such as rapid growth rate, reproduction and immune challenge.

The Bibliography for **Box 6-2** can be found at www.markmorris.org.

but not all of the minerals evaluated. Additional mineral supplementation is warranted for foods known to have reduced mineral availability.

Macrominerals

Calcium

Calcium serves two important functions: 1) as a structural component in bones and teeth and 2) as an intracellular second messenger that enables cells to respond to stimuli such as hormones and neurotransmitters. Calcium's two major physiologic functions in bone are to serve as a structural material and as an ion reservoir. When calcium in bone acts as an ion reservoir, it is in equilibrium with serum ionized calcium and under tight homeostatic control.

The mechanism of calcium homeostasis in blood is complex and involves several organs. Blood concentrations of ionized (or free) calcium are the major initiator of calcium regulatory mechanisms in the body. Calcium in blood is in equilibrium between a free or ionized state (~50%), a protein-bound state (~40 to 45%) and a complexed or chelated state (~5 to 10%). The effects of changing ionized calcium concentration in blood are highlighted below (**Figure 6-2**) (Nap and Hazewinkel, 1994). Low concentrations of ionized calcium:

- Stimulate PTH secretion, which stimulates conversion of 25-hydroxycholecalciferol (25-OH-D_3) to the biologically more potent 1,25-dihydroxycholecalciferol (1,25-$(OH)_2$-D_3) in the kidneys
- 1,25-$(OH)_2$-D_3 stimulates calcium uptake in the gut via receptor-mediated mechanisms
- 1,25-$(OH)_2$-D_3, in conjunction with PTH, stimulates bone resorption
- PTH induces phosphaturia.

High or normal concentrations of ionized calcium:

- Stimulate calcitonin secretion, which does not stimulate 1,25-$(OH)_2$-D_3 production
- 24,25-dihydroxycholecalciferol (24,25-$(OH)_2$-D_3) is now produced in the kidneys, which is considered biologically less active
- No stimulation of gut absorption or bone resorption occurs
- Increased renal calcium excretion results
- Calcitonin decreases osteoclastic activity.

PTH, calcitonin and 1,25-$(OH)_2$-D_3 act together to maintain calcium homeostasis in the face of variable dietary intakes and changing calcium requirements during growth, pregnancy and lactation.

The amount of true calcium absorption may range from 25 to 90%, depending upon calcium status, calcium form or intake (Nap and Hazewinkel, 1994). This exchangeable pool consists of the small amount of calcium in blood, lymph and other body fluids, and accounts for 1% of the total body calcium. The remaining 99% is located in bones and teeth. There are three routes of calcium absorption in the intestine. One is an active, saturable, transcellular process that occurs primarily in the duodenum and proximal jejunum. The process is regulated by vitamin D and involves a vitamin D-dependent, calcium-binding protein (CaBP or cal-bindin).

Active calcium absorption is affected by the physiology of the host (i.e., calcium and vitamin D status, age, pregnancy and lactation).

The other pathways of calcium absorption are facilitated and passive absorption, which are important in the distal gastrointestinal (GI) tract. Passive absorption is a nonsaturable, paracellular route that is independent of vitamin D regulation. The amount of calcium absorbed in this way depends primarily on quantity and availability of calcium in the food. No matter where absorption takes place, vitamin D is the most important regulator of calcium absorption (Birge and Avioli, 1990). Renal handling of calcium is also modulated by PTH and calcitonin but not as much by vitamin D.

Deficiencies and excesses of calcium, as well as calcium-phosphorus imbalances, should be avoided in dogs and cats (**Box 6-3**). A food grossly deficient in calcium, but adequate in phosphorus can cause secondary hyperparathyroidism. An all-meat diet devoid of bones, for example, is a very poor source of calcium. Inadequate calcium intake produces hypocalcemia, which stimulates release of PTH, which in turn stimulates production of 1,25-$(OH)_2$-D_3, resulting in a higher fractional absorption of calcium and phosphate, and lower calcium but higher phosphate concentration in urine. PTH acts with vitamin D to promote bone resorption and turnover, which may lead to pathologic fractures. Hypocalcemia is a common problem in diseased states (chronic or acute renal failure, pancreatitis, eclampsia, etc.), and parenteral supplementation of calcium and/or calcitriol (1,25-$(OH)_2$-D_3) is sometimes warranted (Chew and Carothers, 1995). Calcium excess is probably more detrimental in rapidly growing animals than in adults, especially large- and giant-breed puppies (Chapter 33). **Table 6-1** describes signs of calcium deficiency and excess.

Research suggests that the dietary requirement of calcium for growing puppies (especially large breeds) is higher at 1.2% dry matter (DM) (Hazewinkel et al, 1991; Schoenmakers et al, 1999; Nap et al, 1993) than the previous recommendation of 0.59% (NRC, 1985). The NRC (2006) recommended allowance for adult dogs and growing puppies after weaning is 0.40 and 0.59% DM calcium (both based on foods containing 4,000 kcal/kg), and for large- and giant-breed puppies at risk for developmental orthopedic disease, the recommendation is 0.7 to 1.2% DM calcium (based on foods containing 3,800 kcal/kg) (Chapter 33).

A balance study was conducted to determine the calcium requirement of adult cats (Pastoor et al, 1994). Four levels of calcium ($CaCO_3$) ranging from 0.27 to 1.62% DM were evaluated. The minimum level evaluated (0.27% calcium) resulted in positive mineral balance with no adverse effect on serum phosphorus, calcium, magnesium and alkaline phosphatase concentrations. This level is less than half that of current AAFCO (2007) recommendations (i.e., 0.6% calcium). Likewise, two groups of investigators conducting studies in kittens demonstrated lower calcium and phosphorus requirements than those currently recommended by AAFCO for growth (i.e., requirements for calcium and phosphorus were 0.5 and 0.63% [Morris and Earle, 1996] and 0.36 and 0.28%, respectively [Pastoor, 1993]). These investigators concluded that the 1% DM calcium recommended by AAFCO (2007) for kittens is excessive and that the NRC recommendation (2006) of 0.8% DM calcium was a more defensible allowance for kittens fed typical moist foods. The current AAFCO (2007) canine and feline recommendations for calcium are 1.0% for growth/reproduction and 0.6% for adult maintenance (DM for both values). For dogs, this calcium requirement is based on an energy density of 3.5 kcal/g metabolizable energy (ME), whereas an energy density of 4.0 kcal/g ME is assumed for cats (AAFCO, 2007). Foods with increased energy densities should have a proportionally increased amount of calcium to account for decreased food consumption.

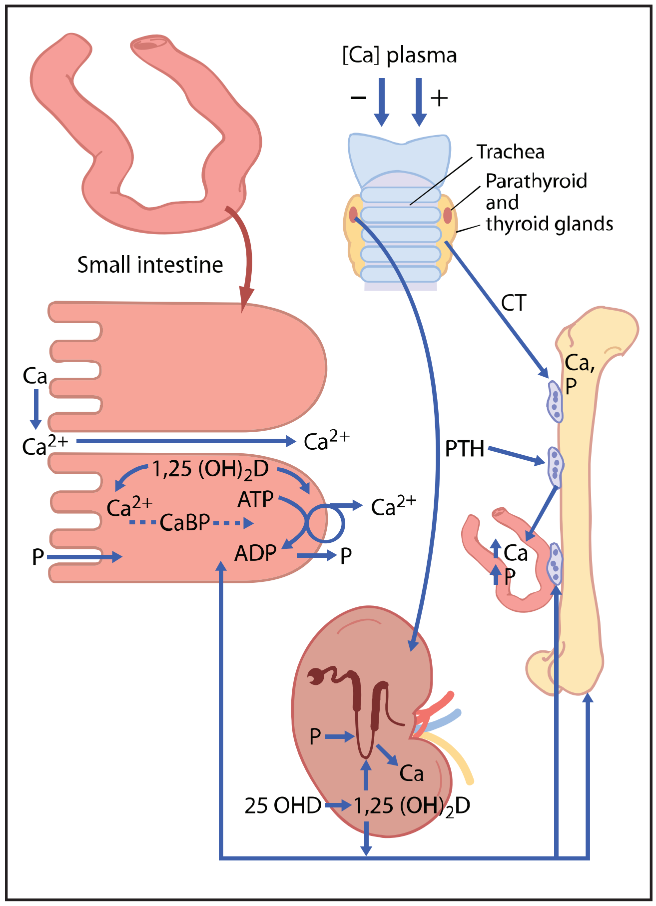

Figure 6-2. Calcium absorption by the intestine and bone resorption and reabsorption in the kidney are closely regulated by calcium-regulating hormones: parathyroid hormone, calcitonin and 1,25-$(OH)_2$-D_3. See text for details.

These meat meals are rich sources of calcium because of their bone content: poultry by-product meal, lamb meal and fish meal. Grains (corn, rice, etc.) are generally poor sources of calcium. Soybean meal and flaxseed have calcium contents between those of meat meals and grains. Meats without bone are poor sources of calcium. The most common calcium supplements used in pet foods are limestone (calcium carbonate), calcium sulfate, calcium chloride, calcium phosphate and bone meal, ranging in calcium from 16 to 39% (**Table 6-2**).

Box 6-3. Calcium-Phosphorus Ratios.

The "ideal" calcium-phosphorus ratio recommended for animals with simple stomachs is generally considered to be between 1:1 and 2:1. A number of factors, however, influence the importance of this ratio. Increasing levels of vitamin D reduce the significance of adverse calcium-phosphorus ratios. Furthermore, the ratio can differ markedly with the form and availability of the calcium and phosphorus supplied in the diet. For example, animals eating foods high in phytate phosphorus require greater phosphorus intake to meet their needs. Thus, the ideal calcium-phosphorus ratio would be lower when foods with these dietary characteristics are fed vs. foods composed of mostly meat ingredients.

Investigators sometimes debate whether the calcium-phosphorus ratio is more important than absolute calcium and phosphorus levels (**Table 1**). For all practical purposes, however, if a food were formulated to meet or slightly exceed an animal's requirement for calcium and phosphorus, it would by default provide an optimal calcium-phosphorus ratio. The more rapid the growth rate (e.g., large- and giant-breed puppies >small-breed puppies >adult dogs), the more critical it is to optimize calcium and phosphorus levels (Chapter 33). Increasing energy density increases the calcium and phosphorus requirement; the younger the animal the more critical it is that calcium and phosphorus be optimal.

Calcium-phosphorus ratios less than one have been evaluated in cats. Kealy et al compared the effects of feeding two foods with different calcium-phosphorus ratios to adult cats for 52 weeks. (The foods had 1:1 vs. 0.6:1 ratios; dry matter calcium and phosphorus levels were 1.27% calcium, 1.29% phosphorus and 0.75% calcium and 1.24% phosphorus, respectively.) Serum concentrations of total calcium, ionized calcium, phosphorus, PTH, alkaline phosphatase and vitamin D analogs did not differ between cats fed the two different foods at any sampling time and no signs of orthopedic diseases or bone loss developed during the study.

Likewise, Morris and Earle evaluated the effects of feeding foods containing calcium-phosphorus ratios as low as 0.65:1 to kittens and found no adverse effects, provided dry matter calcium and phosphorus levels exceeded 0.5 and 0.63%, respectively. Morris and Earle determined these calcium and phosphorus levels to be the calcium and phosphorus requirements for kittens. Results showed that this ratio (0.65:1) was well tolerated by kittens. Feed consumption, body weight gain, hematologic parameters and concentrations of plasma total and ionized calcium, total phosphorus, alkaline phosphatase, PTH, creatine phosphokinase, total plasma protein and albumin and plasma 25-OH-D did not differ from values in kittens fed foods with higher calcium-phosphorus ratios. Investigators noted significant changes in ionizable calcium concentrations; however, at 18 weeks in kittens fed foods with a calcium-phosphorus ratio of 0.38. These studies indicate that cats may tolerate wider dietary calcium-phosphorus ratios than the previously recommended ratios between 1:1 and 2:1.

The Bibliography for **Box 6-3** can be found at www.markmorris.org

Table 1. Examples of calcium-phosphorus percentages and ratios.

Examples	% calcium/% phosphorus (calcium-phosphorus ratio)
AAFCO adult allowance for calcium and phosphorus in dogs	0.6/0.5 (1.2:1)
AAFCO growth allowance for calcium and phosphorus in dogs	1.0/0.8 (1.25:1)
Example of why tuna is a poor source of calcium and has a poor calcium-phosphorus ratio	0.157/1.28 (0.12:1)
Example of a correct ratio, but excessive calcium and phosphorus levels	2/1.6 (1.2:1)

Phosphorus

Phosphorus is a vital participant in a number of tissues and functions. After calcium, phosphorus is the second largest constituent of bone and teeth. Phosphorus is a structural component of RNA and DNA, high-energy phosphate compounds such as ATP and cell membranes composed largely of phospholipids. As a component of nucleic acids, high-energy phosphate compounds and cell membranes, phosphorus is essential in cell growth and differentiation, energy use and transfer, fatty acid transport and amino acid and protein formation.

About 60 to 70% of phosphorus is absorbed from a typical diet (Allen and Wood, 1994). In general, phosphorus availability is greater from animal-based ingredients than from plant-based ingredients. Phosphorus in meat is found mainly in the organic form, whereas in plants, phosphorus is in the form of phytic acid. Phytate phosphorus is only about one-third available to monogastric animals but availability from different grains can vary markedly (McDowell, 1992). Intestinal phosphorus absorption represents the sum of a saturable, carrier-mediated component and a nonsaturable, concentration-dependent component. Regulation of total body phosphorus requires the coordinated efforts of the kidneys and intestine. Under conditions of low dietary phosphorus intake, the intestine increases its absorptive efficiency to maximize phosphorus absorption and the kidneys increase renal phosphorus transport or minimize urinary phosphorus losses. Hormonally, these adaptations result from changes in plasma levels of 1,25-$(OH)_2$-D_3 and PTH. Conversely, under conditions of dietary excess, the kidneys increase excretion of minerals. **Table 6-1** describes effects of deficiency and excess. Avoiding excess dietary phosphorus slows progression of kidney disease (Chapter 37).

There are few data to make a phosphorus recommendation; however, the most recent NRC (2006) suggests 1.0 and 0.30% DM for puppies and adult dogs, respectively.

Similar to the study design for calcium, investigators evaluated the minimum phosphorus requirement for adult cats (Pastoor et al, 1995). Four levels of phosphorus (provided as $NaH_2PO_4 \cdot 2H_2O$) ranging from 0.3 to 1.8% DM were evaluated. The minimum level evaluated (0.3% DM phosphorus) resulted in positive mineral balance with no adverse effect on serum phosphorus, calcium, magnesium and alkaline phos-

Table 6-2. Common mineral sources.*

Mineral	Source	Chemical formula	Mineral content (%)**			
Calcium	Calcium carbonate	$CaCo_4$	39 Ca	0.02 Na		
	Limestone	$CaCO_3$	38 Ca	0.05 Na	0.01 F	
	Calcium citrate		24 Ca			
	Calcium sulfate	$CaSO_4$	23 Ca			
	Calcium chloride	$CaCl_2$	35 Ca	64 Cl		
Calcium and phosphorus	Bone meal		24 Ca	12.6 P	0.37 Na	0.05 F
	Phosphate, curacao		36 Ca	14 P	0.3 Na	0.54 F
	Defluorinated		30-34 Ca	18 P	5.7 Na	0.16 F
	Dicalcium		18-24 Ca	18.5 P	0.6 Na	0.14 F
	Mono and dicalcium		16-19 Ca	21 P	0.6 Na	0.20 F
	Soft rock		17 Ca	9 P	0.1 Na	1.2 F
	Sodium tripolyphosphate		0 Ca	25 P	31 Na	0.03 F
Phosphorus	Phosphoric acid	H_3PO_4	0 Ca	23 P		
	Tricalcium phosphate	Ca_3PO_4	31-34 Ca	18 P		
Magnesium	Magnesium oxide	MgO	54 Mg			
	Magnesium sulfate	$MgSO_4$	9 Mg			
Potassium	Potassium citrate		36 K			
	Potassium chloride	KCl	50 K			
	Potassium sulfate	K_2SO_4	42 K			
Sodium and chloride	Sodium chloride	$NaCl$	39 Na	61 Cl		
	Sodium acetate		28 Na			
	Sodium tripolyphosphate		32 Na	25 P		
Iron	Ferrous sulfate	$FeSO_4 \bullet H_2O$	33 Fe			
	Ferrous sulfate	$FeSO_4 \bullet 7H_2O$	20 Fe			
	Ferric ammonium citrate		16.5-18.5 Fe			
	Ferrous fumarate	$FeC_4 \bullet H_2O_4$	32.9 Fe			
	Ferric chloride	$FeCl_3 \bullet 6H_2O$	20.7 Fe			
	Ferrous carbonate	$FeCO_3$	48.2 Fe			
	Ferric oxide	Fe_2O_3	69.9 Fe			
	Ferrous oxide	FeO	77.8 Fe			
Copper	Cupric carbonate	$CuCO_3 \bullet Cu(OH)_2$	57.5 Cu			
	Cupric chloride	$CuCl_2 \bullet 2H_2O$	37.3 Cu			
	Cupric hydroxide	$Cu(OH)_2$	65.1 Cu			
	Cupric oxide	CuO	79.9 Cu			
	Cupric sulfate	$CuSO_4 \bullet 5H_2O$	25.4 Cu			
Manganese	Manganese carbonate	$MnCO_3$	47.8 Mn			
	Manganous chloride	$MnCl_2 \bullet 4H_2O$	27.8 Mn			
	Manganous oxide	MnO	77.4 Mn			
	Manganese sulfate	$MnSO_4 \bullet 5H_2O$	22.7 Mn			
	Manganous sulfate	$MnSO_4 \bullet H_2O$	32.5 Mn			
Zinc	Zinc carbonate	$5ZnO \bullet 2CO_3 \bullet 4H_2O$	56.0 Zn			
	Zinc chloride	$ZnCl_2$	48.0 Zn			
	Zinc oxide	ZnO	72.0 Zn			
	Zinc sulfate	$ZnSO_4 \bullet 7H_2O$	22.7 Zn			
	Zinc sulfate	$ZnSO_4 \bullet H_2O$	36.4 Zn			
Iodine	Calcium iodate	$Ca(IO_3)_2$	65.1 I			
	Potassium iodide	KI	76.4 I			
	Cuprous iodide	CuI	66.6 I			
	Iodized salt		48.2 mg/kg I			
Selenium	Sodium selenite	Na_2SeO_3	45.6 Se	26.6 Na		
	Sodium selenate	Na_2SeO_4	41.8 Se	24.3 Na		

*Adapted from National Research Council. Nutrient Requirements of Cats. Washington, DC: National Academy of Sciences, 1986.
**Actual mineral levels in technical grade sources may vary.

phatase concentrations. Again, this is lower than the 0.5% DM phosphorus level currently recommended by AAFCO (2007). Levels of phosphorus exceeding 0.6% DM were associated with lower plasma phosphorus concentrations, reduced creatinine clearance and decreased magnesium absorption. Thus, the authors concluded continued feeding of high levels of dietary phosphorus might be detrimental to renal function. The AAFCO (2007) recommendation for phosphorus, for both dogs and cats, is 0.8% for growth and reproduction and 0.5% for adult maintenance (DM). These values (0.72 and 0.26% [DM] for kittens and adult cats, respectively) are higher than those listed in the current NRC (2006).

In general, meat tissue (poultry, lamb, fish, beef) is high in phosphorus. Eggs and milk products are also relatively rich in phosphorus. Oilseeds, protein supplements and grains likewise contribute significant amounts of phosphorus to pet foods, due more to their high inclusion rate than to high-phosphorus concentrations. A number of phosphorus supplements (**Table 6-2**) are used in pet foods, including calcium phosphate (monocalcium, dicalcium and tricalcium phosphate, defluorinated rock phosphate), sodium phosphates and phosphoric acid.

Magnesium

Magnesium is the third largest mineral constituent of bone, after calcium and phosphorus. Magnesium is involved in the metabolism of carbohydrates and lipids and acts as a catalyst for a wide array of enzymes. It is required for cellular oxidation (e.g., ATP production), it catalyzes most phosphate transfers (e.g., alkaline phosphatase, hexokinase and deoxyribonuclease) and it exerts a potent influence on neuromuscular activity. In light of these functions, it is not surprising that magnesium deficiency in animals is manifested clinically in a wide range of disorders, which include retarded growth, hyperirritability and tetany, peripheral vasodilatation, anorexia, muscle incoordination and convulsions. Other metabolic aberrations that may occur in magnesium-deficient animals include calcification of the kidneys and liver, decreased blood pressure and body temperature and decreased thiamin concentrations in tissues (Underwood and Mertz, 1987).

From 20 to 70% of dietary magnesium is absorbed (Brody, 1994). Intestinal magnesium absorption represents the sum of both a carrier-mediated system at low intraluminal concentrations, and simple diffusion at higher concentrations. A number of dietary and physiologic factors negatively influence magnesium absorption, including high levels of dietary phosphorus, calcium, potassium, fat and protein.

The kidneys play a critical role in magnesium homeostasis. Approximately 70% of serum magnesium is filtered by glomeruli; healthy kidneys reabsorb about 95% of the filtered magnesium (Shils, 1996). Several physiologic and metabolic factors, drugs and disease states influence magnesium reabsorption in nephrons. Certain drugs, such as diuretics, aminoglycosides, cisplatin, cyclosporin, amphotericin and methotrexate, can cause increased renal wasting of magnesium (Freeman, 1995).

Avoiding excess dietary magnesium is recommended for the prevention of struvite urinary precipitates in cats and dogs; however, magnesium deficiency is reported to increase the risk of calcium oxalate urolithiasis in rats (Driessens and Verbeeck, 1990). Furthermore, magnesium supplementation has been advocated to prevent calcium oxalate urolithiasis in people. However, this practice is very controversial because clinical trials have demonstrated mixed efficacy. The relationship of magnesium to feline and canine urinary calcium oxalate precipitates is unknown; however, ensuring magnesium concentrations above the minimum requirement is considered safe (Chapters 40, 43 and 46).

Conversely, increased magnesium supplementation may be warranted under certain clinical conditions in which magnesium stores are depleted. The GI tract and kidneys are the primary potential routes for magnesium excretion. Magnesium deficiencies may also result from renal losses secondary to renal tubular acidosis, hypercalcemia, hyperthyroidism, hypoparathyroidism and use of diuretics. Additionally, epidemiologic data and rat studies suggest that low urinary magnesium to calcium ratios may increase the risk for calcium oxalate formation (Driessens and Verbeeck, 1990). **Table 6-1** describes signs of deficiency and excess.

The minimum requirement for magnesium in adult cats has been evaluated (Pastoor, 1993). Four levels of magnesium ($MgCO_3$) were compared. Positive mineral balance was observed even at the lowest magnesium level (0.02% DM) and no adverse effects were noted in serum magnesium and alkaline phosphatase concentrations. This magnesium level is half of the current NRC (2006) and AAFCO recommendation (2007). Extrapolation of these results, which were obtained by feeding semi-purified diets, to commercial foods should be made cautiously because of the differences in ingredients used and the greater potential for mineral antagonisms and decreased availability that may occur in practical diets. AAFCO (2007) recommends 0.08% DM magnesium for growth and reproduction and 0.04% DM magnesium for adult maintenance for cats (AAFCO, 2007). The AAFCO (2007) magnesium recommendation for dogs is 0.04% DM for both lifestages, whereas the current NRC (2006) suggests 0.04% DM for puppies and 0.06% DM for adult dogs.

Ingredients containing bone (bone meal, lamb meal), oilseed/protein supplements (flaxseed, soybean meal and other legumes such as pea protein) and unrefined grains and fiber sources (wheat bran, oat bran, beet pulp, soymill run) are rich in magnesium. Common magnesium supplements include magnesium oxide and magnesium sulfate.

Potassium

Potassium is the most abundant intracellular cation and the third most abundant mineral in the body. Potassium is involved in a number of functions, including: 1) maintaining acid-base balance, 2) maintaining osmotic balance, 3) transmitting nerve impulses, 4) facilitating muscle contractility and 5) serving as a cofactor in several enzyme systems (energy transfer and use, protein synthesis and carbohydrate metabolism).

Potassium is absorbed primarily by simple diffusion from the upper small intestine, although some absorption also occurs in the lower small intestine and large intestine. Potassium availability is relatively high (95% or higher) for most foodstuffs (McDowell, 1992). Yet, in contrast to most minerals, potassium is not readily stored and must be supplied daily in the diet. Thus, it is important that foods for dogs and cats contain adequate potassium. Increased intake of potassium is unlikely to cause sustained hyperkalemia unless renal excretion of potassium is impaired. Administration of certain drugs predisposes patients to hyperkalemia (e.g., nonspecific β-adrenergic blockers and angiotensin-converting enzyme inhibitors).

Table 6-1 describes signs of deficiency and excess. Increasing protein, energy density or chloride, and other factors such as stress (heat, exercise, vomiting and diarrhea) and milk production increase the requirement for potassium. AAFCO (2007) recommends 0.6% DM potassium for both dogs and cats for all lifestages. These levels are higher than the current NRC (2006) DM potassium recommendation of 0.44% for puppies, 0.40% for adult dogs, 0.40% for kittens and 0.52% for adult cats.

Rich sources of potassium include soybean meal, unrefined grains and fiber sources (soymill run, sunflower hulls, rice bran, wheat bran) and yeast. Potassium supplements commonly

added to pet foods include potassium citrate, potassium chloride and potassium sulfate.

Sodium and Chloride

Sodium and chloride, in addition to potassium, are important for maintaining osmotic pressure, regulating acid-base equilibrium and transmitting nerve impulses and muscle contractions via Na-K-ATPase (sodium pump). In addition, sodium and chloride control the passage of nutrients into cells. Sodium ions must be present in the lumen of the small intestine for absorption of sugars and amino acids. Insufficient sodium concentrations decrease the use of digested protein and energy. Sodium also influences calcium absorption and mobilization and may affect absorption of several water-soluble vitamins (e.g., riboflavin, thiamin and ascorbic acid) that are sodium coupled (McDowell, 1992).

Sodium and chloride are readily absorbed, principally from the upper small intestine, and excreted predominantly in the urine with smaller amounts in feces and perspiration. Marked losses of salt can occur through perspiration in some species, secretion in milk, vomiting and diarrhea. When sodium intake is inadequate, the body has a remarkable capacity for conserving sodium by excreting extremely low levels in the urine. Chloride metabolism is controlled in relation to sodium. For example, excess urinary excretion of sodium is accompanied by urinary excretion of chloride.

Hormones acting to maintain a constant sodium-potassium ratio in extracellular fluid regulate sodium concentrations in the body. Aldosterone, secreted from the adrenal cortex, regulates reabsorption of sodium from the renal tubules. Antidiuretic hormone from the posterior pituitary responds to osmotic pressure changes in the extracellular fluid. Both hormones maintain a constant sodium-potassium ratio.

A number of factors influence the sodium requirement. The requirement is increased during reproduction, lactation, rapid growth and heat stress and with high dietary potassium levels. In people, the average sodium intake exceeds the recommended requirement by 15-fold (Stamler, 1995). Likewise, the sodium content of certain pet foods exceeds the recommended level by four- to 15-fold (Chapter 36). Investigators determined the sodium requirement of kittens to be 0.16% (DM or 0.30 mg Na/kcal ME) based on aldosterone concentration in plasma (Yu and Morris, 1997). The same investigators determined the requirement for adult cats was 0.08% DM sodium or 0.15 mg Na/kcal ME (Yu and Morris, 1999). The AAFCO (2007) recommendation for sodium in cats is 0.2% DM for both lifestages, whereas in dogs, the recommendation is 0.3% DM for growth and reproduction and 0.06% DM for adult maintenance. The current NRC (2006) sodium recommendation is 0.14% DM for kittens and 0.068% DM for adult cats. The NRC (2006) suggests a 0.22% minimum DM sodium requirement for puppies and 0.08% DM for adult dogs.

High sodium intake has long been reported to increase the risk of hypertension in people and animals (Stamler, 1995). Pet populations with increased risk of hypertension include senior dogs and cats and those with renal disease, cardiac disease, hyperthyroid disease or obesity. Pet food manufacturers sometimes use dietary salt supplementation to increase water intake in cats with lower urinary tract disease. High sodium intake in the short term effectively increases water intake, urine output and urine dilution, thus lowering the risk of urolithiasis, but may have detrimental effects in the long term. Kirk (2002) showed that high-sodium intake (1.1% DM) over a three-month period, increased serum urea nitrogen, phosphorus and creatinine concentrations in cats with preexisting renal disease. In addition, the high-sodium food increased cardiac left ventricular fractional shortening and lowered plasma aldosterone levels, evidence suggesting that this sodium chloride load required both the heart and kidney to work harder. Similarly, both the NRC Mineral Tolerance of Animals (2005) and the NRC Nutrient Requirements of Dogs and Cats (2006) recommend a safe upper limit for sodium at 1.5% DM for adult dogs, and 1.0 and 1.5% DM for kittens and adult cats, respectively. At higher levels of sodium intake (≥2%), studies showed reduced food intake, negative potassium balance and vomiting.

In the absence of studies establishing chloride requirements for dogs or cats, the DM recommendation for chloride is 1.5 times that of sodium. This value is comparable to the Na:Cl requirement ratio for other species. **Table 6-1** describes signs of deficiency and excess (**Case 6-1**).

The effect of dietary sodium chloride on blood pressure has generally been attributed to the sodium ion. However, it is clear from a number of studies that both sodium and chloride are necessary to inhibit renin production (Kotchen et al, 1978; Kurtz et al, 1987). Salts such as sodium chloride, potassium chloride, lysine hydrochloride (but not lysine glutamate, sodium bicarbonate, potassium bicarbonate) inhibited renin production in sodium chloride-deprived rats and people.

Fish, eggs, dried whey, poultry by-product meal and soy isolate are ingredients high in sodium and chloride. Sodium and/or chloride supplements typically added to pet foods include salt, sodium phosphates, calcium chloride, choline chloride, potassium chloride and sodium acetate.

Microminerals

Iron

Iron is present in several enzymes and other proteins responsible for oxygen activation (oxidases and oxygenases), for electron transport (cytochromes) and for oxygen transport (hemoglobin, myoglobin). Because of the limited capacity of the body to excrete iron, iron homeostasis is maintained primarily by adjusting iron absorption. Iron in foods exists in two forms: 1) heme iron present in hemoglobin and myoglobin and 2) nonheme iron present in grains and plant sources.

Heme iron absorption is not greatly affected by iron status or other dietary factors. (Two exceptions are meat, which enhances heme iron absorption, and calcium, which inhibits heme and nonheme iron absorption.) In contrast to absorption of heme iron, absorption of nonheme iron is markedly influenced by iron status and by several dietary factors such as phytate, tannins and excesses of calcium, phosphorus, manganese, zinc, copper and ascorbic acid (Hallberg and Rossander-

Hulthen, 1993).

The amount of iron absorbed from food is thus determined by three factors: 1) iron status of the body, 2) availability of dietary iron (as affected by other ingredients and nutrients) and 3) amounts of heme and nonheme iron in food (Hallberg and Rossander-Hulthen, 1993).

Iron is transported by plasma and is taken up by the bone marrow for hemoglobin synthesis. Although a small amount of hemoglobin circulates in plasma, by far the greatest amount of plasma iron is complexed to the specific iron-binding β_1-globulin transferrin. The degree of saturation of transferrin affects deposition of iron in liver stores and the supply of iron to red blood cell precursors. At saturation levels above 60%, much of the iron is deposited in the liver. Under normal conditions, only 30 to 40% of the transferrin is saturated; the remaining 60 to 70% represents an unbound or latent reserve (Morris, 1987).

Iron is stored predominantly as ferritin and hemosiderin in liver, bone marrow and spleen. Normally, iron is stored primarily as ferritin. As tissue iron concentrations increase, however, the concentration of hemosiderin increases more than that of ferritin. Excretion of iron is limited. Only negligible amounts of iron appear in urine; the iron appearing in feces is predominantly unabsorbed iron. Iron is continuously lost in sweat, hair and nails.

Investigators determined that the iron requirement of kittens and puppies fed a phytate-free purified diet is 80 mg iron/kg of food (DM) (Chausow and Czarnecki-Maulden, 1987). This requirement is the AAFCO (2007) recommendation for iron for dogs and cats, for both growth/reproduction and adult maintenance lifestages. The new NRC (2006) recommends a minimum of 88 mg/kg DM iron for growth and 30 mg/kg DM iron for adult dogs. Similar to AAFCO allowances (2007), the minimum NRC (2006) iron recommendation for cats is 80 mg/kg DM for growth and adult lifestages. Most pet foods are high in iron because of the high iron concentrations found in meat ingredients, especially organ meats. Furthermore, studies have shown the availability of iron to be relatively high from liver, muscle and animal by-products (Elvehjem et al, 1933; Conrad et al, 1980). Consequently, iron deficiency is not of practical concern with most pet foods.

Although iron levels may be high in pet foods (levels sometimes exceed the requirement by 15-fold without supplementation), AAFCO has set a maximum level of 3,000 mg iron/kg of food for dogs (no maximum is established for cats), which clearly exceeds dietary concentrations of iron in most typical pet foods. Iron excesses should be avoided because of potential antagonism with other minerals (e.g., zinc and copper). **Table 6-1** lists signs of deficiency and excess.

Chronic blood loss eventually depletes iron reserves and causes a microcytic, hypochromic anemia. The most common chronic blood loss in dogs and cats occurs with blood-sucking intestinal (hookworms) and external (fleas, ticks) parasites. Young puppies and kittens are especially vulnerable because of the low-iron content of milk.

Iron concentrations are high in most meat ingredients, especially organ meats such as liver, spleen and lungs. Other ingredients rich in iron include dicalcium phosphate and fiber sources such as beet pulp, soymill run and peanut hulls. In fact, poultry studies have shown that the iron contained in dicalcium phosphate alone in a corn-soybean meal diet can meet a chick's requirement for iron (Deming and Czarnecki-Maulden, 1989).

Typical iron sources include ferrous sulfate, ferric chloride, ferrous fumarate, ferrous carbonate and iron oxide. The iron in iron oxide, however, is not biologically available. Iron oxide is often added to pet foods to impart a "meaty red" color. A relatively high level of iron oxide is added (up to 0.04%) when iron oxide is used as a pigment in pet foods. Analytically, a pet food containing iron oxide will appear to be high in iron, but may not be high in available iron. Thus, the contribution of iron from iron oxide should be considered when evaluating the iron adequacy of foods containing iron oxide (e.g., 0.04% DM iron oxide in a moist food contributes 933 mg iron/kg of food).

Zinc

Zinc is a constituent or activator of more than 200 enzymes, so it is involved in a number of diverse physiologic functions. Some of zinc's primary functions include: 1) nucleic acid metabolism, 2) protein synthesis, 3) carbohydrate metabolism, 4) immunocompetence, 5) skin and wound healing, 6) cell replication and differentiation, 7) growth and 8) reproduction. Zinc also interacts with hormone production, most notably testosterone, adrenal corticosteroids and insulin. Zinc homeostasis is controlled through absorption and excretion.

The mechanism and control of zinc absorption are still not fully understood. Zinc absorption occurs primarily in the duodenum, jejunum and ileum. Only small amounts are absorbed from the stomach. Zinc absorption is markedly affected by other dietary components. Phytate, for example, decreases zinc absorption, whereas low molecular weight binding ligands such as citrate, picolinate, ethylenediaminetetraacetic acid (EDTA) and amino acids such as histidine and glutamate enhance zinc absorption (Hambidge et al, 1986). The liver is the primary organ involved in zinc metabolism. When hepatic zinc content is increased above normal levels, additional zinc is associated with metallothionein, a metal-binding protein thought to have a role in storage and detoxification of zinc, copper, cadmium and other metals.

Zinc in plasma is bound to protein in two forms: 1) firmly bound zinc that appears to bind to globulin (approximately 33% of total plasma zinc) and 2) loosely bound zinc complexed with albumin (66% of total plasma zinc) (McDowell, 1992). Storage of zinc is limited except in bone; stores increase only slightly as dietary zinc increases. Zinc concentration in bone has been used as a measure of zinc absorption and/or zinc status in young growing animals, whereas plasma zinc is only a reliable index under controlled experimental conditions.

Zinc is excreted primarily in the feces as unabsorbed and endogenous zinc (pancreatic juice, bile, other digestive secretions). Excretion of endogenous zinc in feces varies according to the balance between true absorption and metabolic needs. Variable excretion is one of the primary mechanisms used to

maintain zinc homeostasis. Thus, both absorption and excretion are important in regulating zinc balance.

Zinc deficiency is probably more of a practical concern with pet foods than is toxicity, because: 1) zinc is relatively nontoxic and 2) its availability is decreased by a number of factors (phytate, high dietary levels of calcium, phosphate, copper, iron, cadmium and chromium). The antagonistic effects of calcium are greatest when phytate is also present, resulting in the formation of a highly insoluble complex of calcium, phytate and zinc. Signs of zinc deficiency have been reported to occur in dogs fed cereal-based dry foods (e.g., grains may contain significant concentrations of phytate), even when the zinc content of the food exceeded NRC minimum requirements (NRC, 2006; Morris and Rogers, 1994).

AAFCO recommends 120 mg/kg DM zinc for dogs and 75 mg/kg DM zinc for cats (2007). For trace minerals, AAFCO makes the same recommendations for adult maintenance and growth/reproduction foods. In livestock, however, the requirement for zinc is greatly increased during growth and reproduction. NRC (2006) recommends a minimum of 100 mg/kg DM zinc for growth vs. 60 mg/kg DM zinc for adult dogs; NRC makes similar zinc recommendations for cats (i.e., 75 and 74 mg/kg DM zinc in foods for growth and adults, respectively).

Signs of zinc deficiency include anorexia, decreased growth rate, alopecia, parakeratosis, impaired reproduction, depressed immune function and growth disorders of the skeleton (Chapter 33). Naturally occurring zinc-responsive dermatoses have been described (Chapter 32).

Although relatively nontoxic, excess dietary zinc can interfere with other minerals (iron and copper), thus excesses should be avoided. The only reported cases of zinc toxicosis in dogs or cats have been due to dietary indiscretion (e.g., consumption of die-case nuts from animal carriers or pennies) (**Case 6-2**). **Table 6-1** describes effects of zinc deficiency and excess. Ingredients naturally high in zinc include most meats, fiber sources and dicalcium phosphate. Zinc supplements most commonly used in pet foods are zinc oxide, zinc sulfate, zinc chloride and zinc carbonate.

Copper

Of the many copper-containing proteins, four enzyme systems may play key roles in the clinical signs associated with copper deficiency: 1) the ferroxidase activity of ceruloplasmin explains in part the disturbances of hematopoiesis in copper deficiency, 2) the monoamine oxidase enzymes may account for the role of copper in pigmentation and control of neurotransmitters and neuropeptides, 3) lysyl oxidase is essential for maintaining the integrity of connective tissue, a function that explains disturbances in lungs, bones and the cardiovascular system and 4) the copper enzymes cytochrome C oxidase and superoxide dismutase (SOD) play a central role in the terminal steps of oxidative metabolism and the defense against superoxide radicals, respectively. These functions have been postulated to account for the disturbances of the nervous system as seen in neonatal ataxia in several animal species with copper deficiency (Davis and Mertz, 1987).

In most species, copper can be absorbed in all segments of the GI tract; however, the small intestine is the major site of absorption (Davis and Mertz, 1987). Although the biochemical mechanisms are not fully understood, there is good evidence that intestinal absorption of copper is regulated by the need of the animal and that metallothionein (a metal-binding protein) plays a key role in regulation. Copper appears to be absorbed by two mechanisms, one saturable, suggesting active transport at low dietary copper concentrations and the other unsaturable, suggesting simple diffusion at high dietary copper levels.

Most copper in plasma is bound to ceruloplasmin, a copper-binding protein. Newly absorbed copper, however, may be transported from the intestine loosely bound to albumin or certain amino acids. In this form, the element is readily available to the liver and other tissues, in contrast to the much more tightly regulated distribution of ceruloplasmin-bound copper. This difference in availability may explain the tissue damage caused by copper accumulation in hepatotoxicosis seen in Bedlington terriers and people with Wilson's disease, in which the ceruloplasmin transport protein is lacking.

The liver is the central organ for copper metabolism. Hepatic concentrations reflect an animal's intake and copper status. Copper is excreted primarily through the feces. Most fecal copper is unabsorbed, but active excretion also occurs via the bile. Copper homeostasis is maintained primarily through absorption.

Dietary copper deficiency has been reported to occur in dogs and cats and thus is of practical concern (Morris and Rogers, 1994) (**Case 6-3**) Availability of copper from different foods and supplements can vary greatly, so the requirement for copper is difficult to define. The requirement can vary several-fold depending on the source of copper in the food and the level of other ingredients/nutrients/non-nutrients (e.g., interactions with phytate, calcium, zinc and iron). The AAFCO (2007) recommendation for copper in dogs is 7.3 mg/kg DM.

Separate copper requirements are recommended for extruded cat foods (15 mg/kg DM) vs. moist cat foods (5 mg/kg DM) during growth/reproduction. The recommended AAFCO (2007) copper level for maintenance of adult cats is 5 mg/kg DM, regardless of the food form. The rationale for separate copper requirements for cats (extruded vs. canned) is unclear. Investigators demonstrated increased needs for copper during reproduction in queens fed extruded foods.[a] Separate requirements for extruded and canned foods were recommended in the absence of reproduction data for cats fed moist foods.

Researchers studied chicks to evaluate the availability of copper from feed ingredients typically used in pet foods (Aoyagi et al, 1993). Results showed that copper availability was essentially zero from copper oxide and pork liver. Beef, sheep and turkey liver, however, were highly available sources of copper. AAFCO (2007) has recommended that pet food companies discontinue the use of copper oxide as a copper source based on studies of swine, poultry, dogs and cats in which researchers have demonstrated the poor availability of copper from copper oxide (Aoyagi and Baker, 1993; Cromwell et al, 1989; Czarnecki-

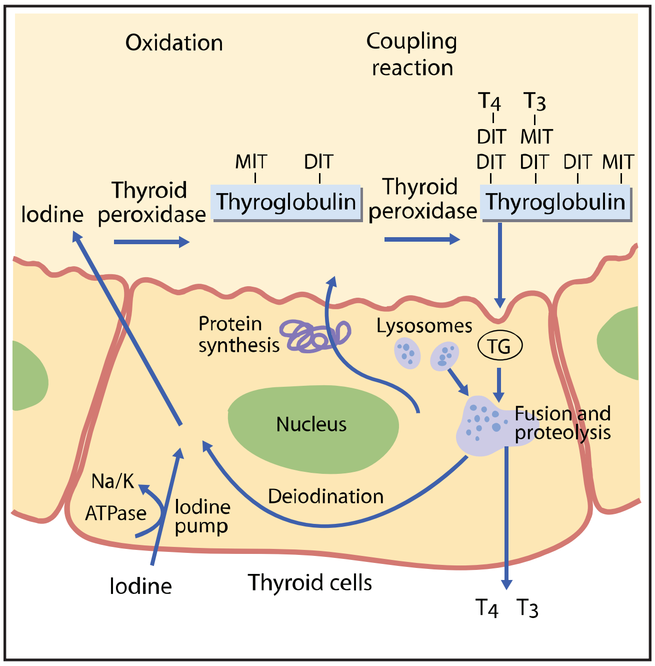

Figure 6-3. Diagram showing pathways of thyroid-hormone synthesis from iodine within the thyroid gland. (Adapted with permission from Hetzel BS, Maberly GF. Iodine. In: Mertz W, ed. Trace Elements in Human and Animal Nutrition, 5th ed. San Diego, CA: Academic Press Inc, 1986; 147.) See text for details.

Mauldin et al, 1993; Fascetti et al, 1998, 2000).

Signs of copper deficiency in cats include poor reproductive performance, early fetal loss, fetal deformities, cannibalism, coat hypopigmentation, kinked tails and inverted carpi.[a] Clinical signs in dogs include hair depigmentation and hyperextension of the distal forelimbs (Zentek and Meyer, 1991). **Table 6-1** lists signs of deficiency and excess.

Copper excess in dogs and cats with normal metabolism is of much less practical concern than copper deficiency, but can interfere with iron and zinc use. Bedlington, West Highland white and Skye terriers, however, are predisposed to hereditary autosomal recessive disease resulting in copper hepatoxicosis (Chapter 68). Anti-copper therapies such as zinc supplementation and orally administered tetrathiomolybdate have been used to treat dogs with this genetic disorder (NRC, 2006). AAFCO (2007) has set a safe upper limit of 250 mg/kg DM copper for dogs, but no safe upper limit for cats. NRC (2006) lists no safe upper limit of copper for either dogs or cats.

Most meat ingredients, especially organ meats, are rich in copper. Ruminant livers are extremely high in copper; concentrations are five to 10 times higher than in monogastric livers.[b] Typical copper supplements include cupric sulfate, cupric carbonate and cupric chloride.

Manganese

Manganese deficiency is of little practical relevance in dogs and cats, but is of practical relevance in birds. AAFCO (2007) recommends 5 mg/kg DM manganese for dogs and 7.5 mg/kg DM for cats, which is similar to NRC (2006) recommendations. The manganese requirement for birds is 10 to 12 times higher than that for people, pigs, dogs and cats (McDowell, 1992). Manganese functions as an enzyme activator or as a constituent of metalloenzymes. Although there are only a few manganese-containing metalloenzymes (e.g., arginase, pyruvate carboxylase and manganese-superoxide dismutase), many enzymes are activated by manganese, including hydrolases, kinases, decarboxylases and transferases. Other cations (especially magnesium), however, can partially substitute for manganese with little or no loss in enzymatic activity, thus manganese deficiency may not adversely affect physiologic or metabolic function (McDowell, 1992).

Manganese is also essential in bone and cartilage development because it activates glycosyltransferases (i.e., enzymes important for polysaccharide and glycoprotein synthesis). In addition, manganese is involved in reproduction and lipid metabolism (e.g., manganese is involved in the biosynthesis of choline and cholesterol).

Manganese homeostasis is maintained through regulation of absorption and excretion. Manganese is absorbed throughout the small intestine in a rapidly saturable process. Low molecular weight ligands, such as L-histidine and citrate, enhance absorption, whereas excessive concentrations of phosphorus, iron and cobalt can reduce absorption. Manganese is excreted via several routes that combine to provide an efficient homeostatic mechanism to regulate manganese levels in tissues. Bile flow is the primary route of excretion, but manganese is also excreted in pancreatic juice and in the small intestine.

Table 6-1 lists signs of manganese deficiency and excess. Ingredients rich in manganese include fiber sources, menhaden fish meal and dicalcium phosphate. Manganese supplements include manganese oxide, manganese sulfate, manganous chloride and manganese carbonate.

Iodine

Iodine is a constituent of the thyroid hormones 3,5,3',5'-tetraiodothyronine (thyroxine, T_4) and 3,5,3'-triiodothyronine (T_3). Thyroid hormones have an active role in thermoregulation, intermediary metabolism, reproduction, growth and development, circulation and muscle function. Thyroid hormones also: 1) influence physical and mental growth and differentiation and maturation of tissues, 2) affect other endocrine glands, especially the hypophysis and the gonads, 3) influence neuromuscular functioning and 4) have an effect on the integument, hair and fur (McDowell, 1992).

The thyroid glands actively trap iodine daily to ensure an adequate supply of thyroid hormone. This trapping mechanism regulates a more or less constant iodine supply to the thyroid glands over a wide range of plasma iodide levels. **Figure 6-3** outlines the steps of thyroid-hormone biosynthesis (Hetzel and Maberly, 1986). Iodine trapping is an active transport mechanism linked to Na^+/K^+-ATPase activity. Thyroid-stimulating hormone, which is released from the pituitary gland to regulate thyroid activity, also regulates this mechanism. A thyroid-peroxidase enzyme oxidizes iodide, which is released from thyroid

cells into the colloid space. Iodine then combines with tyrosine residues associated with thyroglobulin protein to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). The oxidation process proceeds further under the influence of the thyroid-peroxidase enzyme to couple MIT and DIT to form various iodothyronines (e.g., T_3 and T_4). Finally, iodinated thyroglobulin and thyroid hormones are reabsorbed into the thyroid cells and exposed to proteolytic enzymes. Much of the protein and iodinated tyrosines are lysed and returned as substrates to repeat the process. At the same time, some thyroid hormones are released into the circulation. Regulating the action of thyroid hormones is a complex process involving interaction among neurotransmitters, hormones and enzymes in the central nervous system, the pituitary gland, the thyroid glands, the circulation and peripheral tissues.

Investigators have estimated the iodine requirement for adult dogs to be 0.56 mg/kg DM (Belshaw et al, 1975). AAFCO (2007) recommends an iodine level of 1.5 mg/kg DM for dogs. This margin of safety is prudent in practical foods to overcome potential effects of goitrogens and negative mineral antagonisms.

A recent study (Wedekind et al, In press) estimated the iodine requirement for adult cats to be 0.46 mg/kg DM. This estimate was based upon three measurements of iodine status: regression of Tc 99m thyroid:salivary ratio (scintigraphy), iodine balance and urinary iodine excretion after iodine intake. These estimates agreed closely with the iodine requirement determined for dogs (Belshaw et al, 1975) and people (DRI, 2001). This estimate is higher than current AAFCO (2007) minimum iodine recommendations for adult cats (i.e., 0.35 mg/kg DM iodine), but is much lower than the NRC (2006) recommended iodine allowance (1.4 mg iodine/kg diet). Note that the NRC (2006) recommendation does not agree closely with current AAFCO recommendations and was based upon data derived from two studies (Scott et al, 1961; Ranz et al, 2002). Unfortunately, these studies should not have been used as a basis for establishing the iodine requirement of cats. The Scott (1961) study used a nutritionally incomplete or imbalanced diet (i.e., the diet used was an all meat diet [beef hearts], which was grossly deficient in calcium). The Ranz (2002) study was of short duration (i.e., 54 days total with only a seven-day period for each iodine level). In this study, the minimum iodine level evaluated, approximately 4.1 mg/kg iodine, was not low enough to yield a valid iodine requirement estimate. Interestingly, the previous NRC (1986) did not cite the Scott (1961) reference.

The iodine requirement is influenced by physiologic state and diet. Lactating animals require more dietary iodine because about 10% of the iodine intake is normally excreted in milk (McDowell, 1992). Likewise, the presence of goitrogenic substances and nutrient excesses of certain minerals (e.g., arsenic, bromide, fluoride, cobalt, manganese, calcium and potassium) may increase the need for iodine (NRC, 2005). Potential sources of goitrogens in pet foods include peas, peanuts, soybeans and flaxseed. Fish, eggs and iodized salt are rich sources of iodine, whereas most animal proteins are moderate sources of iodine. Iodine supplements typically used in pet foods include calcium iodate, potassium iodide and cuprous iodide.

Since the late 1970s, feline hyperthyroidism has become a more frequently diagnosed condition. However, much remains to be learned about this endocrinopathy (e.g., prevalence and cause). Hypothyroidism is a much more prevalent thyroid disorder in dogs. Both iodine excess and deficiency may result in subclinical or overt thyroid dysfunction.

Current AAFCO (2007) guidelines set a maximum safe level for iodine for dogs at 50 mg/kg, whereas NRC (2006) recommends 4 mg/kg as a safe upper limit. Neither NRC nor AAFCO sets a safe upper limit for iodine for cats. However, estimates for establishing safe upper limits and/or lowest observable adverse effect level for cats were determined in a recent study (Wedekind et al, In press). In people, guidelines have been established to define deficiency, adequacy and iodine excess (Laurberg et al, 2001) based upon urinary iodine concentrations. When these guidelines are applied to cats (corrected for metabolic equivalent basis; $BW^{0.67}$), dietary intakes between 0.46 and 3.5 mg/kg were considered optimal, whereas dietary intakes exceeding 3.5 mg/kg were defined as excessive. In addition, cats fed the highest dietary iodine intake (8.8 to 9.2 mg/kg iodine) for one year had significantly reduced FT_4 and numerically lowered TT_4 and TT_3 at 12 months. Thus, these findings suggest 3.5 mg/kg as a no observable adverse effect level or safe upper level and intakes of 8.8 mg/kg as a lowest observable adverse effect level. **Table 6-1** lists signs of iodine deficiency and excess. See Chapter 29 for more information about iodine.

Selenium

Selenium is an essential constituent of glutathione peroxidase, which helps protect cellular and subcellular membranes from oxidative damage. Glutathione peroxidase and vitamin E work synergistically to reduce the destructive effects of peroxidative reactions on living cells. Selenium spares vitamin E in at least three ways: 1) preserves the integrity of the pancreas, which allows normal fat digestion, and thus normal vitamin E absorption, 2) reduces the amount of vitamin E required to maintain integrity of lipid membranes via glutathione peroxidase and 3) aids retention of vitamin E in the blood plasma in some unknown way.

Vitamin E reduces the selenium requirement in at least two ways: 1) maintains body selenium in an active form, or prevents losses from the body and 2) prevents destruction of lipids within membranes, thereby inhibiting production of hydroperoxides and reducing the amount of the selenium-dependent enzyme needed to destroy peroxides formed in cells (Scott et al, 1982). Selenium also has a vital role in maintaining normal thyroid hormone and iodine metabolism, particularly through the control of deiodinase enzymes that regulate conversion of T_4 to T_3 (Arthur, 1993).

The duodenum is the main site of selenium absorption. There is no homeostatic control of selenium absorption regardless of the dietary selenium concentration. Likewise, selenium status also appears to have little effect on selenium uptake. Excretion of selenium, however, is homeostatically regulated. Urinary

excretion of selenium is closely related to dietary intake in rats and people (Levander, 1986). A dietary threshold is reached at low-selenium intakes, wherein excretion is shut down, thus conserving selenium. Urinary selenium increases proportionally at higher selenium intakes. Fecal excretion, on the other hand, remains constant over a wide range of selenium intakes.

Although selenium deficiency has been observed experimentally in dogs (Van Vleet, 1975), the incidence of selenium deficiency has not been reported for dogs and cats. Likewise, selenium toxicity has not been noted in dogs and cats, despite high concentrations (>4 mg selenium/kg food) in seafood and fish-containing cat foods. AAFCO (2007) selenium recommendations are 0.11 mg/kg of food DM for dogs and 0.1 mg/kg of food DM for cats. The NRC (2006) recommended allowance is 0.35 and 0.30 mg DM selenium/kg diet for dogs and cats, respectively (growth and adult recommendations were not different). This increase in minimum recommendations, relative to previous NRC publications, takes into account potentially low availability of selenium in pet food ingredients.

Selenium availability is highly influenced by the chemical form of selenium (supplied as a supplement or from foodstuffs). Furthermore, the requirement for selenium can be partially replaced by vitamin E. Selenium in animal feeds is highly variable primarily due to the variable selenium status of soils. Studies with pigs demonstrated that inorganic selenium (sodium selenite) and organic selenium (selenium yeast) were equally effective in supporting glutathione peroxidase activity, but that selenium stores in tissues (liver and muscle) were greater when organic selenium was fed (Mahan, 1995). Selenium content in milk is also higher when selenium is supplied in the organic form.

Fish products are rich in selenium (1 to 6 mg selenium/kg), but selenium availability in these ingredients is low (Wedekind et al, 1997; Wedekind et al, 1998; Combs and Combs, 1986). Selenium levels exceeding 2 mg selenium/kg of food DM have not been reported to be toxic for cats. Cats may be able to tolerate higher selenium levels because the high-protein foods typically fed to cats are protective against high-selenium levels (Levander, 1986).

Current AAFCO (2007) guidelines set a maximum safe selenium level for dogs at 2 mg/kg; however, NRC (2006) does not list a safe upper limit for cats. Neither NRC nor AAFCO has listed a safe upper limit for selenium for cats. Fish, eggs and liver are ingredients rich in selenium. **Table 6-1** lists signs of deficiency and excess (**Case 6-4**). Typical selenium supplements include sodium selenite and sodium selenite. See Chapter 29 for more information about selenium.

Ultra-Trace Minerals

The minimum dietary requirements for ultra-trace elements in dogs and cats have not been determined. Based on research in other species, it is probable that supplemental micronutrients, such as chromium and boron, may be beneficial under certain physiologic and dietary circumstances.

Chromium

In 1957, investigators identified a compound they called glucose tolerance factor (GTF) that restored impaired glucose tolerance in rats (Schwarz and Mertz, 1959). Chromium was identified as the active component. Chromium is ubiquitous in water, soil and living matter; however, tissue levels in animals are very low because of limited uptake by plants and absorption by animals. Furthermore, many forms of chromium are poorly available. Therefore, supplementation with an available form may be warranted. Chromium in an organically bound form (e.g., GTF) is absorbed better, has a different tissue distribution and is more available to fetuses than inorganic chromium (Mertz and Roginski, 1971).

Several studies in people and other animals have demonstrated beneficial effects of chromium supplementation (in chromium deficiency or diabetics) including: 1) improved glucose tolerance, 2) reversed hyperglycemia and glycosuria, 3) decreased circulating insulin concentrations, 4) decreased plasma lipid concentrations, 5) decreased body fat, 6) increased protein accretion, 7) improved immune response and 8) reduced cortisol production in response to heat and transport stress (Anderson, 1987; Page et al, 1993; Moonsie-Shageer and Mowat, 1993). Not all studies have shown improvements in these variables. This lack of consistent response may be accounted for by an adequate chromium nutriture for some individuals or some factor other than chromium deficiency that may have compromised the variable (impaired glucose tolerance, etc.). Few tests are available to specifically diagnose chromium status. The glucose tolerance test has been most commonly used to evaluate chromium deficiency. **Table 6-1** lists signs of deficiency and excess.

Boron

Boron indirectly influences PTH activity, thus it influences calcium, phosphorus, magnesium and cholecalciferol (vitamin D_3) metabolism. Investigators demonstrated that boron acts by at least three different mechanisms (Hunt et al, 1994): 1) it compensates for perturbations in energy substrate use induced by vitamin D deficiency, 2) it enhances macromineral content in normal bone and 3) it enhances some indices of growth and cartilage maturation, independent of vitamin D. Boron has a role in the control of urolithiasis. It decreases oxalate production in women fed magnesium-deficient diets (Hunt et al, 1994a). Boron also decreases calcium loss and bone demineralization in postmenopausal women (Nielsen et al, 1987). **Table 6-1** lists signs of deficiency and excess.

VITAMINS

Definition

The term "vitamine" was coined by Casmir Funk in 1912 when he described a class of nitrogen-containing compounds that were "vital-amines" (i.e., being vital to life). This term was later changed to vitamin when it was found that not all of these compounds contained nitrogen. The discovery, isolation and synthesis of vitamins have occurred in the last 100 years, although the effects of vitamin deficiency, specifically scurvy,

have been recorded since about 1150 B.C. (Combs, 1998).

A vitamin can be defined by its physical and physiologic characteristics. For a substance to be classified as a vitamin, it must have five basic characteristics: 1) it must be an organic compound different from fat, protein and carbohydrate, 2) it must be a component of the diet, 3) it must be essential in minute amounts for normal physiologic function, 4) its absence must cause a deficiency syndrome and 5) it must not be synthesized in quantities sufficient to support normal physiologic function.

These definitions are important to note because not all vitamins are essential for every species. For example, vitamin C is essential for primates, guinea pigs and some species of fish, but not for most other animal species. Lack of the enzyme L-gulonolactone oxidase prevents those species from synthesizing vitamin C from glucose, thereby, making vitamin C a required vitamin. Under certain conditions of disease or increased metabolism, however, vitamin C may be "conditionally essential" in those species that have de novo synthesis.

Two other terms warrant definition: vitamers and provitamins. A vitamer is chemically the same compound as a vitamin, but may exert varying physiologic effects because it is an isomer. Vitamin E is a good example of vitamers, because of its many forms. α-tocopherol is the most biologically active form, whereas γ-tocopherol has little biologic function, but acts as an in vitro antioxidant. A provitamin is a compound that requires an activation step before it becomes biologically active. β-carotene, for example, is cleaved by enzymatic processes to release two molecules of retinol (vitamin A).

The two main categories of vitamins are distinguished by their miscibility in either lipids (fat soluble) or water (water soluble). There are four fat-soluble vitamins (A, D, E and K) and nine generally recognized water-soluble vitamins (thiamin [B_1], riboflavin [B_2], niacin, pyridoxine [B_6], pantothenic acid, folic acid, cobalamin [B_{12}], biotin and vitamin C). Though not a true vitamin in the classic sense, choline is generally added to commercial dog and cat foods and treated as a vitamin in this chapter. The AAFCO dog food nutrient profiles list three fat-soluble and eight water-soluble vitamins including choline (vitamin K, biotin and vitamin C are not listed). The AAFCO cat food nutrient profiles list four fat-soluble and nine water-soluble vitamins including choline (vitamin C is not listed) (2007). There are also a number of compounds that are classified as "vitamin-like compounds" or "quasi-vitamins," which will also be discussed later in this section.

Function

Vitamins have incredibly diverse physiologic functions. Vitamins act as potentiators or cofactors in enzymatic reactions (**Figure 6-4**). They also play a significant role in DNA synthesis, energy release from nutrient substrates, bone development, calcium homeostasis, normal eye function, cell membrane integrity, blood clotting, free radical scavenging, amino acid and protein metabolism and nerve impulse transduction (**Table 6-3**).

Because of the differences between fat and water solubility and in chemical structure, vitamins are absorbed in the body through a variety of means. Fat-soluble vitamins require bile salts and fat to form micelles for absorption. They are then passively absorbed, usually in the duodenum and ileum, and transported in conjunction with chylomicrons to the liver via the lymphatic system. In contrast, most of the water-soluble vitamins are absorbed via active transport. Some vitamins (e.g., cobalamin) require a carrier protein called "intrinsic factor" whereas others need a sodium-dependent, carrier-mediated absorption pump.

Deficiency/Adequacy/Toxicity

Similar to other essential trace or micronutrients, differences in ingestion levels of vitamins create deficiency, adequacy or toxicity. The biologic dose-response curve (Figure 5-2) is appropriate for vitamins (Box 5-5). A deficiency is a lack of the vitamin in quantities required for normal physiologic function. In general, fat-soluble vitamins are stored in the lipid depots of all tissues, making them more resistant to deficiency, but also more likely to cause toxicity. Conversely, water-soluble vitamins are depleted at a faster rate because of limited storage; therefore, they are less likely to cause toxicity and more likely to be acutely deficient.

Within the range of adequate intake, requirements are met for each lifestage and tissue stores are maximized. Consuming more vitamins than is required to maximize stores can, in many cases, lead to clinical signs of toxicity if the ingestion period is prolonged and the body cannot excrete excesses. It is, therefore, prudent to provide vitamins in the appropriate balance for each lifestage to meet requirements and build tissue stores, but not to over-supplement in the pharmaco-toxicologic range.

Factors Affecting Requirements

Different lifestages of animals affect vitamin requirements. Growing and reproducing animals accrete tissues and therefore require higher levels of vitamins, minerals, protein and energy for optimal performance. Over-supplementation, however, is still contraindicated because these animals are also more susceptible to toxicity. As animals age, metabolic and physiologic changes may increase the requirement for some vitamins.

Various disease conditions also affect vitamin status. Prolonged anorexia deprives animals of vitamins and other nutrients and depletes vitamin stores. Polyuric diseases such as diabetes mellitus and kidney disease may increase excretion of water-soluble vitamins. Kidney disease can also lead to a secondary vitamin D deficiency by reducing the final hydroxylation step converting 25-OH-D_3 to 1,25-$(OH)_2$-D_3, which occurs in the proximal tubules of the kidneys.

In addition, certain drugs (e.g., antibiotics) may decrease the intestinal microflora responsible for vitamin K synthesis. Also, diuretic therapy may increase excretion of water-soluble vitamins. Some vitamin requirements depend on other nutrient levels. The amount of cobalamin required is related to the amount of folic acid, choline and methionine present because these nutrients interact metabolically and are dependent on each other. In addition, the amount of tryptophan influences

Table 6-3. Summary of names, functions and clinical syndromes associated with deficiency and toxicity of vitamins.

Vitamin	Function	Deficiency	Toxicity
Vitamin A	Component of visual proteins, (rhodopsin, iodopsin), differentiation of epithelial cells, spermatogenesis, immune function, bone resorption	Anorexia, retarded growth, poor coat, weakness, xerophthalmia, nyctalopia, increased CSF pressure, aspermatogenesis, fetal resorption	Cervical spondylosis (cats), tooth loss (cats), retarded growth, anorexia, erythema, long-bone fractures
Vitamin D	Calcium and phosphorus homeostasis, bone mineralization, bone resorption, insulin synthesis, immune function	Rickets, enlarged costochondral junctions, osteomalacia, osteoporosis	Hypercalcemia, calcinosis, anorexia, lameness
Vitamin E	Biologic antioxidant, membrane integrity through free radical scavenging	Sterility (males), steatitis, dermatosis, immunodeficiency, anorexia, myopathy	Minimally toxic. Fat-soluble vitamin antagonism, increased clotting time (reversed with vitamin K)
Vitamin K	Carboxylation of clotting proteins II (prothrombin), VII, IX, X and other proteins, cofactor of the bone protein osteocalcin	Prolonged clotting time, hypoprothrombinemia, hemorrhage	Minimally toxic. Anemia (dogs)
Thiamin (B_1)	Component of thiamin pyrophosphate (TPP), cofactor in decarboxylase enzyme reactions in the TCA cycle, nervous system	Anorexia, weight loss, ataxia, polyneuritis, ventriflexion (cats), paresis (dogs), cardiac hypertrophy (dogs), bradycardia	Decreased blood pressure, bradycardia, respiratory arrhythmia
Riboflavin (B_2)	Component of flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN) coenzymes, electron transport in oxidase and dehydrogenase enzymes	Retarded growth, ataxia, collapse syndrome (dogs), dermatitis, purulent ocular discharge, vomition, conjunctivitis, coma, corneal vascularization, bradycardia, fatty liver (cats)	Minimally toxic
Niacin	Component of nicotinamide-adenine dinucleotide (NAD) and adenine dinucleotide phosphate (NADP) coenzymes, hydrogen donor/ acceptor in energy-releasing dehydrogenase reactions	Anorexia, diarrhea, retarded growth, ulceration of soft palate and buccal mucosa, necrosis of the tongue (dogs), reddened ulcerated tongue (cats), cheilosis, uncontrolled drooling	Low toxicity. Bloody feces, convulsions
Pyridoxine (B_6)	Coenzyme in amino acid reactions (transaminases and decarboxylases), neurotransmitter synthesis, niacin synthesis from tryptophan, heme synthesis, taurine synthesis, carnitine synthesis	Anorexia, retarded growth, weight loss, microcytic hypochromic anemia, convulsions, renal tubular atrophy, calcium oxalate crystalluria	Low toxicity. Anorexia, ataxia (dogs)
Pantothenic acid	Precursor to coenzyme A (CoA), protein, fat and carbohydrate metabolism in the TCA cycle, cholesterol synthesis, triglyceride synthesis	Emaciation, fatty liver, depressed growth, decreased serum cholesterol and total lipids, tachycardia, coma, lowered antibody response	No toxicity established in dogs and cats
Folic acid (folate)	Methionine synthesis from homocysteine (vitamin B_{12} dependent), purine synthesis, DNA synthesis	Anorexia, weight loss, glossitis, leukopenia, hypochromic anemia, increased clotting time, elevated plasma iron, megaloblastic anemia (cats), sulfa drugs interfere with gut synthesis, cancer drugs (methotrexate) are antagonistic	Nontoxic
Biotin	Component of four carboxylase enzymes: pyruvate carboxylase, acetyl-CoA carboxylase, propionyl-CoA carboxylase and 3-methylcrotonyl CoA carboxylase	Hyperkeratosis, alopecia (cats), dry secretions around eyes, nose and mouth (cats), hypersalivation, anorexia, bloody diarrhea	No toxicity established in dogs and cats
Cobalamin (B_{12})	Coenzyme functions in propionate metabolism, aids tetrahydrofolate-containing enzymes in methionine synthesis, leucine synthesis/degradation	Cessation of growth (cats), methylmalonic aciduria, anemia	Altered reflexes (reduction in vascular conditioned reflexes and an exaggeration of unconditioned reflexes)
Vitamin C	Cofactor in hydroxylase enzyme reactions, synthesis of collagen proteins, synthesis of L-carnitine, enhances iron absorption, free radical scavenging, antioxidant/pro-oxidant functionality	Liver synthesis precludes dietary requirement, no signs of deficiency have been described in normal cats and dogs	No toxicity established in dogs and cats
Choline	Component of phosphatidylcholine found in membranes, neurotransmitter acetylcholine, methyl group donor	Fatty liver (puppies), increased blood prothrombin times, thymic atrophy, decreased growth rate, anorexia, perilobular infiltration of the liver (cats)	None described for cats and dogs
L-carnitine*	Transport long-chain fatty acids into the mitochondria for use in β-oxidation	Hyperlipidemia, cardiomyopathy, muscle asthenia	None described for cats and dogs

*L-carnitine is a vitamin-like substance.

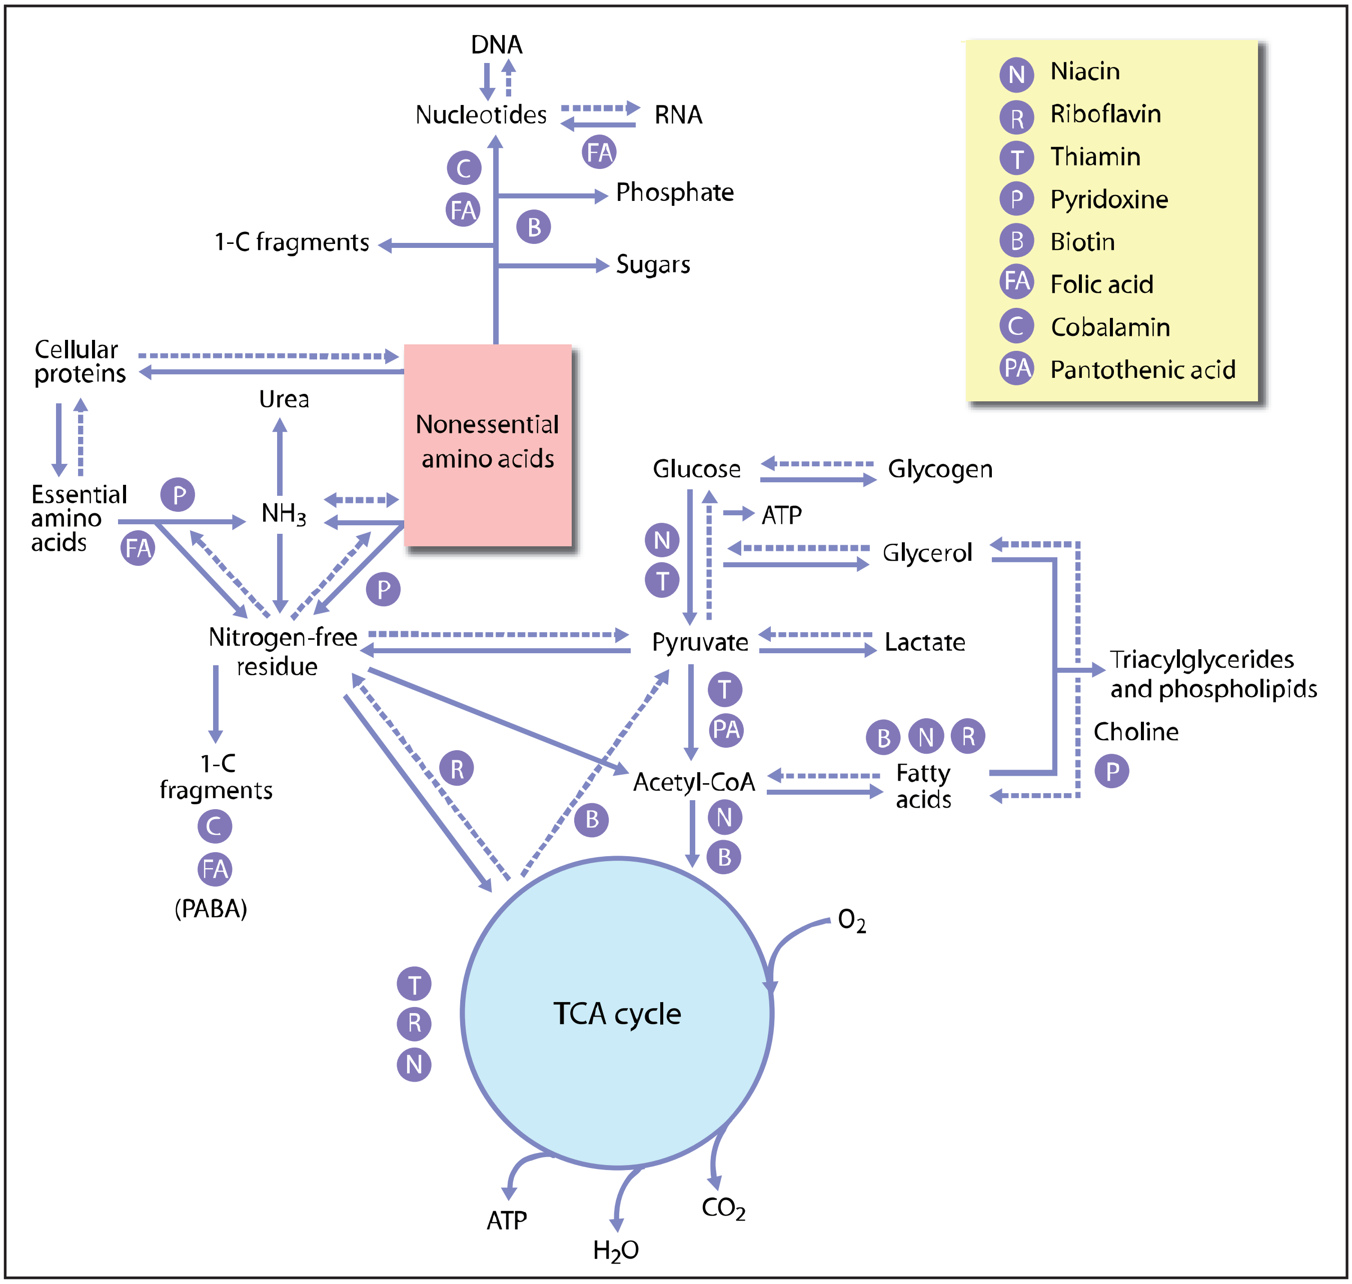

Figure 6-4. The role of B vitamins in intermediary metabolism.

niacin requirements because tryptophan is the precursor for that vitamin.

Finally, certain foods may contain antivitamin activity, for example, thiaminases in tissues of some fresh water fish may deactivate thiamin.

Feeding scientifically based formulas that specifically target the lifestage, nutrient interaction and disease condition will address changing vitamin requirements.

Vitamin Interactions

Much of the experimental work with vitamin deficiency disease has focused on the deficiency of a single vitamin. However, multiple deficiencies occur more frequently than a single-vitamin deficiency in patients. Pellagra is a classic example, in which deficiencies of niacin and tryptophan are usually accompanied by deficiencies of vitamin B_6 and riboflavin.

Many critical pathways require the concerted action of several B-complex vitamins (**Figure 6-4**). For example, one of the key reactions of metabolism is the conversion of pyruvate to acetyl-CoA. It is a key reaction because it occurs at the intersection of glycolysis and the TCA cycle. This pathway point is critical in the production of energy and the synthesis of fat and protein. Four different vitamins (niacin, thiamin, pantothenic acid and biotin) act as coenzymes in this one enzymatic conversion. Thus, a deficiency of any one of these four vitamins compromises the efficiency of the other three.

Table 6-4. Examples of vitamin-vitamin interactions.*

One vitamin needed for optimal absorption of another
Vitamin B_6 for vitamin B_{12}
Folate for thiamin
A high level of one vitamin may interfere with absorption or metabolism of another
Vitamin E interferes with vitamin K
Vitamin B_6 interferes with niacin
Thiamin interferes with riboflavin
One vitamin needed for metabolism of another
Riboflavin needed for vitamin B_6 and niacin
Vitamin B_6 needed for niacin
One vitamin protects against excess catabolism or urinary losses of another
Vitamin C spares vitamin B_6
One vitamin protects against oxidative destruction of another
Vitamin E spares vitamin A
Vitamin C spares vitamin E
A high level of one vitamin can obscure the diagnosis of deficiency of another
Folate deficiency obscures vitamin B_{12} deficiency

*Adapted from Machlin LJ, Langseth L. Vitamin-vitamin interactions. In: Bodwell LE, Erdman JW Jr, eds. Nutrient Interactions. New York, NY: Marcel Dekker Inc, 1988; 287-306.

The interactions between vitamins may involve the processes of absorption, metabolism, catabolism and excretion. Some vitamins may spare the requirements of others, whereas others may have potentially adverse effects. Even the marginal deficiency of one vitamin can exacerbate a deficiency or increase the requirement of another vitamin. Some examples of vitamin-vitamin interactions appear in **Table 6-4**.

Availability

Estimating the vitamin content of foods and foodstuffs and ultimately the adequacy of a given food is difficult at best because of cumulative errors made in estimating vitamin content and availability. These errors include: 1) analytical errors in sampling and determination of the vitamin, 2) variation in the actual amount of the vitamin (e.g., lot-to-lot variation, seasonal effects, demographics, different cultivars), 3) the presence of vitamins in bound forms in many foodstuffs and foods, 4) storage losses and 5) processing losses. All of these factors make it difficult to define what vitamin level is optimal for a given lifestage and food. To account for potential errors, references recommend that analytical values in databases be discounted by 10 to 25% (Combs, 1998).

Supplementation

Nearly all commercial pet foods contain added vitamins. Formulating a ration to meet vitamin requirements entirely from ingredient sources is extremely difficult and poses risks for the animal. The body uses synthetic and naturally formed vitamins in the same way, although they may have different availabilities. The effects of processing on vitamin stability and the availability in conjunction with disputed requirement levels in complex foods make fortification necessary (Chapter 8).

Commercial pet foods, therefore, are fortified to meet an animal's vitamin requirement for a given lifestage, overcome processing and storage losses and avoid toxicity. Because commercial pet foods are fortified with vitamins, it is usually unnecessary, and perhaps contraindicated, to concurrently give multipurpose vitamin-mineral supplements. Supplementation may be warranted in the management of diseases that affect vitamin metabolism, but should be monitored if long-term treatment is planned.

Fat-Soluble Vitamins

Vitamin A

Vitamin A is a general term describing a group of compounds with the biologic activity of retinol. Carotenoids are provitamin A. There are about 600 carotenoids known in nature, but only about 10% (e.g., α-carotene, β-carotene and β-cryptoxanthin) are provitamin A (Yeum and Russell, 2002). The international unit (IU) is still used by the pet food industry to measure the biologic activity of vitamin A. One IU of vitamin A activity can be provided by 0.3 µg of all-trans-retinol. In people, 12 µg β-carotene, 24 µg α-carotene or 24 µg β-cryptoxanthin is equal to one retinol activity equivalent (1 µg retinol) (DRI, 2001). Dogs, but not cats, can use provitamin A as a source of vitamin A. The retinol equivalent of β-carotene in dogs has not been defined. Most of the preformed vitamin A in food is in the form of retinyl esters, whereas the source of vitamin A from plants is in the form of provitamin A carotenoids.

FUNCTION

Vitamin A is essential for a number of distinct biologic functions. It is necessary for normal vision, growth, reproduction, immune function and maintenance of healthy epithelial tissue. Vitamin A is also involved in the expression and regulation of many genes (McClintick et al, 2005).

METABOLISM

Retinyl esters in food are hydrolyzed by hydrolases from the pancreas and the mucosal brush border to yield retinol. Retinyl esters and carotenoids are hydrophobic, thus their dispersion into the aqueous environment of the small intestinal lumen requires bile salts for micellar solubilization. This process allows access of hydrolytic enzymes to retinyl esters and exposes retinol to the mucosal surface, allowing free retinol and intact β-carotene to diffuse passively into mucosal epithelial cells. Absorption of vitamin A esters appears to be high (80 to 90%), but absorption may vary depending on the level and type of dietary fat and protein, which exert surfactant effects (Combs, 1998).

Dietary carotenoids are only absorbed half as well as preformed dietary vitamin A. As the amount of carotenoids in the food increases, however, the absorption efficiency decreases. Intestinal absorption of carotenoids is much more critically dependent on the presence of bile salts than is absorption of vitamin A. Cats can absorb β-carotene but are unable to convert it to retinol (Schweigert el al, 2002).

In the body, enzymes convert provitamin A carotenoids to retinols. β,β-carotene 15,15'-monooxygenase is a central cleav-

age enzyme that cleaves β,β-carotene into two molecules of retinol at the 15,15' double bond. The gene encoding for the enzyme has been cloned from several species including people, mice and chicks (Wyss, 2004). This central cleavage enzyme is found in the intestinal mucosa, liver, lungs, kidney, testes and brain. Recently, a second type of cleavage enzyme, β,β-carotene 9',10'-dioxygenase, was identified and cloned in mice (Kiefer et al, 2001). This enzyme exclusively catalyzes the asymmetric oxidative cleavage of β-carotene at the 9',10' double bond, resulting in the formation of β-apo-10'-carotenal and β-ionone.

Vitamin A is absorbed almost exclusively as the free alcohol retinol. Within mucosal cells, retinol is re-esterified mostly to palmitate and incorporated into the chylomicrons of the mucosa. Afterwards, it diffuses into lymph. A small amount of retinol may be oxidized first to retinal and then to retinoic acid, which may form a compound (glucuronide) that passes into the portal blood. Vitamin A is transported through the lymphatic system with low-density lipoprotein (LDL) to the liver, where it is deposited mainly in hepatocytes and stellate and parenchymal cells.

Some vitamin A derivatives are re-excreted into the intestinal lumen via the bile. This is true for much of retinoic acid and some retinol. The major vitamin A components of bile are vitamin A glucuronides, many of which are reabsorbed. Thus, enterohepatic circulation may provide an important means of conserving vitamin A. Although dogs and cats excrete vitamin A in urine, cats excrete a lesser amount.

When vitamin A is mobilized from the liver, stored vitamin A ester is hydrolyzed before it is released into the bloodstream. Vitamin A retinol is transported to tissues in the bloodstream by a specific transport protein called retinol-binding protein (RBP). RBP is synthesized and secreted by hepatic parenchymal cells.

In contrast to most other species, dogs and cats have a unique way of metabolizing vitamin A. Cats require preformed vitamin A because they lack the oxygenase enzyme necessary for β-carotene cleavage. In addition, studies have shown that cats and dogs do not depend on RBP to transport vitamin A in plasma (Schweigert, 1988; Wilson et al, 1987; Schweigert et al, 1990; Schweigert et al, 1990a). Cats and dogs transport vitamin A as retinyl esters (mostly retinyl stearate) bound to LDL and very low-density lipoprotein in amounts 10 to 50 times those of other mammals (Schweigert, 1988). This is of interest because free circulating retinyl esters are a sign of hypervitaminosis A in almost all other animal species, including people.

REQUIREMENTS

The AAFCO (2007) recommended allowance for vitamin A is 5,000 IU/kg DM for dogs for all lifestages (growth, reproduction and maintenance) and 9,000 IU/kg DM for cats for growth and reproduction and 5,000 IU/kg DM for maintenance. NRC (2006) recommends a vitamin A allowance of 1,515 RE (retinal equivalent) (5,050 IU)/kg DM for dogs for all lifestages, 1,000 RE (3,333 IU)/kg DM for cats for growth and maintenance and 2,000 RE (6,667 IU)/kg DM for cats during gestation and lactation. Unlike dogs, cats cannot meet their vitamin A requirement from carotenoids.

DEFICIENCY AND TOXICITY

The appreciable stores of vitamin A in the body are mobilized as needed to mitigate against the effects of low dietary intakes of the vitamin. The only unequivocal signs of vitamin A deficiency are the ocular lesions nyctalopia (night blindness) and xerophthalmia (extreme dryness of the conjunctiva). Other signs include anorexia, weight loss, ataxia, skin lesions, increased susceptibility to infection, retinal degeneration, poor coat, weakness, increased cerebrospinal fluid pressure, nephritis, skeletal defects (periosteal overgrowth and narrowing of foramina) and impaired reproduction (NRC, 2006).

Vitamin A toxicities have been encountered in numerous species. The most characteristic signs of hypervitaminosis A are skeletal malformation, spontaneous fractures and internal hemorrhage (**Case 6-5**). Other signs include anorexia, slow growth, weight loss, skin thickening, suppressed keratinization, increased blood clotting time, reduced erythrocyte count, enteritis, congenital abnormalities, conjunctivitis, fatty infiltration of the liver and reduced function of liver and kidneys. Queens fed a diet with 606,000 RE/kg food had an increased number of kittens born with defects such as cleft palate, cranioschisis, foreshortened mandible, stenotic colon, enlarged heart and agenesis of the spinal cord and small intestine (Freytag et al, 2003). Dogs seem less sensitive to excess dietary vitamin A than some other mammals (Cline et al, 1997).

The dietary maximum of vitamin A in the AAFCO (2007) dog and cat nutrient profiles is 250,000 IU/kg DM for dogs and 750,000 IU/kg DM for cats. NRC (2006) proposed a safe upper limit of 15,000 RE (50,000 IU)/kg DM for growing puppies and gestating and lactating bitches, and 64,000 RE (213,333 IU)/kg DM for adult dogs. The safe upper limit of vitamin A for cats is 80,000 RE (266,667 IU)/kg DM for growth and 100,000 RE (333,333 IU)/kg DM for maintenance, gestation and lactation.

SOURCES

Naturally rich sources of vitamin A include fish oil, liver, egg and dairy products. The most common vitamin A supplements used in pet foods include vitamin A esters (all trans retinyl palmitate, acetate or propionate) or vitamin A provided as fish oils. Because of stability issues, vitamin A sources are often coated, beaded, prilled or spray dried with antioxidants and emulsifying agents.

Concentrations of carotenoids in plants vary widely according to geographic location, maturity, method of harvest, amount and type of processing, length and conditions of storage and exposure to high temperature, sunlight and air. As a result, vitamin A is among the most variable nutrients in the diet. The vitamin A content in animal tissues can also be variable; concentrations can be very high in certain tissues such as liver. Levels of vitamin A in animal tissue vary depending on either the level of vitamin A or carotenoid present in the dog's or cat's diet.

Vitamin D

Two important forms of vitamin D are cholecalciferol (vitamin D_3), which occurs in animals and ergocalciferol (vitamin D_2), which occurs predominantly in plants. In pet food, vitamin D activity is typically expressed in IU. One IU of vitamin D can be provided by 0.025 µg of cholecalciferol or vitamin D_3. The skin of most mammals can produce cholecalciferol from the provitamin 7-dehydrocholesterol via activation with ultraviolet-B light. However, this photosynthesis pathway is inefficient in dogs (Hazewinkel et al, 1987) and cats (Morris, 1999) because of the higher activity of the enzyme 7-dehydrocholesterol- Δ^7 reductase that converts 7-dehydrocholesterol to cholesterol. Therefore, dogs and cats need dietary vitamin D.

FUNCTION

The primary function of vitamin D is to enhance intestinal absorption and mobilization, as well as retention and bone deposition of calcium and phosphorus. This function is manifested through its active form of 1,25-$(OH)_2$-D_3 as a hormone that binds to the nuclear 1,25-$(OH)_2$-D_3 receptor (VDR) in many types of cells. The active vitamin D_3 also has a direct effect on Ca^{2+} channels located on the plasma membrane (Norman et al, 1992).

METABOLISM

Vitamin D is absorbed from the small intestine by nonsaturable, passive diffusion, which depends on bile salts. Vitamin D then enters the lymphatic circulation primarily (~90%) in association with chylomicrons; the remainder of vitamin D is associated with an α-globulin fraction (Combs, 1998). Like other steroids, vitamin D is transported in association with proteins. In most species, the binding protein is vitamin D-binding protein (DBP) or "transcalciferin." The concentration of DBP greatly exceeds the concentration of vitamin D metabolites in blood. This concentration difference, in conjunction with the binding affinity, results in less than 5% of the available binding sites being occupied by vitamin D compounds. The distribution between bound and free vitamin D compounds greatly favors the bound form. In this fashion, DBP facilitates peripheral distribution of vitamin D from dietary origin and mobilizes endogenously produced vitamin D from the skin.

Vitamin D is distributed relatively evenly among the various tissues where it resides in lipid depots. Vitamin D can be found in adipose, kidneys, liver, lungs, aorta and heart. The primary circulating form of vitamin D is the parent vitamin D (~50%), with the next most abundant form (i.e., 25-OH-D_3 [also called calcidiol]) accounting for approximately 20% of the total (Combs, 1998).

In mammals, both vitamin D_2 and D_3 are not the active form of vitamin D. They are activated in the body by hydroxylation to 25-OH-D_3 first in the liver and again to 1,25-$(OH)_2$-D_3 (also called calcitriol) in the kidneys. Vitamin D_2 is less efficiently used than vitamin D_3 in cats (Morris, 2002). At normal plasma concentrations, only small amounts of 25-OH-D_3 are released from this pool to enter tissues. Thus, circulating levels of 1,25-$(OH)_2$-D_3 are a good indicator of vitamin D status.

Several factors tightly regulate the vitamin D endocrine system: 1,25-$(OH)_2$-D_3, PTH, calcitonin, several other hormones and circulating levels of calcium and phosphate. The vitamin D-dependent homeostatic system responds to perturbations in calcium concentration. For example, when serum calcium falls below a given level, PTH is secreted by the parathyroid glands, which function to detect hypocalcemia. The kidney responds to PTH, resulting in phosphate diuresis and stimulation of 25-OH-D_3 1-hydroxylase. The latter effect increases production of 1,25-$(OH)_2$-D_3, which acts to increase enteric absorption of calcium and phosphate. In addition, 1,25-$(OH)_2$-D_3 acts jointly with PTH in bone to promote mobilization of calcium and phosphate. The combined result of these responses is to increase plasma concentration of calcium and phosphate. Calcitonin is secreted by the thyroid gland ("C" cells) when circulating concentrations of calcium are increased. Calcitonin suppresses bone mobilization and may increase the renal excretion of calcium and phosphate. In that situation, 25-OH-D_3 1-hydroxylase may be inhibited by 1,25-$(OH)_2$-D_3, and may actually be converted to 24,25-$(OH)_2$-D_3, which may down-regulate the absorption of calcium in dogs (Tryfonidou et al, 2002).

These events tightly regulate hydroxylase activity and maintain nearly constant plasma concentrations of 1,25-$(OH)_2$-D_3, calcium and phosphorus. Once formed, 1,25-$(OH)_2$-D_3 binds to specific receptors on the enterocyte nucleus and initiates events that stimulate calcium and phosphorus absorption. In addition, 1,25-$(OH)_2$-D_3, acting with PTH, mediates resorption of bone with the release of calcium and phosphorus.

Many metabolites of vitamin D circulate in plasma other than 25-OH-D_3 and 1,25-$(OH)_2$-D_3. One metabolite, 24,25-$(OH)_2$-D_3, may also be biologically active, whereas other metabolites are generally considered physiologically inactive excretory forms (Combs, 1998).

REQUIREMENTS

The AAFCO (2007) dietary allowance for vitamin D is 500 IU/kg DM for dogs for all lifestages. For cats, the AAFCO (2007) allowance is 750 IU/kg DM for growth and reproduction and 500 IU/kg DM for maintenance. The vitamin D allowance recommended by NRC (2006) is 13.8 µg cholecalciferol (552 IU)/kg DM for dogs regardless of lifestage. The NRC recommended vitamin D allowance for cats is 5.6 µg cholecalciferol (250 IU)/kg DM for growth and 7 µg cholecalciferol (280 IU)/kg DM for maintenance and reproduction.

DEFICIENCY AND TOXICITY

Signs of vitamin D deficiency are frequently confounded by a simultaneous deficiency or imbalance of calcium and phosphorus. Clinical signs generally include rickets (young animals), enlarged costochondral junctions, osteomalacia (adult animals), osteoporosis (adult animals) and decreased serum calcium and inorganic phosphorus concentrations. Experimental vitamin D deficiency has been produced in cats, resulting in neurologic abnormalities associated with degeneration of the

cervical spinal cord (Morris, 1996). Other signs included hypocalcemia, elevated PTH concentrations, posterior paralysis, ataxia and eventual quadriparesis.

Excessive intake of vitamin D is associated with increases in 25-OH-D_3, with the D_3 form being more toxic than the D_2 form. When circulating at very high concentrations, 25-OH-D_3 can compete effectively with 1,25-$(OH)_2$-D_3 for receptors in the intestine and bone. Therefore, during vitamin D toxicosis, 25-OH-D_3 can induce actions usually attributed to 1,25-$(OH)_2$-D_3. Thus, 25-OH-D_3 is believed to be the critical factor in vitamin D intoxication (NRC, 1987). Excessive vitamin D_3 supplementation below the toxic level decreases bone remodeling and causes focal enlargement of the growth plate in growing puppies (Tryfonidou et al, 2003). Excessive vitamin D concentrations may result in hypercalcemia, soft-tissue calcification and ultimately death (Morita et al, 1995; Nakamura et al, 2004) (**Case 6-6**).

The vitamin D maximum in the AAFCO (2007) dog and cat nutrient profiles is 5,000 IU/kg DM for dogs and 10,000 IU/kg DM for cats. The NRC (2006) proposed a safe upper limit of 80 µg cholecalciferol (3,200 IU)/kg DM for dogs and 750 µg cholecalciferol (30,000 IU)/kg DM for cats regardless of lifestages.

SOURCES

Marine fish and fish oils are the richest natural sources of vitamin D in foodstuffs but they may pose a risk for toxicity. One group of investigators found that moist foods generally contained higher levels of vitamin D than extruded foods and that some moist foods exceeded the AAFCO maximal recommended allowance of 10,000 IU/kg for cats (Morris, 1996). Other sources of vitamin D include fresh water fish and eggs (especially yolks). Beef, liver and dairy products contain smaller amounts of vitamin D. The most common synthetic sources of vitamin D in pet foods include cholecalciferol (D-activated animal sterol), vitamin D_3 supplement, ergocalciferol (D-activated plant sterol) and vitamin D_2 supplement.

Vitamin E

Vitamin E is a term for a group of compounds with the biologic activity of α-tocopherol. In nature, there are eight isomeric forms of vitamin E, four tocopherols (α, β, γ, δ) and four tocotrienols (α, β, γ, δ). Naturally occurring α-tocopherol (*d*-α-tocopherol) is now designated as RRR-α-tocopherol based on RS or CIP system of chiral configuration. Synthetic α-tocopherol (*dl*-α-tocopherol), a mixture of eight stereoisomers of α-tocopherol, is designated as all-*rac* (racemic)-α-tocopherol. Vitamin E activity in pet food is generally expressed in international units. One IU of vitamin E equals 1 mg of all-*rac*-α-tocopheryl acetate or 0.91 mg of all-*rac*-α-tocopherol. The most biopotent form of vitamin E is α-tocopherol. The relative biopotencies of vitamin E isomers are as follows: α >β >δ >γ (McDowell, 1989). Also, tocopherols are generally more available than tocotrienols (Combs, 1998). Because some forms of vitamin E have little biologic activity, total vitamin E analysis is not a reliable means of determining vitamin E activity.

FUNCTION

Vitamin E functions as an antioxidant in the body and in food. Of the vitamin E isomers, α-tocopherol is the most active biologic form in the body, whereas the γ-isomer is the most active form in food. Mixed tocopherols, including γ-tocopherols, are widely used to prevent lipid oxidation in pet food products (Chapter 8).

Vitamin E works in conjunction with glutathione peroxidase to protect cells against the adverse effects of reactive oxygen and other free radicals that initiate the oxidation of polyunsaturated membrane phospholipids. Vitamin E in cellular and subcellular membranes is the first line of defense against peroxidation of vital phospholipids. However, some peroxides are formed even when adequate levels of vitamin E are present.

Selenium, as part of the enzyme glutathione peroxidase, is a second line of defense that destroys peroxides before they damage membranes. Therefore, selenium, vitamin E and sulfur-containing amino acids, through different biochemical mechanisms, are capable of preventing some of the same nutritional diseases (McDowell, 1992). Vitamin E prevents fatty acid hydroperoxide formation, sulfur-containing amino acids are precursors of glutathione peroxidase and selenium is a component of glutathione peroxidase. In addition, vitamin E is important for normal reproduction and is involved in modulating cellular signaling, regulating gene transcription, modulating immune function and inducing apoptosis (Brigelius-Flohe et al, 2002).

METABOLISM

Vitamin E is absorbed from the small intestine by nonsaturable, passive diffusion, which depends on micellar solubilization. Whether presented as free alcohol or as esters, most vitamin E is absorbed as the alcohol. Esters are largely hydrolyzed in the gut wall before absorption, probably by a duodenal mucosal esterase. The free alcohol enters the intestinal lacteals and is transported via lymph to the general circulation.

The efficiency of vitamin E absorption is low and variable (35 to 50%); the absorption efficiency is much lower than that of vitamin A (Combs, 1998). Absorption of vitamin E is enhanced by the simultaneous digestion and absorption of dietary lipids. Transfer of vitamin E across epithelial cells may require several stages, most of them poorly understood. In mammals, vitamin E is transported from the intestine to lymphatic capillaries in association with chylomicrons. Conversely, in birds, tocopherol is transported via the portal vein directly to the liver. Unlike cholesterol or vitamin A, α-tocopherol is not re-esterified during the absorption process.

Vitamin E circulates in the lymph and blood bound to all of the lipoproteins. There is a very high correlation between tocopherol levels and the total lipid or cholesterol concentration in serum.

All tissues show linear increases in tocopherol concentrations with increases in tocopherol intake. This relationship differs from that of most other vitamins, which usually have distinct deposition thresholds in tissues other than the liver, and may provide an explanation for the pharmacologic effects of vitamin

E. Vitamin E levels in tissues vary markedly with no consistent relationship to lipid parameters. The vitamin is most concentrated in membrane-rich cell fractions such as mitochondria and microsomes.

Vitamin E undergoes very little metabolism. Usually less than 1% of orally ingested vitamin E is excreted in urine (Combs, 1998). The major route of excretion is fecal elimination.

The need for vitamin E in the diet is markedly influenced by dietary composition. The requirement increases with increasing levels of polyunsaturated fatty acids (PUFA), oxidizing agents, vitamin A, carotenoids and trace minerals and decreases with increasing levels of fat-soluble antioxidants, sulfur-containing amino acids and selenium. Various researchers have recommended up to 60 mg of α-tocopherol per g of PUFA; however, there is no consensus among experts about the quantitation of this relationship (Combs, 1998).

REQUIREMENTS

The AAFCO (2007) recommended allowance for vitamin E is 50 IU/kg DM for dogs and 30 IU/kg DM for cats, irrespective of the lifestage. For cat foods containing fish oils, AAFCO recommends an additional 10 IU vitamin E/g of fish oil/kg of food above the allowance. The vitamin E allowance recommended by NRC (2006) is 30 mg α-tocopherol (33 IU)/kg DM for dogs for all lifestages. For cats, the vitamin E allowance is 38 mg α-tocopherol (42 IU)/kg DM for growth and maintenance and 31 mg α-tocopherol (34 IU)/kg DM for gestation and lactation.

DEFICIENCY AND TOXICITY

The clinical manifestations of vitamin E deficiency vary markedly between species. In general, however, the neuromuscular, vascular and reproductive systems are affected most commonly. Signs of vitamin E deficiency are mostly attributed to membrane dysfunction as a result of the oxidative degradation of polyunsaturated membrane phospholipids and disruption of other critical cellular processes. Clinical findings of vitamin E deficiency in dogs include degenerative skeletal muscle disease associated with muscle weakness, degeneration of testicular germinal epithelium and impaired spermatogenesis, failure of gestation, brown pigmentation (lipofuscinosis) of intestinal smooth muscle and decreased plasma tocopherol concentrations. In cats, deficiency signs include steatitis, focal interstitial myocarditis, focal myositis of skeletal muscle and periportal mononuclear infiltration in the liver (**Case 6-7**).

Vitamin E is one of the least toxic fat-soluble vitamins. Animals and people apparently tolerate high levels without adverse effects. However, at very high doses, antagonism with other fat-soluble vitamins may occur, resulting in impaired bone mineralization, reduced hepatic storage of vitamin A and coagulopathies as a result of decreasing absorption of vitamins D, A and K, respectively. A maximum of 1,000 IU/kg DM was recommended by AAFCO for dogs; however, AAFCO (2007) set no maximum for cats. There is no evidence of vitamin E toxicity in dogs and very limited information when vitamin E is given orally to cats. In certain conditions, higher dietary vitamin E levels may be beneficial (Morris and Rogers, 1994). A number of inflammatory dermatoses in animals have been treated with oral vitamin (Chapter 32). People have been given much higher dietary concentrations of vitamin E without adverse clinical signs (Combs, 1998).

SOURCES

Only plants synthesize vitamin E. The richest sources of vitamin E are vegetable oils and, to a lesser extent, seeds and cereal grains. Tocopherol concentrations are highest in green leaves. Tocotrienols are not found in green leaves, but instead are found in the bran and germ fractions of certain plants. Animal tissues tend to be low in vitamin E, with the highest levels occurring in fatty tissues. Common vitamin E supplements used in pet foods include α-tocopherol and α-tocopherol acetate.

Vitamin K

Like other fat-soluble vitamins, vitamin K is a generic descriptor for a group of compounds exhibiting the antihemorrhagic activity of phylloquinone. Phylloquinone (vitamin K_1) and menaquinone (vitamin K_2) are the two major naturally occurring forms of vitamin K. Green leafy vegetables are the primary sources of vitamin K_1 whereas vitamin K_2 is produced from actinomycete bacteria found in normal intestinal microflora. Vitamin K_2 is now called menaquinone-7 (MK-7) in recognition of the seven-isoprenoid units. Menadione or vitamin K_3 (2-methyl-1,4-napthoquinone) is the parent compound of the vitamin K series. When used in pet food, it is usually added in a complex form such as menadione sodium bisulfate complex (MSBC) or menadione dimethylpyrimidinol bisulfate (MPB), as the bioactive form of vitamin K.

FUNCTION

Vitamin K plays a major role in the carboxylation of proteins (factors II, VII, IX, X and proteins C and S) to convert prothrombin to thrombin for normal blood clotting. Vitamin K is also involved in the synthesis of osteocalcin, a protein that regulates the incorporation of calcium phosphates in growing bone (Combs, 1998).

METABOLISM

The absorption of natural vitamin K in food is between 40 and 70% (Combs, 1998). Ingested phylloquinone is absorbed from the proximal small intestine into the lymphatic system by an energy-dependent process. Menaquinone is absorbed from the small intestine by a passive noncarrier-mediated process. Conditions that impair lipid absorption also adversely affect vitamin K absorption. Upon absorption, vitamin K is transported to the liver in chylomicrons. The vitamin is rapidly concentrated in the liver, but in contrast to other fat-soluble vitamins, vitamin K has a very rapid turnover in this organ. No specific carriers have been identified for any of the K vitamers.

Although phylloquinones and menaquinones are ingested, much of the vitamin K in tissues is from bacterial origin. Menadione is rapidly excreted in urine as the phosphate, sulfate or glucuronide form of menadiol. However, catabolism of phyl-

loquinones and menaquinones is much slower than that of menadione and they are primarily excreted in feces as a glucuronide conjugate.

Because microbially synthesized K_2 is readily absorbed by passive diffusion in the colon in most mammalian species, dietary supplementation is unnecessary for most cats and dogs.

REQUIREMENTS

AAFCO (2007) does not have a recommended allowance for vitamin K for dogs, but recommends 0.1 mg/kg DM for cats when cat foods contain more than 25% fish. This recommendation is warranted because vitamin K deficiency has been observed in cats fed certain commercial foods containing high levels of salmon or tuna (**Case 6-8**). NRC (2006) recommends that the vitamin K allowance is 1 mg/kg DM for cats for all lifestages. For dogs, the recommended allowance of vitamin K is 1.64 mg/kg DM for growth, 1.63 mg/kg DM for maintenance and 1.6 mg/kg DM for gestation and lactation.

DEFICIENCY AND TOXICITY

Prolonged clotting times and excessive bleeding have been reported in vitamin K deficiency in cats and dogs under various conditions. Vitamin K deficiency usually occurs secondary to other conditions such as malabsorptive diseases (inflammatory bowel disease), ingestion of coagulant antagonists (coumarin, indanedione), destruction of gut microflora by antibiotic therapy (sulfonamides and broad-spectrum antibiotics) and congenital defects (γ-glutamyl carboxylase defect in Devon Rex breed of cats). Vitamin K_3 (menadione) has lower lipid solubility and is the most effective form of vitamin K for cases of malabsorption. Vitamin K_1 is the only form of vitamin K effective in anticoagulant antagonism (Edwards and Russell, 1987).

Phylloquinone produces no adverse effects when administered to animals in massive doses by any route (NRC, 1987). The menaquinones are similarly thought to have negligible toxicity. Menadione, however, can produce fatal anemia, hyperbilirubinemia and severe jaundice. The intoxicating doses appear to be at least three orders of magnitude above those levels required for normal physiologic function (Combs, 1998). Neither AAFCO nor NRC has set maximum or safe upper limits for dogs and cats.

SOURCES

Data for vitamin K content of foods are limited by the lack of good analytical methods. Nevertheless, because dietary needs for vitamin K are low, most foods contribute significantly to those needs. Rich sources of vitamin K include alfalfa meal, oilseed meals, liver and fish meals. Menadione sodium bisulfite complex and menadione dimethypyrimidinol bisulfate are commonly used as vitamin K sources in pet food because of their stability during manufacturing and storage.

Water-Soluble Vitamins

Deficiency of B vitamins occurs in veterinary medicine but may be difficult to specifically diagnose because analytical tests are not readily available. Therefore, diagnosis relies almost entirely upon clinical signs and nutrient intake history.

B vitamins are relatively nontoxic and may be supplied to veterinarians in individual or combination forms. Because many of the B-vitamin deficiencies present with overlapping clinical signs, it may be prudent to treat deficiency with vitamin-B complex. If signs are specific for a particular B-vitamin deficiency, and if the single preparation form of the vitamin is available, individual targeted treatment may be initiated. However, individual preparations of B vitamins are often more expensive, and the relative nontoxic levels of B vitamins warrant treatment with the combination form.

Thiamin

Thiamin or vitamin B_1 consists of one pyrimidine ring and one thiazole ring linked via a methylene group. Thiamin may exist as free thiamin or in the mono-, di-(pyro), or triphosphate configuration. Thiamin pyrophosphate (80%) is the major form found in tissues; the other three forms are found in lesser amounts (Rindi, 1996; Brody, 1994a). Thiamin is very labile, especially in wet foods, being susceptible to neutral and alkaline conditions, heat, oxidation and ionizing radiation.

FUNCTION

Thiamin pyrophosphate (TPP) is the major coenzymatic form of thiamin and is required for only a small number of enzymatic reactions. TPP is involved in the following general scheme of reactions: 1) nonoxidative decarboxylation of α-ketoacids, 2) oxidative decarboxylation of α-ketoacids and 3) transketolation reactions. Thiamin may also have a function unrelated to coenzyme activity. TPP is concentrated in neuronal cells and may affect chloride permeability by controlling the number of functional channels, possibly by phosphorylation.

METABOLISM

Dietary thiamin may be present in any of the four forms mentioned above or may be of synthetic origin. Whatever the form, thiamin is hydrolyzed to free thiamin by intestinal phosphatases before absorption by enterocytes. Absorption takes place primarily in the jejunum by an active, carrier-mediated transport that also phosphorylates the vitamin. Passive diffusion becomes an important mode of absorption when dietary thiamin intake is high.

Absorbed thiamin is transported in erythrocytes, which contain free thiamin and its phosphorylated forms, and in plasma, which only contains free thiamin and its monophosphate form. Tissues take up thiamin and may interconvert it between any of its four forms. The liver, heart and kidneys have the highest concentration of thiamin.

REQUIREMENTS

The AAFCO (2007) recommended allowance for thiamin is 1 mg/kg DM for dogs and 5 mg/kg DM for cats, irrespective of the lifestage. NRC (2006) recommends a thiamin allowance for dogs of 1.38 mg/kg DM for growth and 2.25 mg/kg DM for maintenance and reproduction. For cats, the NRC (2006)

Table 6-5. Blood levels, allowances and tests for B-complex vitamins in cats and dogs.

Vitamin	Blood level	AAFCO allowance*	NRC allowance*	Best test
Cats				
Thiamin	20-90 ng/ml (WB)	5 mg/kg	5.6 mg/kg	Erythrocyte transketolase activity
Riboflavin	196-660 ng/ml (WB)	4 mg/kg	4 mg/kg	Erythrocyte glutathione reductase** Urine riboflavin
Niacin	1.8-5.8 µg/ml (WB)	60 mg/kg	40 mg/kg	Urine methyl nicotinamide or methyl-pyridones**
Pantothenic acid	104-270 ng/ml (WB)	5.0 mg/kg	5.75 mg/kg	Urinary excretion of pantothenate
Pyridoxine	86-350 ng/ml (P)	4.0 mg/kg	2.5 mg/kg	Blood levels of pyridoxine Urinary metabolites of pathway intermediates
Folic acid	3.2-34 ng/ml (P)	0.8 mg/kg	0.75 µg/kg	Serum folate
Vitamin B_{12}	120-1,200 pg/ml (WB)	20 µg/kg	22.5 µg/kg	Blood levels of cobalamin Serum and urine methylmalonic acid
Biotin	1,000-3,000 pg/ml (WB)	70 µg/kg	75 µg/kg	Urinary biotin Urinary organic acids
Choline	180-490 µg/ml (P)	2,400 mg/kg	2,550 mg/kg	Plasma choline and phosphatidylcholine
Dogs				
Vitamin	**Blood level**	**AAFCO allowance***	**NRC allowance***	**Best test**
Thiamin	46-112 ng/ml (WB)	1.0 mg/kg	2.25 mg/kg	Erythrocyte transketolase activity
Riboflavin	185-420 ng/ml (WB)	2.2 mg/kg***	5.25 mg/kg	Erythrocyte glutathione reductase** Urine riboflavin
Niacin	2.7-12 µg/ml (WB)	11.4 mg/kg	17 mg/kg	Urine methyl nicotinamide or methyl-pyridones**

Choline	235-800 µg/ml (P)	1,200 mg/kg	1,700 mg/kg	Plasma choline and phosphatidylcholine

Key: WB = whole blood, P = plasma, AAFCO = Association of American Feed Control Officials, NRC = National Research Council.
*AAFCO allowances are similar for growth and adult maintenance and are expressed on dry matter basis (AAFCO Official Publication, 2007). NRC allowances are "recommended allowances" for adult maintenance and are also expressed on a dry matter basis (NRC. Nutrient Requirements of Dogs and Cats. Washington, DC: National Academies Press, 2006.
**Not currently available in veterinary medicine.
***Investigators have shown a riboflavin requirement approximately 20 to 33% higher than the AAFCO allowance listed here. (Cline JL, Odle J, Easter RA. The riboflavin requirement of adult dogs at maintenance is greater than previous estimates. Journal of Nutrition 1996; 126: 984-988.)
†For normal foods not containing raw egg whites, adequate biotin is probably provided by intestinal microbial synthesis (assuming the patient is not receiving antimicrobial therapy).

recommended allowance for thiamin is 5.5 mg/kg DM for growth, 5.6 mg/kg DM for maintenance and 6.3 mg/kg DM for gestation and lactation. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Clinical thiamin deficiency is rarely observed in dogs and cats because most commercial pet foods have adequate supplementation. Signs of thiamin deficiency are often related to the nervous system and heart. They include anorexia, failure to grow, muscle weakness, paraparesis, convulsions, seizures, ventriflexion of the head, ataxia and cardiac hypertrophy (Read and Harrington, 1981; Jubb et al, 1956; Everett, 1944).

Thiamin deficiency may result from inadequate intake of thiamin, attributable to foods with low-thiamin content or processing losses, or high intake of thiamin antagonists. The processing conditions used to prepare commercial pet foods are destructive to thiamin. However, this anticipated loss is overcome by adding synthetic thiamin before processing (**Case 6-9**).

Thiamin antagonists may be synthetic or natural compounds that modify the thiamin structure rendering it inactive. The natural antagonists include thiaminases (enzymes that degrade thiamin), and polyhydroxyphenols (caffeic acid, chlorogenic acid, tannins), which inactivate thiamin by an oxyreductive process. Thiaminases are found in high concentrations in raw fish, shellfish, bacteria, yeast and fungi (**Table 6-6**). Cooking destroys thiaminases.

Thiamin deficiency may be diagnosed by measuring erythrocyte transketolase activity or thiamin metabolites in blood directly. **Table 6-5** lists concentrations of thiamin in blood for cats and dogs (Baker et al, 1986). Activity of erythrocyte transketolase is an excellent indicator of thiamin status, if determined in a laboratory familiar with the analysis. Thiamin toxicosis via the oral route is very rare.

SOURCES

Thiamin occurs in animal tissues almost entirely in phospho-

rylated forms, whereas it occurs mostly as free thiamin in plants. Thiamin is widely distributed in foods, but is mostly present at low concentrations. The richest sources are whole grains, yeast and liver (especially pork liver). Meat products may also supply significant amounts of thiamin. Up to 90% of thiamin in natural ingredients may be lost as a result of processing (Morris and Rogers, 1994). Therefore, thiamin supplementation is common in pet foods. Thiamin hydrochloride and thiamin mononitrate are the most commonly used supplements in commercial foods for dogs and cats.

Table 6-6. Thiaminase activity in fish products.*

Food	Thiaminase activity**
Marlin	0
Yellowfin tuna	265
Red snapper	265
Skipjack tuna	1,000
Dolphin (mahi mahi)	120
Ladyfish	35
Clam	2,640

**mg thiamin destroyed/100 g fish/hour.

Riboflavin

Riboflavin, or vitamin B_2 belongs to the class of isoalloxazines. Riboflavin has a planar structure and has limited solubility in water. This property has clinical significance because it is difficult to deliver massive doses of the vitamin via intravenous solutions. Riboflavin is heat stabile, but sensitive to light, and acidic and alkaline conditions.

FUNCTION

Riboflavin is the precursor to a group of enzymatic cofactors called flavins. Flavins linked to protein are called flavoproteins. The two major coenzymes derived from riboflavin are flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD). Flavins are used as coenzymes in about 50 enzymes in mammals. Flavins participate in intermediary energy metabolism and function mainly in oxidoreductase types of reactions (**Figure 6-4**).

METABOLISM

Most riboflavin found in food sources is in the form of free coenzyme derivatives that are not readily absorbed unless hydrolyzed, and covalently bound riboflavin that is not well used. The free flavin compounds are hydrolyzed before they are absorbed in the upper GI tract. A specialized transport system that is saturable and sodium dependent is necessary for absorption of flavins. After absorption, about 50% of the riboflavin in blood is bound to albumin and the other half to globulins (Brody, 1994a; Rivlin, 1996). Tissues requiring riboflavin convert it to FMN by phosphorylation catalyzed by flavokinase and subsequently to FAD catalyzed by FAD synthase. Excess riboflavin in the body is eliminated largely as riboflavin via the kidneys.

REQUIREMENTS

The AAFCO (2007) recomended allowance for riboflavin is 2.2 mg/kg DM for dogs and 4 mg/kg DM for cats for all lifestages. The NRC (2006) recommended allowance for riboflavin for dogs is 5.25 mg/kg DM for growth and maintenance and 5.3 mg/kg DM for gestation and lactation. For cats, the NRC (2006) recommended allowance for riboflavin is 4.0 mg/kg DM for all lifestages. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Deficiency of riboflavin in dogs and cats is uncommon but may manifest as dermatitis, erythema, weight loss, cataracts, impaired reproduction, neurologic changes and anorexia (NRC, 1985; Street and Cowgill, 1939; Street et al, 1941). Measurement of erythrocyte glutathione reductase activity is commonly used to evaluate riboflavin status in people and animals. **Table 6-5** lists riboflavin blood values for dogs and cats. Most commercial pet foods are supplemented with synthetic riboflavin. Toxicity has not been reported to occur in dogs and cats.

SOURCES

Riboflavin is widely distributed in foods, primarily bound to proteins as FMN and FAD. Rich sources include dairy products, organ meats (e.g., liver, heart, kidney), muscle meats, eggs, green plants and yeast. Cereal grains are poor sources of vitamin B_2. The supplemental form for addition to foods is usually riboflavin.

Niacin

Niacin is the generic term used to describe compounds that exhibit biologic activity of nicotinamide. Two major forms of niacin are nicotinic acid and nicotinamide.

FUNCTION

Nicotinic acid and nicotinamide are substituted pyridine ring structures (pyridine 3-carboxylic acid and nicotinic acid amide). Niacin must be converted to either nicotinamide-adenine dinucleotide (NADH) or nicotinamide-adenine dinucleotide phosphate (NADPH) to participate in enzymatic reactions or protein modification.

Niacin, in its cofactor form, is essential to several physiologic reactions: 1) oxidoreductive reactions, 2) nonredox reactions, 3) cleavage of β-N-glycosidic bonds with transfer of ADP-ribose to proteins (post-translational modification) and 4) formation of cyclic ADP-ribose (mobilizes intracellular calcium).

Oxidoreductive reactions are the primary function, but the others are significant in proper cell function. Generally, NAD/NADH is involved in catabolic reactions and transfers the reducing power (electrons) acquired from intermediary metabolites to the electron transport chain to ultimately produce adenosine triphosphate. Alternatively, NADP/NADPH is generally involved in biosynthetic reactions that transfer reducing power (electrons) to macromolecules such as fat, protein and carbohydrate.

METABOLISM
Niacin in foods is found mainly as NADH and NADPH, which may be free or bound to other macromolecules. After ingestion, NADH and NADPH undergo hydrolysis by the intestinal mucosa to release free nicotinamide, which is readily absorbed (Brody, 1994a). Dietary niacin (nicotinic acid and nicotinamide) is absorbed readily through the gastric and small intestinal mucosa. Both free nicotinic acid and nicotinamide are found in blood. Tissues readily take up these compounds to synthesize required cofactors, which also trap the compound in cells. Excess niacin is methylated and excreted in urine.

Niacin may also be synthesized from tryptophan via the kynurenin pathway, which results in formation of nicotinic acid ribonucleotide. Some enzymes in this pathway require vitamin B_6 and iron as cofactors. In most mammals, foods high in tryptophan can alleviate signs of niacin deficiency. However, cats cannot efficiently use tryptophan to synthesize niacin because they have a very high enzymatic activity of picolinic carboxylase that decisively leads the metabolism of tryptophan to acetyl-CoA and CO_2 instead of NAD (Sudadolnik et al, 1957; Baker and Czarnecki-Maulden, 1991). Thus, cats have a strict dietary requirement for preformed niacin.

REQUIREMENTS
The AAFCO (2007) recommended allowance for niacin is 11.4 mg/kg DM for dogs and 60 mg/kg DM for cats for all lifestages. The NRC (2006) recommended allowance for niacin is 17 mg/kg DM for dogs and 40 mg/kg DM for cats for all lifestages. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY
Deficiency of niacin results in pellagra with its classic 4D signs: dermatitis, diarrhea, dementia and death. Clinical deficiency is uncommon in dogs because most commercial pet foods are supplemented with niacin. Cats, however, are more likely to develop signs of deficiency because of their strict requirement for niacin. Niacin is a fairly stable vitamin. Processing conditions may release some bound niacin, which increases availability. Niacin deficiency may occur when foods with low quantities of niacin and tryptophan are ingested.

Measurement of methylated nicotinamide levels in urine best substantiates niacin deficiency. Niacin metabolites in whole blood have been reported for dogs and cats (**Table 6-5**), but these values generally have not been useful markers of deficiency in other species (Baker et al, 1986; Jacob and Swendseid, 1996). No niacin toxicity information in cats is available. However, excessive ingestion of nicotinic acid causes bloody stool, convulsions and even death (Chen et al, 1938).

SOURCES
Niacin is a very stable vitamin found in a variety of foodstuffs. The greatest amounts of niacin are found in yeast, animal/fish by-products, cereals, legumes and oilseeds. Niacin occurs in animal tissues as NAD and NADP and in plants mostly as protein-bound forms. Niacin is generally added to most pet foods as nicotinic acid or nicotinamide.

Pyridoxine
Pyridoxine is also generally called vitamin B_6. However, vitamin B_6 is a generic descriptor for all 3-hydroxy-2-methylpyridine derivatives exhibiting the biologic activity of pyridoxine. The three naturally occurring forms of vitamin B_6 are pyridoxal, pyridoxine and pyridoxamine.

FUNCTION
The biologically active forms of vitamin B_6 are the coenzymes pyridoxal phosphate (PLP) and pyridoxamine phosphate (PMP). PLP is involved in most reactions of amino acid metabolism, including transamination, decarboxylation, desulfhydration and nonoxidative deamination. PLP is also involved in the catabolism of glycogen and metabolism of lipids. As a coenzyme for decarboxylase enzymes, PLP functions in the synthesis of serotonin, epinephrine, norepinephrine and γ-aminobutyric acid (GABA). Pyridoxine is involved in vasodilatation through the production of histamine and is required in the pathway where niacin is produced from tryptophan. Pyridoxine helps catalyze the synthesis of taurine from cysteine and participates with ascorbic acid and NAD in the synthesis of carnitine from the amino acid lysine. Pyridoxine is also involved with the synthesis of the heme precursor porphyrin (as a coenzyme for δ-aminolevulinate synthase).

METABOLISM
The various forms of vitamin B_6 (pyridoxine, pyridoxal, pyridoxamine, PLP, PMP) are freely absorbed via passive diffusion in the small intestine. The glucuronide form is not absorbed.

The predominant form of vitamin B_6 in blood is PLP, which is tightly bound to proteins. Pyridoxal crosses cell membranes more readily than PLP does. After uptake by cells, the vitamin is again phosphorylated by pyridoxal kinase to yield the predominant tissue form, PLP, which is considered to be the most active vitamin B_6 form.

The vitamin B_6 forms are readily interconverted metabolically by reactions involving phosphorylation/dephosphorylation, oxidation/reduction and amination/deamination. Phosphorylation appears to be an important means of retaining the vitamin intracellularly. Only small quantities of vitamin B_6 are stored in the body. The products of vitamin B_6 metabolism are excreted in the urine; pyridoxic acid is the predominant metabolic product. Different from other species, cats excrete little pyridoxic acid in urine even after a large oral dose of pyridoxine hydrochloride (Coburn and Mahuren, 1987). The main metabolites of vitamin B_6 in cat urine are pyridoxine 3-sulfate, pyridoxal 3-sulfate and N-methylpyridoxine.

REQUIREMENTS
The AAFCO (2007) recommended allowance for pyridoxine is 1 mg/kg DM for dogs and 4 mg/kg DM for cats for all lifestages. The NRC (2006) recommended allowance for

pyridoxine is 1.5 mg/kg DM for dogs and 2.5 mg/kg DM for cats for all lifestages. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Signs of vitamin B_6 deficiency include anorexia, reduced growth, muscle weakness, neurologic signs, (e.g., hyperirritability and seizures), anemia, and irreversible kidney lesions. Oxalate crystalluria is also a notable sign in pyridoxine-deficient cats (NRC, 2006). **Table 6-5** lists normal plasma levels of pyridoxine for cats and dogs (Baker et al, 1986).

Because pyridoxic acid is not detected in the urine of vitamin B_6-deficient subjects, this metabolite is useful in the clinical assessment of vitamin B_6 status. Measurement of xanthurenic acid excretion after a tryptophan load, however, is a more sensitive indicator of vitamin B_6 status. When vitamin B6 is deficient, the conversion of tryptophan to niacin is impaired, resulting in increased production of xanthurenic acid. Other indices of vitamin B_6 status are plasma concentrations of PLP and erythrocyte transaminase.

The prevalence of vitamin B_6 toxicity appears to be low. Earliest detectable signs include ataxia and loss of small motor control. Many of the signs of toxicity resemble those of vitamin B_6 deficiency: ataxia, muscle weakness and loss of balance. Histologic examination of tissues from dogs fed more than 200 mg pyridoxine hydrochloride/kg body weight/day revealed bilateral loss of myelin and axons in the dorsal funiculi and loss of myelin in the dorsal nerve roots (Phillips et al, 1978). There is no information regarding vitamin B_6 toxicity in cats.

SOURCES

Vitamin B_6 is widely distributed in foods, occurring in greatest concentrations in meats, whole-grain products, vegetables and nuts. The chemical forms of vitamin B_6 tend to vary among foods of plant and animal origin; plant tissues contain mostly pyridoxine, whereas animal tissues contain mostly pyridoxal and pyridoxamine. Pyridoxine is far more stable than either pyridoxal or pyridoxamine, thus processing losses are greatest in foods containing animal products. Losses can be as high as 70% (average losses from 0 to 40%) (McDowell, 1989). Pyridoxine hydrochloride is most often used for supplementation because it is relatively stable.

Pantothenic Acid

Pantothenic acid is the trivial designation for dihydroxy-β, β-dimethylbutyryl-β-alanine. Only the dextrorotatory form of pantothenic acid has biologic activity. It occurs mainly in bound form, (i.e., coenzyme A [CoA] and acyl-carrier protein), in most foods and feedstuffs. Pantothenic acid in foods is fairly stable at cooking temperatures and during storage. However, appreciable losses (up to 50%) have been reported during canning and storage of some foods at pH values greater than 7 and less than 5 (Combs, 1998).

FUNCTION

CoA is found in all tissues and is one of the most important coenzymes for metabolism. CoA plays a critical role in the tricarboxylic acid cycle for production of ATP from fat (glycerol and fatty acids), glucose and amino acids. CoA is also involved in the synthesis of fatty acids, steroid hormones and cholesterol. CoA is necessary for oxidation of fatty acids, pyruvate and ketoglutarate (Machlin, 1991).

METABOLISM

CoA and acyl-carrier protein are the predominant forms of pantothenic acid in foods and foodstuffs. Thus, hydrolytic digestion of these protein complexes is the first step in metabolism of this vitamin. Both forms are degraded to pantothenic acid in the lumen of the intestine in a series of steps. Absorption occurs via a saturable, sodium-dependent, energy-requiring process. At high concentrations, simple diffusion occurs throughout the small intestine. In dogs, more than 80% of free pantothenate is absorbed from the gut (Taylor et al, 1974). Urinary β-glucuronide is the major form of excretion (Taylor et al, 1972). Pantothenic acid is transported in the free acid form in plasma. Erythrocytes contain predominantly acetyl-CoA.

REQUIREMENTS

The AAFCO (2007) recommended allowance for pantothenic acid is 10 mg/kg DM for dogs and 5 mg/kg DM for cats for all lifestages. Less pantothenic acid is apparently required to optimize growth when high-protein foods are fed, whereas high-fat diets may increase the requirement for pantothenic acid (McDowell, 1989). The NRC (2006) recommendation for pantothenic acid allowance is 15 mg/kg DM for dogs regardless of lifestage. For cats, the NRC (2006) allowance for pantothenic acid is 5.7 mg/kg DM for growth, and 5.75 mg/kg DM for maintenance and reproduction. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Naturally occurring deficiency of pantothenic acid is rare. Dogs with pantothenic acid deficiency have erratic appetites, depressed growth, fatty livers, decreased antibody response, hypocholesterolemia and coma, in later stages. Pantothenic acid-deficient cats developed fatty livers and became emaciated (NRC, 2006). Normal whole blood concentrations of pantothenic acid for dogs and cats are listed in **Table 6-5** (Baker et al, 1986).

Pantothenic acid is generally regarded as nontoxic. No adverse reactions or clinical signs other than gastric upset have been observed in any species following ingestion of large doses.

SOURCES

"Pantothenic acid" is derived from the Greek word "pantos" meaning "found everywhere." Although this vitamin is found in practically all foodstuffs, the quantity present is generally insufficient for most monogastric species. The most important sources are meats (especially liver and heart), rice and wheat bran, alfalfa, peanut meal, yeast and fish solubles. Calcium pantothenate is the predominant form added to pet foods.

Folic Acid

Folic acid was first discovered in 1943 and was classified as vitamins B_{10} and B_{11}. The structure of folic acid may be subdivided into three functional components: the middle group is para-aminobenzoic acid (PABA), flanked on one side by a pteridine ring, and on the other side by a polyglutamic acid chain. Folate is the name commonly used to designate a family of compounds with the biologic activity of folic acid (Brody, 1994a; Selhub and Rosenberg, 1996).

FUNCTION

Folic acid functions as a one-carbon (methylene, methenyl, methyl) donor and acceptor molecule in intermediary metabolism. Specific pathways include nucleotide biosynthesis, phospholipid synthesis, amino acid metabolism, neurotransmitter production and creatinine formation. In addition, vitamin B_{12} is closely paired with folate in the production of methionine from homocysteine, which will be discussed later in this section.

METABOLISM

Natural sources of folic acid undergo hydrolysis by the intestinal enzyme γ-glutamyl hydrolase to form folylmonoglutamate, which is subsequently absorbed by enterocytes. Thus, the major form of folic acid in blood is the monoglutamate form. After target cells absorb folylmonoglutamate, additional glutamates are added to the tail, which trap the molecule within cells.

Folic acid must be in the reduced form (i.e., dihydro or tetrahydro) to participate in one-carbon metabolic reactions. The enzyme dihydrofolate reductase (DHFR) interconverts dihydrofolates to tetrahydrofolates. Inhibition of this enzyme interferes with intermediary pathways that require reduced folates for coenzymes. C677T mutation in the methylenetetrahydrofolate reductase (MTHFR) gene also affects folate metabolism and requirement (Golbahar et al, 2005).

REQUIREMENTS

The AAFCO (2007) recommended allowance for folic acid is 0.18 mg/kg DM for dogs and 0.8 mg/kg DM for cats for all lifestages, respectively. The NRC (2006) recommended allowance for folic acid is 270 µg/kg DM for dogs and 750 µg/kg DM for cats regardless of lifestage. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Folate deficiency is characterized by poor weight gain, megaloblastic anemia, anorexia, leukopenia, glossitis and decreased immune function. In cats, folate deficiency is associated with hyperhomocysteinemia and greatly augmented urinary excretion of formiminoglutamic acid (Yu and Morris, 1998). Folate deficiency has been linked to the risk of neural tube defects in people (Mitchell, 2005). Folate levels in blood may be measured to confirm a deficiency suggested by clinical signs. **Table 6-5** lists plasma levels for healthy cats and dogs (Baker et al, 1986).

There have been no reported cases of folate toxicity. Neither NRC nor AAFCO has proposed a dietary maximum concentration for folic acid.

SOURCES

Folate is found in several foods, but is unstable in a variety of conditions. Liver, egg yolks and green vegetables are good sources of folate. The vitamin is destroyed by heating, prolonged freezing and during storage in water. Commercial pet foods are supplemented with folate to overcome the effects of processing and storage.

Biotin

Biotin consists of an imidazole ring fused to a tetrahydrothiophene ring with a valeric acid side chain. It has eight possible stereoisomers in nature but only d-(+)-biotin is physiologically active (NRC, 2006). Biotin is unstable to oxidation and heat.

FUNCTION

Biotin is an essential cofactor for four different carboxylase reactions in mammals. These carboxylases have important functions in the metabolism of lipids, glucose, some amino acids and energy.

METABOLISM

The majority of biotin in food sources is thought to be covalently bound to proteins. After ingestion, biotin must be hydrolyzed from protein by the enzyme biotinidase in pancreatic juice before absorption in the intestine (Brody, 1994a; Mock, 1996). After hydrolysis, free biotin is actively absorbed through a biotin transporter that requires both an intact ureide group and a free carboxyl group on valeric acid (NRC, 2006). Avidin in raw egg white can tightly bind biotin and is resistant to intestinal proteolysis and heat treatment, making biotin unavailable for absorption. After absorption from the intestine, biotin is transported in the free form in the plasma to the required tissues where it is linked to its target apoenzyme by the enzyme holocarboxylase synthetase. The kidneys eliminate excess biotin. Increasing urinary excretion of 3-hydroxyisovaleric acid, an indicator of reduced activity of the biotin-dependent enzyme methylcrotonyl-CoA carboxylase, and decreasing biotin in urine are early and sensitive indicators of biotin deficiency (Mock et al, 2002).

REQUIREMENTS

Neither AAFCO (2007) nor NRC (2006) has a recommendation for biotin for dogs. However, diets containing raw egg white and/or antibiotics may need biotin supplementation. The AAFCO (2007) biotin recommendation for cats is 0.07 mg/kg DM for all lifestages. The NRC (2006) recommended allowance for biotin for cats is 75 µg/kg DM regardless of lifestage. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Naturally occurring biotin deficiency is very rare in dogs and cats (NRC, 2006). Feeding raw egg whites and administering oral antimicrobials are probably the two most common causes of biotin deficiency. Raw egg whites contain the glycoprotein avidin, which binds biotin rendering it unavailable for absorp-

tion. Feeding avidin to cats may result in signs of biotin deficiency that include dermatitis, alopecia and a dull coat (Pastoor et al, 1993). Because gut microbial synthesis may meet half the biotin requirement, antimicrobials that decrease the population of the intestinal microflora may also result in signs of biotin deficiency. Clinical signs include poor growth, dermatitis, lethargy and neurologic abnormalities (**Case 6-10**). **Table 6-5** lists biotin blood values for dogs and cats (Baker et al, 1986).

Biotin toxicity has not been reported. Neither AAFCO (2007) nor NRC (2006) has proposed a dietary maximum concentration for biotin.

SOURCES

Mammalian tissues are incapable of synthesizing biotin. The biotin requirement is probably met by two sources: diet and microbes (Brody, 1994a; Mock, 1996). Biotin is widely distributed in foods, but mostly in very low, highly variable concentrations. Oilseeds, egg yolks, alfalfa meal, liver and yeast are the most important natural sources of biotin. Marked losses of biotin may occur as a result of oxidation, canning, heat and solvent extraction of foodstuffs. Less than one-half of the biotin in various foodstuffs is biologically available (McDowell, 1989). Most commercial pet foods are supplemented with synthetic biotin.

Vitamin B_{12}

Vitamin B_{12} or cobalamin is the generic descriptor for all corrinoids exhibiting the biologic activity of cyanocobalamin. Vitamin B_{12} is the largest and most complex B vitamin and the only one to contain a metal ion, cobalt. The structure consists of four pyrrole rings linked to form a macrocyclic ring designated as corrin, which is similar to hemoglobin. Substitutions on the corrin ring account for the different recognized forms of vitamin B_{12}. The active forms of B_{12}, 5'deoxyadenosylcobalamin and methylcobalamin, are very unstable (Brody, 1994a; Herbert, 1996). Substituted forms of vitamin B_{12} are much more stable and may be used as pharmaceutical supplements (cyanocobalamin, hydroxocobalamin, nitritocobalamin).

FUNCTION

Vitamin B_{12} is important in one-carbon metabolism. In dogs and cats, methylcobalamin, which contains cobalt in the 1^+ state, is a coenzyme for methionine synthase and 5'deoxyadenosylmethionine, which contains cobalt in the 2^+ state is a coenzyme for methylmalonyl-CoA mutase. Vitamin B_{12} is required by the enzyme methionine synthase that removes a methyl group from methyl tetrahydrofolate (THF) to regenerate THF, which is needed for pyrimidine biosynthesis. This intimate relationship with folate may result in folate trapping in B_{12} deficiency and the resultant megaloblastic anemia of folate deficiency.

METABOLISM

Dietary vitamin B_{12} is freed from food peptides and proteins by hydrolysis (gastric acidification and pancreatic enzymes). Free vitamin B_{12} binds to intrinsic factor (IF), a glycoprotein secreted from gastric parietal cells. IF is essential for vitamin B_{12} absorption in people. In dogs, the pancreas is the major and the stomach a lesser source of IF. In cats, the pancreas appears to be the sole source of IF (NRC, 2006). The stable vitamin B_{12}-IF complex is absorbed in the ileum via cell surface specific receptors. Vitamin B_{12} may also be absorbed in the jejunum of dogs and cats (Gazet and McColl, 1967). After absorption, vitamin B_{12} is transported in blood by transcobalamin I and II. Transcobalamin I (haptocorrin) is a glycoprotein that carries almost all vitamin B_{12} in the blood of people. Transcobalamin II, a protein without a carbohydrate moiety, carries about 75% of vitamin B_{12} in the blood of dogs and cats. Cat and dog plasma do not contain transcobalamin I, but have another transport protein, transcobalamin O, which carries about 10 to 15% of vitamin B_{12} (Linnel et al, 1979). All DNA-synthesizing cells take up vitamin B_{12} from the blood via cell surface specific receptors.

REQUIREMENTS

The AAFCO (2007) recommended allowance for vitamin B_{12} is 0.022 mg/kg DM for dogs and 0.020 mg/kg cats for all lifestages. The NRC (2006) recommended allowance for vitamin B_{12} is 35 µg cobalamin/kg DM for dogs and 22.5 µg/kg DM for cats regardless of lifestages. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Vitamin B_{12} deficiency is very rare but may result in poor growth and neuropathies in dogs (**Case 6-11**). Because vitamin B_{12} is only made by microbes and found in animal tissue, long-term feeding of vegetarian diets may lead to vitamin B_{12} deficiency.

Vitamin B_{12} may be directly assessed by determination of serum vitamin B_{12} levels or indirectly by determination of serum or urine methylmalonic acid (MMA) (Brody, 1994a). MMA levels in serum and urine increase with vitamin B_{12} deficiency. A newer test, serum holotranscobalamin II, may prove useful in the future to detect early vitamin B_{12} deficiency (Herbert, 1996). Whole blood levels of cobalamin for dogs and cats are listed in **Table 6-5** (Baker et al, 1986).

Oral toxicity of vitamin B_{12} has not been reported in dogs and cats. Neither AAFCO (2007) nor NRC (2006) has proposed a dietary maximum concentration for vitamin B_{12}.

SOURCES

Only certain microorganisms synthesize cobalamin. Microbes and yeast can make vitamin B_{12} for absorption by animals. Plants generally contain very small amounts of vitamin B_{12}. Meat and, to some degree, milk products are good sources of vitamin B_{12}. Most commercial pet foods are supplemented with stable vitamin B_{12}.

Choline

Choline is traditionally classified as one of the B-complex vitamins although it does not entirely satisfy the strict definition of a vitamin; many animals can synthesize choline in the liver. In

addition, choline is required in the body in substantially greater amounts (>1,000 mg/kg) than the other B vitamins (<100 mg/kg). Furthermore, choline does not function as a coenzyme or cofactor as do most other B vitamins.

Choline, 2-hydroxy-N, N, N-trimethylethanaminium, has three methyl groups that enable choline to serve as a methyl donor in the body. It is an integral component of lecithin (phosphatidylcholine). Choline is a strong base and decomposes in alkaline solution.

FUNCTION

Choline plays several important roles in the body. It is an integrated component of phosphatidylcholine, a structural element of biologic membranes. Phosphatidylcholine also promotes lipid transport. Diminished synthesis of phosphatidylcholine in the liver due to choline deficiency results in accumulation of lipids in the liver. Choline, as acetylcholine, is a neurotransmitter. Choline, as a component of platelet-activating factor (1-O-alkyl-2acetyl-sm-glycero-3-phophocholine), is important in clotting and inflammation. After oxidation to betaine, choline is a source of labile methyl groups for transmethylation reactions (e.g., the formation of methionine from homocysteine and creatine from guanidoacetic acid).

METABOLISM

Choline is present in food predominantly as phosphatidylcholine; less than 10% is present as either the free base or sphingomyelin (Combs, 1998). Choline is released from phosphatidylcholine and sphingomyelin by digestive enzymes and absorbed from the jejunum and ileum mainly by a carrier-mediated process. Intestinal microorganisms metabolize most free choline ingested to trimethylamine, which is absorbed and excreted in urine. Phosphatidylcholine is not subject to such extensive microbial metabolism; therefore, metabolism of phosphatidylcholine results in less urinary trimethylamine. Once absorbed, choline is transported in the lymphatic circulation primarily in the form of phosphatidylcholine bound to chylomicrons.

Most species can synthesize choline, as phosphatidylcholine, by the sequential methylation of phosphatidylethanolamine. The activity is greatest in the liver, but is also found in many other tissues.

REQUIREMENTS

The requirement for choline is affected greatly by dietary factors such as methionine, betaine, myoinositol, folate and vitamin B_{12}, as well as the combination of different levels and composition of fat, carbohydrate and protein in the diet. In addition, age, gender, caloric intake and growth rate influence the lipotrophic action of choline and thereby its requirement.

Choline and methionine are the two principal methyl donors in transmethylation. Therefore, dietary adequacy of methionine and choline directly affects the requirement of the other. Methionine can completely replace choline as a methyl donor. For example, in cat foods, if dietary methionine exceeds 0.62% DM, 3.75 parts of methionine can be substituted for 1 part choline (AAFCO, 2007).

Vitamin B_{12} and folate are required for the synthesis of methyl groups and metabolism of the one-carbon unit. Biosynthesis of labile methyl from a formate carbon requires folate, whereas vitamin B_{12} plays a role in regulated transfer of the methyl group to tetrahydrofolic acid. Therefore, a deficiency of one or both of these vitamins increases the requirement for choline.

Excess dietary protein and/or high-fat foods increase the choline requirement. In most species, the choline requirement is greater for younger animals than for adults. Some adult species may not require choline.

The AAFCO (2007) recommended allowance for choline is 1,200 mg/kg DM for dogs and 2,400 mg/kg DM for cats for all lifestages. The NRC (2006) recommended allowance for choline is 1,700 mg/kg DM for dogs and 2,550 mg/kg DM for cats regardless of lifestage. **Table 6-5** lists AAFCO and NRC allowances for dogs and cats.

DEFICIENCY AND TOXICITY

Choline deficiency in most animal species is characterized by depressed growth, hepatic steatosis and hemorrhagic renal degeneration (Combs, 1998). Additional signs of choline deficiency in dogs include thymic atrophy and elevated plasma phosphatase values and increased blood prothrombin time. **Table 6-5** lists normal plasma levels of choline for cats and dogs (Baker et al, 1986). Choline and phosphatidylcholine levels in blood may be measured to confirm deficiency suggested by clinical signs.

Studies with dogs suggested a low tolerance to lecithin (phosphatidylcholine). Reduced erythrocytes resulted from daily oral administration of lecithin (equivalent to 150 mg of choline) (NRC, 1987). However, neither AAFCO (2007) nor NRC (2006) has recommended a maximum or safe upper limit for dietary choline for dogs and cats.

SOURCES

All natural fats contain some choline; therefore, choline is widely distributed in foods and foodstuffs. Lecithin has also been shown to be an effective emulsifying agent in foods and is the form of choline ingested in most foods. Egg yolks, glandular meals and fish are the richest animal sources and cereal germs, legumes and oilseed meals are the best plant sources. Choline is added to most pet foods as choline chloride and is added separately from the vitamin premix because of its hygroscopic nature and propensity to reduce the stability of other vitamins if added in the premix.

Vitamin C

Because of de novo synthesis, vitamin C is not technically a vitamin for healthy dogs and cats. (See vitamin definition.) However, it is included here because of its biochemical functions, including in vivo and in vitro antioxidant properties (Chapter 7).

FUNCTION

Vitamin C, ascorbic acid or specifically L-ascorbic acid, is a very labile compound that is readily oxidized to dehy-

droascorbic acid. It requires a reducing enzyme (dehydroascorbic acid reductase) to transform it back to the active form. Vitamin C primarily functions in the body as an antioxidant and free radical scavenger. Ascorbic acid is best known for its role in collagen synthesis, where it is involved in hydroxylation of prolyl and lysyl residues of procollagen (Combs, 1998). It is also involved in drug, steroid and tyrosine metabolism (McDowell, 1989) and electron transport. Ascorbic acid is also necessary for synthesis of L-carnitine, an important carrier of acyl groups across mitochondrial membranes. Normal circulating plasma levels are 4 µg/ml in dogs and 3 µg/ml in cats (Baker et al, 1986).

More recently, research into the role of ascorbic acid has shifted from prevention of deficiency to the treatment and prevention of disease. Because ascorbic acid protects against free-radical damage induced by the "oxidative burst" of neutrophils (Combs, 1998; Levine et al, 1994), and stimulates the phagocytic effect of leukocytes, it plays a role in immune function (McDowell, 1989). Larger doses may play a protective role against carcinogenesis. Ascorbic acid acts as a nitrate scavenger, thereby reducing nitrosamine-induced carcinogenesis. Vitamin C has been associated with a reduced risk for gastric cancer, oral cancer and perhaps lung cancer, but had no effect on cancer of the pancreas, colon and prostate gland (Sauberlich, 1991).

Vitamin C may even play a role in the prevention of gingival and periodontal disease. Studies with people have shown that 600 mg/day (10x the recommended dietary allowance) significantly reduced gingival bleeding upon probing (Leggott et al, 1986). Whether this effect can be demonstrated in species that synthesize their own ascorbate (i.e., cats and dogs) remains to be seen.

Ascorbic acid may have some benefit in exercise stress recovery (Kronfeld, 1983). However, megadose supplementation to prevent hip dysplasia has not proved effective (Richardson, 1992).

METABOLISM

Most higher animals can synthesize vitamin C from glucose via the glucuronic acid pathway. People and some animals such as guinea pigs, fish, fruit-eating bats, insects and some birds cannot synthesize vitamin C because they lack the key enzyme L-gulonolactone oxidase. In these species, vitamin C is absorbed by a saturable, carrier-mediated, active-transport mechanism that is sodium dependent. Species that can synthesize ascorbic acid absorb it strictly by passive diffusion. In either case, absorption efficiency of physiologic doses is more than 80% (Combs, 1998).

Vitamin C is transported in the plasma in association with albumin, mostly in a reduced form. Under physiologic conditions, vitamin C exists as ascorbate, which cannot cross most membranes readily. Cellular uptake of vitamin C involves dehydroascorbic acid in erythrocytes, lymphocytes and neutrophils. Once inside the cell, dehydroascorbic acid is quickly reduced to ascorbic acid by an intracellular enzyme (dehydroascorbic acid reductase), which uses reduced glutathione (GSH) as the source of reducing equivalents. Ascorbic acid is widely distributed throughout tissues, both in animals capable of synthesizing ascorbic acid and those that depend on dietary vitamin C. The pituitary and adrenal glands have the highest concentrations of vitamin C; high levels are also found in the liver, spleen, brain and pancreas. Ascorbic acid is excreted in urine, sweat and feces. Losses in feces and sweat are usually minimal.

Because vitamin C is not an essential nutrient for dogs and cats, neither AAFCO nor NRC lists recommendations.

DEFICIENCY AND TOXICITY

Acute vitamin C deficiency results in scurvy (in animals unable to synthesize the vitamin). In general, high intake of vitamin C is considered to be of low toxicity.

SOURCES

Fruits, vegetables and organ meats are generally the best sources of vitamin C. The vitamin C content of most foods decreases dramatically during storage and processing. Polyphosphorylated forms of vitamin C are available that can survive processing conditions.

Vitamin-Like Substances

Vitamin-like substances are substances that exhibit properties similar to those of vitamins, but do not fit the strict definition of a vitamin. They have physiologic functionality, but questionable essentiality. These compounds can be "conditionally essential" depending on the metabolic capacity of the animal.

L-carnitine

L-carnitine is one of the most well known vitamin-like substances. L-carnitine is a natural component of all animal cells (Bremer, 1983; Rebouche and Paulson, 1986). Its primary function is to transport long-chain fatty acids across the inner mitochondrial membrane into the mitochondrial matrix for β-oxidation (Bremer, 1983; Fritz, 1958). Skeletal and cardiac muscle contain 95 to 98% of the L-carnitine in the body and are significant storage sites (Rebouche and Engel, 1983).

The biosynthesis of L-carnitine requires five enzymatic steps that occur in many cells in the body (Bremer, 1983). The final step in which butyrobetaine is converted to L-carnitine is rate limiting and occurs primarily in the liver (Bremer, 1983). Lysine, methionine, ascorbic acid, ferrous ions, vitamin B_6 and niacin are important in L-carnitine metabolism; these nutrients are required substrates and cofactors for the enzymes involved in L-carnitine biosynthesis (Borum, 1986).

Clinical signs of L-carnitine deficiency include chronic muscle weakness, fasting hypoglycemia, cardiomyopathy, hepatomegaly and dicarboxylic aciduria (Stanley, 1987). In many cases of L-carnitine deficiency, no clinical signs are apparent (Borum, 1986).

Carotenoids

Carotenoids are a class of lipophilic natural pigments that are widely distributed throughout the plant and animal kingdom. Only plants, bacteria, fungi and algae synthesize carotenoids; however, animals can accumulate carotenoids in their tissues

after oral ingestion. In plants, carotenoids play essential light-harvesting roles during photosynthetic events and protect membranes against photo-oxidative damage. More than 600 different compounds are classified as carotenoids, but fewer than 10% can be metabolized into vitamin A. In contrast to many other mammals, cats are unable to convert β-carotene to vitamin A; therefore, cats must rely solely on preformed vitamin A in their diet (Schweigert et al, 2002). The carotenoids found in greatest abundance in a variety of foodstuffs are β-carotene, α-carotene, lutein, lycopene, β-cryptoxanthin, zeaxanthin, canthaxanthin and astaxanthin. A primary characteristic of the carotenoids is their conjugated polyene structure.

ABSORPTION AND TRANSPORT

Because carotenoids are lipophilic compounds, concurrent ingestion of fat facilitates intestinal carotenoid absorption. Bile salts are necessary for absorption of ingested fat and carotenoids. The aggregation of bile salts into micelles, and the formation of mixed micelles with the products of lipid digestion and other lipid-soluble food constituents are essential in facilitating absorption of lipophilic compounds from the intestine. At the brush border, micelles interact with enterocytes where the lipophilic contents of micelles diffuse out of the micelles and across the cell membrane. It is believed that the uptake of carotenoids by enterocytes occurs passively and is not carrier-mediated. Enterocytes package carotenoids into chylomicrons, which migrate to the basal-lateral cell membrane where they are exocytosed into the intracellular space for passage to the lymphatic system. After transportation in chylomicrons via the lymphatic system, carotenoids are carried by lipoproteins and transported in the bloodstream.

FUNCTION

Although carotenoids do not strictly fit the definition of a vitamin for mammalian species, they have biologic activity beyond their provitamin A role. Carotenoids with nine or more double bonds function as antioxidants by quenching singlet oxygen and other reactive oxygen species such as hydroxyl radicals, superoxide anion radicals and hydrogen peroxide, which are produced in normal metabolism (Chew, 1995; Bendich, 1989). Carotenoids sacrifice highly reactive multiple double bonds to free radicals via hydrogen donation, thereby stabilizing reactive products. Carotenoids also protect cell membranes by stabilizing the oxygen radicals produced when phagocytic granulocytes undergo respiratory bursts that destroy intracellular pathogens (Bendich, 1989).

The immune-modulating properties of carotenoids have been studied in dogs and cats. Supplementation with β-carotene increases the CD4 T cell population in older dogs to levels found in young dogs and improves T-cell proliferation (Massimino et al, 2003). Supplementation with β-carotene or lutein, an oxycarotenoid found in corn and other vegetables, stimulates cell-mediated and humoral immune responses in dogs and cats (Chew et al, 2000; Kim et al, 2000; Kim et al, 2000a).

SOURCES

Carotenoids are responsible for the striking colors of many yellow, orange and red fruits and vegetables, plant leaves, as well as the colors in some species of fish, crustaceans and plumage of some birds.

Bioflavonoids

The flavonoids are a group of red, blue, yellow and colorless compounds that have vitamin-like activity. This class of compounds was originally mistaken for vitamin C because crude extracts of lemon juice and yellow peppers had antiscorbutic effects. Originally called citrin (mixture of eriodictyol and hesperidin), vitamin P or vitamin C_2, these compounds were reclassified as flavonoids in 1950 (Combs, 1998; Machlin, 1991; Harborne, 1994). More than 5,000 flavonoids have been identified (Harborne and Baxter, 1999). Flavonoids are classified in major and minor groups. Classes include flavonols, flavanols, flavones, isoflavones and anthocyanins. Flavonols, (e.g., kaempferol, quercetin and myricetin, are present in tea, apples and onions. Flavanols (also called catechins) are found in tea, apples and red wine. Isoflavones such as genistein and daidzein are constituents of soybeans. Anthocyanins provide the deep red color to fruits such as berries.

ABSORPTION AND TRANSPORT

The availability varies widely among flavonoids depending on the food source and the forms of flavonoids they contain. Flavonoids are usually found naturally as glycosides linked to sugars, except for catechins. The type of sugar moiety of the glycoside affects availability, (e.g., quercetin glucosides are more efficiently absorbed than quercetin rutinosides) (Hollman et al, 1999). Mammalian enzymatic systems are unable to hydrolyze flavonoid glycosides, but the necessary glycosidases are present in the gut microflora. After hydrolysis and absorption in the small intestine, flavonoids are bound in the liver as glucuronides or sulfate conjugates (Machlin, 1991). Recent studies with flavanols have shown that glycosides can be absorbed without previous hydrolysis by microorganisms (Hollman et al, 1995). Most of the flavonoids are further metabolized into phenolic compounds and rapidly excreted, usually within 24 hours.

FUNCTION

Although many different flavonoids exist with many different physiologic effects, this class of compounds shares some similar functions. The most notable is the sparing effect that flavonoids have on vitamin C. Flavonoids have the ability to perform similarly to vitamin C: reduce capillary fragility and permeability and chelate the divalent metal ions copper and iron (Combs, 1998). Flavonoids can act as antioxidants because they are very effective scavengers of free radicals. In fact, flavonoid assays in vitro often exhibit stronger antioxidant activity than vitamins E and C. Other non-antioxidant related beneficial effects include prevention of angiogenesis (Cao and Cao, 1999) and inhibition of cyclooxygenase and lipoxygenase (Laughton et al, 1991). Catechins, found in abundance in tea, have been shown to modulate signal transduction pathways,

have antiinflammatory activities and decrease cell proliferation (Dong et al, 1997; McCarty, 1998). Data from studies using animal models have shown that green and black tea consistently decrease cancers of the skin, lung, stomach, liver, mammary gland and colon (Chung et al, 2003). Isoflavones present in soybeans have been associated with reduced risk of cardiovascular disease, certain cancers and other degenerative diseases.

SOURCES

Flavonoids are ubiquitous in the plant kingdom. Significant variation in the flavonoids present in leaf, petal, root, fruit and seed can occur within the same plant. Flavonoid concentration can vary within a given plant organ (i.e. in apples), flavonoids tend to concentrate in the skin (Harborne, 2000).

Other Vitamin-Like Substances

Some other substances with vitamin-like activity include lipoic acid, ubiquinones, orotic acid, inositol and p-aminobenzoic acid. Animals synthesize most of these compounds, which are important metabolic intermediates. They function: 1) in the metabolism of fatty acids, 2) in the electron transport chain, 3) as antioxidants and 4) as growth factors. Continued research in "conditionally essential" nutrients may lead to vitamin classification for many of these compounds.

CASE 6-1

Seizures in an Airedale Terrier

Patient Assessment

A 20-kg, eight-year-old, neutered male Airedale terrier was admitted to an emergency clinic after a 45-minute episode of continuous seizure activity. The dog was moribund at presentation. Thirty-six hours before the onset of seizures, the dog had ingested a salt-flour figurine, weighing approximately 100 g. The dog vomited a clear fluid three times within 12 hours after ingesting the figurine and became progressively more polydipsic and polyuric. The dog then consumed an unknown additional volume of uncooked salt-flour dough. Within an hour after ingesting this mixture, the dog developed generalized, fine-muscular fasciculations, which rapidly progressed to clonic-tonic motor activity.

The moribund dog was unresponsive to painful stimuli, pyrectic (41.6°C [106.9°F]), tachypneic and had an irregular heart rhythm. A generalized seizure occurred during the examination. Serum electrolyte and blood gas analysis revealed severe hypernatremia (serum sodium 211 mEq/l, normal 145 to 158), hyperchloremia (serum chloride 180 mEq/l, normal 105 to 122) and metabolic acidosis (serum pH 7.135, normal 7.32 to 7.38).

Treatment Plan

Treatment was initiated with intravenous fluids (5% dextrose in water), sodium bicarbonate, diazepam, phenobarbital and furosemide. The dog was also cooled with ice-water wraps and electric fans. The dog suffered cardiopulmonary arrest five hours later and died.

Further Assessment

At postmortem examination, one liter of putty-like, grayish-white material and clear, watery fluid were found in the stomach. Hemorrhage was noted throughout the stomach and the proximal two-thirds of the small intestine. Acute renal and hepatic necrosis was found histopathologically. Sodium and chloride levels in tissues were higher than normal. The brain sodium level was 108 mEq/l (80 mEq/l is considered indicative of sodium salt toxicosis). Analysis of the liquid portion of the gastric contents showed that a minimum of 20 g of sodium chloride remained in the stomach.

CASE 6-2

Vomiting and Diarrhea in a Yorkshire Terrier

Patient Assessment

A one-year-old, intact female Yorkshire terrier weighing 2.7 kg had a sudden onset of lethargy, watery diarrhea, vomiting, icterus and red-colored urine. Abnormal laboratory findings included hemolyzed plasma, anemia, azotemia, leukocytosis, hemoglobinuria and an elevated total bilirubin concentration. Abdominal radiographs revealed a metal object at the pylorus. The object was recognized by the owner as a nut that had been missing for two weeks from an airfreight kennel used to house the dog. Serum zinc concentration was 32 mg/kg, compared with 1.1 mg/kg in serum obtained from a clinically normal dog at the same time.

Assess the Food and Feeding Method

No dietary history was available. The manufacturer of the kennel indicated that the nut was made of pure zinc.

Treatment Plan

The nut was removed from the stomach using a fiberoptic endoscope. Additional therapy included intravenous fluids and a blood transfusion.

Reassessment

The dog stopped vomiting but remained depressed and continued to have profuse watery diarrhea. Semi-solid feces were passed on Day 5 after removal of the nut. The dog's appetite returned on Day 6 and the dog steadily improved until discharge seven days later. Serum zinc concentrations on Days 11 and 21 were 8.5 mg/kg and 1.0 mg/kg respectively (values for a clinically normal dog were 0.7 mg/kg). The owner reported that the dog seemed completely normal three months after discharge.

On analysis, the nut contained 97% zinc, 2% aluminum and other elements. The nut removed from the stomach was highly corroded and when its weight was compared with that of a new nut of the same design, it appeared that the dog received a total dose of 703 mg zinc/kg body weight.

CASE 6-3

Reproductive Problems in a Group of Cats

Patient Assessment

A group of breeding domestic shorthair cats, ranging in age from two to five years and weighing from 3 to 4.5 kg, was presented for poor reproductive performance, including failure to conceive, fetal resorption, small weak kittens and cannibalism. Neonatal kittens from these queens had graying of hair, dry and curled coat texture and skeletal abnormalities including inverted carpi and metatarsi, "kinked" tails and fused digits.

Physical examinations of the unbred queens were unremarkable. Some pregnant queens appeared slightly underweight for their date of gestation but were otherwise normal when examined. Newborn litters contained several small kittens, weighing less than 70 g or kittens with gray-to-whitish coats over the caudal one-half to three-fourths of the body. The coat color over the head and feet was unaffected. The coat texture of kittens less than three days old was somewhat dry and had a slightly curled appearance. Several newborn kittens had kinked tails and inverted carpi. Kittens older than three weeks had normal coats and improvements in carpal and tarsal malformations, but normal function or structure did not return in many kittens. Kittens with kinked tails and fused toes did not improve with age.

Reproductive problems included a decline in conception rate from 100% to between 0 to 50% over an eight-month period. In utero monitoring of pregnant queens through biweekly ultrasound examinations showed that the fetal loss rate was 67% and occurred between 25 to 30 days of gestation. Food intake was only about two-thirds of that expected for the queens.

The initial evaluation included complete blood counts and serum biochemistry profiles for many of the queens and serum trace mineral analyses and heavy metal toxicity screens for queens and affected kittens. The hemogram results included normal hematocrit and hemoglobin values with low mean corpuscular hemoglobin concentrations (hypochromasia) in four of six queens evalu-

ated. Heavy metal toxicity screens of affected kittens were unremarkable with the exception of high-hepatic zinc level in one kitten and a single low-hepatic iron value. Serum copper concentrations for queens were normal, but hepatic copper values were not determined because queens were in active reproduction. In one- to two-week-old affected kittens, hepatic copper concentrations ranged from 26.6 to 35.7 mg/kg and serum copper values from 0.3 to 0.4 mg/kg, which were deemed borderline low based on literature values.

Assess the Food and Feeding Method

A commercial dry cat food that had passed an AAFCO feeding trial for feline growth and maintenance had been fed for approximately eight months to cats in this colony before any abnormalities were noted. The food was plant-based; the first four ingredients were corn, corn gluten meal, soybean meal and poultry by-product meal. In addition to containing typical vitamin and mineral supplements, the food also included copper oxide as a copper source and iron oxide as a colorant.

Analysis of the food disclosed no deficiencies when compared with recommended levels established for growing kittens. However, high levels of zinc and iron were noted in the food. High levels of dietary phytates, which can reduce mineral absorption, were expected to be in the food because of the plant ingredients it contained.

Feeding Plan

A dietary copper deficiency was considered the most likely cause of the reproductive failure noted in these queens. Although food analysis revealed that dietary copper levels were more than adequate, the copper oxide used in the food is a completely unavailable copper source for animals. Additionally, factors that impair copper absorption by chelation (phytates in plants) or transport competition (zinc and iron) were found in high concentrations in the food and would further impair absorption of available copper.

The cat food was supplemented with 15 mg/kg copper from an available source (i.e., copper sulfate).

Reassessment

After the food was supplemented with copper sulfate, the conception rate increased to 80% of breedings and in utero fetal death rates decreased to 12.5%. Food intake increased to expected levels. Three months after feeding the supplemented food, coat pigmentation abnormalities and limb and tail deformities again became evident in newborn kittens. Serum samples were again collected from pregnant queens for copper analysis. Copper values were low in four of nine queens, indicating continuing copper deficiency. An additional 10 mg/kg of dietary copper as copper sulfate were added for a total of 25 mg/kg supplemental copper. No abnormal kittens were born during the next five months.

Some less severe clinical signs of copper deficiency in kittens not consuming copper-supplemented food (i.e., queen's milk only) were reversible. Pigmentation and coat texture returned to normal and improved carpal flexion was observed with skeletal maturation.

CASE 6-4

Sudden Death in a Chihuahua

Patient Assessment

A three-year-old female Chihuahua was found dead one hour after being given 1.5 ml of a vitamin E preparation by intramuscular injection. The owner routinely administered the vitamin preparation twice yearly to all dogs of breeding age in his kennel. One week earlier, a similar incident occurred with a two-year-old female Yorkshire terrier. The owner had purchased the vitamin E product from the same veterinarian for several years. The Chihuahua and the vitamin E preparation were delivered to a diagnostic laboratory for examination.

At necropsy, the lungs were wet, glistening and mottled pink. White foam was found in the trachea and bronchi. All other internal organs appeared normal. Histopathologic examination of the lungs showed congested capillaries, perivascular edema and abundant proteinaceous fluid in the alveolar lumina. Liver and kidney specimens from the dog contained 12.9 and 12.1 mg selenium/kg, respectively (normal values <3 mg/kg).

Assess the Food and Feeding Method

No food was available for evaluation. When contacted, the veterinarian suggested that the bottle of vitamin preparation might also

contain selenium. Selenium had been added to a bottle of vitamin E intended for use in calves, but the mixture had not been dispensed. The veterinarian was concerned that the bottle might have been sold inadvertently to the owner of the dog.

Two liquid phases, one oily and the other watery, were visible in the vitamin preparation bottle. The water-base liquid from the bottle contained 5,317 mg selenium/l. Subcutaneous tissue at the injection site contained 129 mg of selenium/kg. The calculated dose of selenium that had been administered to the dog was 2.5 mg/kg. The minimal lethal dose of selenium administered by intramuscular injection in dogs is 2.0 mg/kg.

Comments
Selenium toxicosis in cattle, sheep, horses, swine and poultry has been documented and usually develops as a subacute to chronic disease resulting from ingestion of seleniferous plants or feeds that contain high concentrations of selenium because of errors in ration formulation. Lesions of subacute to chronic selenium toxicosis have also been produced in dogs by long-term parenteral selenium administration. Acute selenium toxicosis causes increased vascular permeability, which is manifested as hemorrhages and edema in many tissues.

Bibliography
Janke BH. Acute selenium toxicosis in a dog. Journal of the American Veterinary Medical Association 1989; 195: 1114-1115.

CASE 6-5

Cervical Rigidity in a Cat

Patient Assessment
A 10-year-old, castrated domestic shorthair cat weighing 7 kg was examined for lethargy, decreased appetite and weight loss of several months' duration. Weight loss of 2 kg over the preceding 12 months was evident from the medical record.

The cat appeared depressed, had a matted, unkempt coat and extended its cervical region and held its head low and directly in front of its body. The cat was afebrile, obese and dehydrated. On palpation, the cervical region was rigidly extended with tense musculature. A hard mass was palpable in the midcervical region. The rigidly extended neck was the only neurologic abnormality.

Evaluation included a complete blood count (mild leukocytosis with mature neutrophilia), serum biochemistry analysis (mild hyperglycemia and hypercholesterolemia), feline leukemia virus antigen test (negative) and cervical and thoracic radiographs. Radiography revealed a bone-dense, cervical mass ventral to the C_1-C_2 intervertebral space. Much of the normal vertebral architecture appeared to be obliterated and the trachea and soft tissues were deviated ventrally and laterally. Thoracic radiography revealed ventral, bony proliferations extending from thoracic vertebrae T_2 through T_7. Marked bony proliferation was evident along the sternum and several of the costal cartilages.

The cat's serum vitamin A concentration was markedly high (315 µg/dl, normal 20 to 80 µg/dl).

Assess the Food and Feeding Method
The cat was fed a commercial dry cat food ad libitum supplemented with fresh beef liver daily.

Treatment and Feeding Plan
A tentative diagnosis of hypervitaminosis A was made based on the dietary history, clinical signs and radiographic lesions. The daily liver supplementation was considered the source of the excess dietary vitamin A. The cat was given a single intramuscular injection of dexamethasone and an oral analgesic was prescribed. The owner was advised to discontinue feeding beef liver and to feed only a balanced commercial cat food. The owner was further advised to encourage the cat to eat with hand feeding.

Reassessment
Six months later, the cat was euthanatized for reasons unrelated to the hypervitaminosis A. The cat had been eating fairly well, although its stiff-necked posture remained.

CASE 6-6

Vomiting and Anorexia in a German Shepherd Mixed-Breed Dog

Patient Assessment

A five-year-old, 10.6-kg, neutered female German shepherd mix was examined after three days of vomiting, anorexia and lethargy. The owners reported the dog was allowed free access to the neighborhood, which included a radiator machine shop where cholecalciferol-based rodenticides were used. The dog appeared depressed and moderately dehydrated.

Abnormal laboratory findings included moderate hypercalcemia, mild azotemia, proteinuria and isosthenuria. These results suggested vitamin D_3 toxicosis.

Assess the Food and Feeding Method

No dietary history was available.

Treatment and Feeding Plan

Treatment consisted of intravenous 0.9% saline solution, diuretics, salmon calcitonin and corticosteroids. Hypercalcemia persisted throughout hospitalization. Further diagnostic testing did not identify a cause for persistent hypercalcemia. After seven days of hospitalization, the dog improved markedly and was discharged to the owners' care. Oral prednisone (at tapering dosages) and a veterinary therapeutic food formulated for renal patients were given at home.

Reassessment

The dog was evaluated several times during the next four weeks and appeared normal despite persistent hypercalcemia. The dog became normocalcemic five weeks after discharge from the hospital and remained normocalcemic when examined at two and three months.

CASE 6-7

Subcutaneous Nodules in a Young Cat

Patient Assessment

A five-month-old female domestic shorthair cat was examined for depression, anorexia, firm nodular subcutaneous fat in the groin region and abdominal hyperesthesia of one week's duration. The cat was normally docile and tractable but began to resist being handled and petted. Body condition was normal (3/5).

Hematologic abnormalities included a neutrophilic leukocytosis and a normocytic, normochromic, nonregenerative anemia. Urinalysis and fecal examination results were normal. Biopsy specimens were obtained from the affected subcutaneous tissue. The biopsy specimens were firm, nodular and brownish-orange when examined grossly. Serosanguineous fluid oozed from the biopsy sites. Histopathologic examination revealed pyogranulomatous panniculitis, ceroid pigment and multifocal areas of fat necrosis and mineralization.

Assess the Food and Feeding Method

Since weaning, the cat had only been fed sardines, anchovies and mackerel free choice.

Treatment and Feeding Plan

A diagnosis of pansteatitis was made based on the dietary history and histopathologic lesions. Treatment included α-tocopherol (50 mg/kg body weight) once daily per os for two months and prednisolone for 15 days in a decreasing dosage schedule. A fish-free, complete and balanced moist cat food was offered. Because the cat was anorectic and unaccustomed to commercial cat food, it was initially force-fed.

Reassessment
Marked clinical improvement occurred within one week and the cat appeared clinically normal within one month.

Comments
Vitamin E protects cells against lipid peroxidation. α-tocopherol appears to localize within cell membranes to prevent or inhibit initiation of lipid peroxidation. Animals fed oily fish and fish oils containing high levels of unsaturated fat require greater amounts of vitamin E to limit fat oxidation.

Koutinas AF, Miller WH, Kritsepi M, et al. Pansteatitis (steatitis, "yellow fat disease") in the cat: A review article and report of four spontaneous cases. Veterinary Dermatology 1993; 3: 101-106.

CASE 6-8

Hemorrhagic Diathesis in a Group of Kittens

Patient Assessment
A group of adult intact female cats and their kittens were involved in an AAFCO feeding trial to establish nutritional adequacy for gestation, lactation and growth. Necropsy of four kittens that died during the feeding trial revealed hepatic or GI hemorrhages. Fourteen of the surviving kittens were divided into two groups. Blood samples were taken on Days 1, 3, 4 and 6. After the Day 3 blood samples were taken, seven of the kittens were injected subcutaneously with a vitamin K preparation (200 mg K_1), and the other seven were left untreated. Clotting times were determined for each sample.

The mean clotting time for kittens not receiving vitamin K treatment was 50 ± 9 seconds (values for normal kittens 22 ± 0.1 seconds). Mean clotting times for kittens receiving treatment decreased significantly from 59 ± 10 seconds for Days 1 and 3 to 22 ± 0.4 seconds for Days 4 and 6.

Assess the Food and Feeding Method
Queens and kittens were fed a commercial feline food formulated primarily from tuna, free choice. Individual food intake measurements were not available for the kittens because they were group housed for the AAFCO feeding protocol.

Feeding Plan
Further studies using purified diets did not identify the specific cause of vitamin K deficiency in kittens eating this fish-based food. These studies led to a recommendation that pet food companies include a supplemental source of vitamin K in moist fish-based foods for cats.

Bibliography

CASE 6-9

Weight Loss in a Group of Cats

Patient Assessment
Twenty-eight cats in a humane shelter in England developed lethargy, a mild decrease in food consumption and weight loss. Analysis of blood samples taken from three of the cats revealed a normocytic, normochromic anemia.

Three days after the onset of clinical signs, 13 of the cats rapidly lost body condition and developed an uncoordinated gait. Within eight to 12 hours, these cats developed ventriflexion of the head and had fully dilated pupils with no light reflex. Five of the cats subsequently developed seizures and died despite treatment with anticonvulsant drugs. A diagnosis of thiamin deficiency was made based on necropsy results.

Assess the Food and Feeding Method

The cats were fed a commercial moist cat food for six months. The food was not a complete and balanced product but was designed as a "complementary" food to be mixed with other complete dry foods. Two different lots of the moist food contained 0.56 and 0.04 mg thiamin/kg food. Assuming the food contained 75% water and had a metabolizable energy content of 1.25 kcal/g as fed, the food should contain at least 1.25 mg/kg food of thiamin for kittens and 0.5 mg/kg food of thiamin for adult cats.

Treatment and Feeding Plan

The other severely affected cats were treated with intravenous fluids and intramuscular injections of vitamin B complex for five days. These cats responded to therapy within 12 hours and were clinically normal five days later. No other cases have occurred since the humane shelter switched to a complete and balanced moist cat food.

CASE 6-10

Skin and Hair Disorders in a Group of Kittens

Patient Assessment

Twenty female kittens were involved in a feeding trial to evaluate dietary phosphorus requirements. The kittens were eight weeks old at the beginning of the trial. After eating the experimental food for 11 weeks, most kittens developed dried secretions around the eyes, mouth, nose and feet, focal dermatitis of the lips near the canine teeth, alopecia along the back, neck and tail, achromotrichia, dull fur and a brownish appearance of the skin. Growth of the kittens was not impaired. Results of hemograms and urinalyses were normal.

Assess the Food and Feeding Method

The food was a purified diet that contained dried egg whites, fish meal, beef tallow, corn oil, glucose, cooked starch, cellulose, taurine, vitamins and minerals. Food and demineralized water were provided free choice.

Feeding Plan

A tentative diagnosis of biotin deficiency was made based on the dietary history and clinical signs. The biotin content of the food was increased from 0.066 mg/kg to 3.0 mg/kg of food.

Reassessment

The kittens were markedly improved after eating the biotin-supplemented food for 10 weeks. Serum biotin concentrations of kittens fed unsupplemented food was about one-fifth of that of adult female cats fed a commercial complete and balanced dry cat food. Serum biotin concentrations responded to increased biotin intake.

Comments

Biotin deficiency induced by avidin in raw egg whites is a classic example of vitamin deficiency in experimental nutrition. Avidin is a glycoprotein that irreversibly binds biotin and renders it unavailable. Biotin deficiency was an unwanted side effect in this group of research cats due to egg whites in the formulation. The researchers ordered ovalbumin expecting to receive a purified fraction of egg protein. However, they received dried total egg whites, which contained avidin.

CASE 6-11

Cachexia in a Young Giant Schnauzer

Patient Assessment

A five-month-old female giant schnauzer was admitted for lethargy, depression and cachexia (body condition score 1/5). The dog weighed 7.8 kg and was 47 cm high at the shoulder. It had gained no weight in the previous eight weeks. The dog's four normal female littermates weighed 20.5 to 22.5 kg and were 48 to 52 cm high at the shoulder.

Hematologic abnormalities included chronic nonregenerative anemia and neutropenia. Peripheral blood smears revealed marked erythrocyte anisocytosis and poikilocytosis, occasional hypersegmented neutrophils and large platelets. Analysis of bone marrow aspirates revealed decreased to normal cellularity with adequate iron stores. Serum iron and total iron binding capacity were normal. Serum biochemistry analyses were within normal limits for age-matched controls.

Intestinal maldigestion and malabsorption were ruled out based on normal GI contrast radiography, normal absorption of starch and fat and normal serum trypsin-like immunoreactivity. Normal hepatic function was documented by ammonia tolerance and BSP retention tests.

A urine sample was submitted for metabolic screening. Analysis revealed methylmalonic aciduria, which is a sign of vitamin B_{12} deficiency. Two serum samples had vitamin B_{12} concentrations of 21 and 36 pg/ml (values for normal dogs 209 to 483 pg/ml). Results of a test to measure intestinal absorption of an orally administered dose of vitamin B_{12} were suboptimal.

Assess the Food and Feeding Method

The puppy was fed a variety of homemade and commercial dog foods free choice, supplemented with an oral liquid hematinic.

Treatment and Feeding Plan

Vitamin B_{12} (1 mg) was administered intramuscularly once daily for seven days. A complete and balanced commercial dry growth dog food was offered free choice.

Reassessment

Within 12 hours of the vitamin B_{12} injection, the puppy became bright and alert and developed a voracious appetite. Two weeks after treatment, the puppy had gained 7 kg; six weeks after treatment the puppy weighed 25 kg. Reticulocytosis occurred five days after parenteral vitamin B_{12} therapy was started. Neutrophil counts increased within 10 days and all hematologic abnormalities resolved within two months. The dog remained clinically normal when given 1 mg vitamin B_{12} intramuscularly every four to five months.

Subsequent testing of this puppy's mother documented an inborn error of vitamin B_{12} metabolism leading to selective vitamin B_{12} malabsorption. Inherited selective malabsorption of vitamin B_{12} has been described in other giant schnauzer puppies and in a cat.

Chapter 7

Antioxidants

Steven C. Zicker
Karen J. Wedekind

"Scientists now believe that free radicals are causal factors in nearly every known disease, from heart disease to arthritis to cancer to cataracts. In fact, radicals are a major culprit in the aging process itself."
Lester Packer

INTRODUCTION

Oxidation is characterized by the loss of electrons, which results in an increase in positive or a decrease in negative charges on an atom. Usually, in biologic systems this occurs by the loss of one or two electrons by transfer to another atom, which accepts the electron(s) into its orbit, resulting in a more stable state. Conversely, reduction of an atom is the gain of electrons. A substance that donates electrons (i.e., becomes oxidized) to another substance is a reducing agent and one that accepts electrons (i.e., becomes reduced) is an oxidizing agent. Oxidizing agents are always reduced in a reaction, whereas reducing agents are always oxidized. Redox reactions occur when oxidation and reduction take place in the same chemical equation between two substances. In general, the balance of this potential energy equation is a measure of the ease with which a molecule gives up an electron compared to its willingness to accept an electron in relation to the hydrogen half-cell equation developed by Nernst.

An antioxidant is any substance, that when present in low concentrations compared with those of an oxidizable substrate, significantly delays or prevents oxidation of that substrate (i.e., it prevents oxidation) (Halliwell, 2002). Thus, antioxidants may preserve the structural integrity and function of biologic molecules in cells. However, this concept may be too simplistic because some cellular signaling pathways appear to depend on redox chemistry to manifest "normal" biologic function.

Free radicals are unstable atoms (e.g., oxygen, nitrogen) with at least one unpaired electron in the outermost shell. Oxygen free radicals (also called reactive oxygen species or ROS) will be used as the prototypical molecule for this chapter (**Figure 7-1**).

An unpaired electron creates a thermodynamically unstable situation; therefore, the molecule will either attempt to gain (reduction) or lose (oxidation) an electron to achieve thermodynamic stability. Thus, a free radical may act as either an oxidizing or reducing agent depending on its thermodynamic propensity for stability. For example, superoxide (O_2^-) is a normal byproduct of cellular respiration. Thermodynamically, superoxide attempts to lose an electron to become oxygen and eventually water by a hydrogen peroxide intermediate. Alternatively, the hydroxyl radical (OH) strongly prefers to gain an electron (i.e., oxidize other molecules) to achieve its OH^- configuration. The chemistry of free radical reactions depends not only on which free radical species is generated in vivo but also where the molecule is generated within the cell. For example, a highly reactive free radical produced in mitochondria is unlikely to diffuse into the cytoplasm. A less reactive species, however, such as hydrogen peroxide may diffuse into the cytoplasm before it engages chemically in a redox reaction.

Redox and free radical chemistry reactions may occur directly or be catalyzed by other molecules, metals or proteins acting

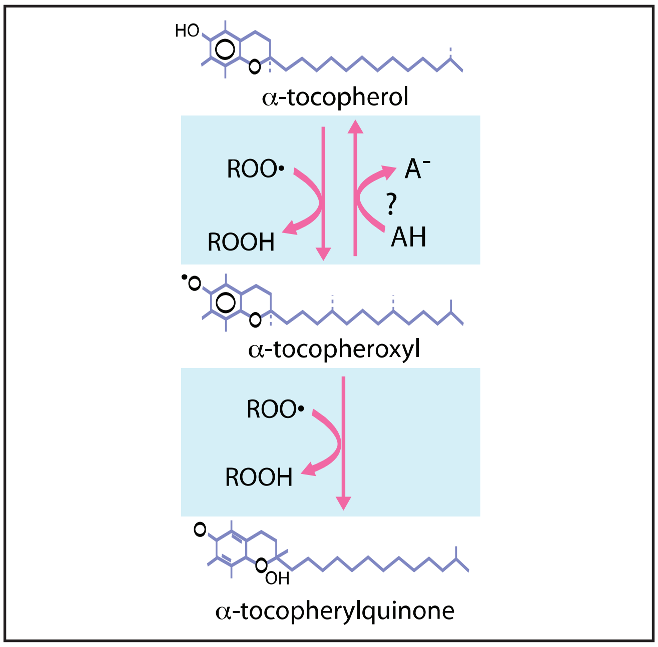

Figure 7-1. Oxidation of tocopherols by reaction with peroxyl radicals.

Reaction 1	$2O_2^{-\cdot} + 2H^+$ superoxide dismutase	$H_2O_2 + O_2$
Reaction 2	$2\ H_2O_2$ catalase	$2H_2O + O_2$
Reaction 3	$H_2O_2 + Fe^{2+}$	$OH + OH^- + Fe^{3+}$
Reaction 4	$O_2^- + Fe^{3+}$	$O_2 + Fe^{2+}$

Figure 7-2. An example of detoxifying free radicals.

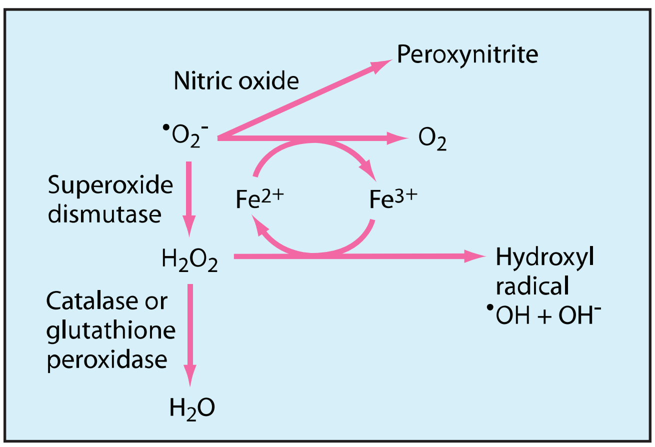

Figure 7-3. Metabolic schemes of superoxide anion.

as enzymes. Also, these systems may work in networks that depend on the proximity and species of redox coupling required. For example, mitochondria produce superoxide as a normal byproduct of cellular respiration. Normally, electrons "leak" from the electron transport chain, converting 1 to 3% of oxygen molecules into superoxide.

Cells can detoxify free radicals by several mechanisms; in the case of superoxide, cells use a two-step enzymatic method.

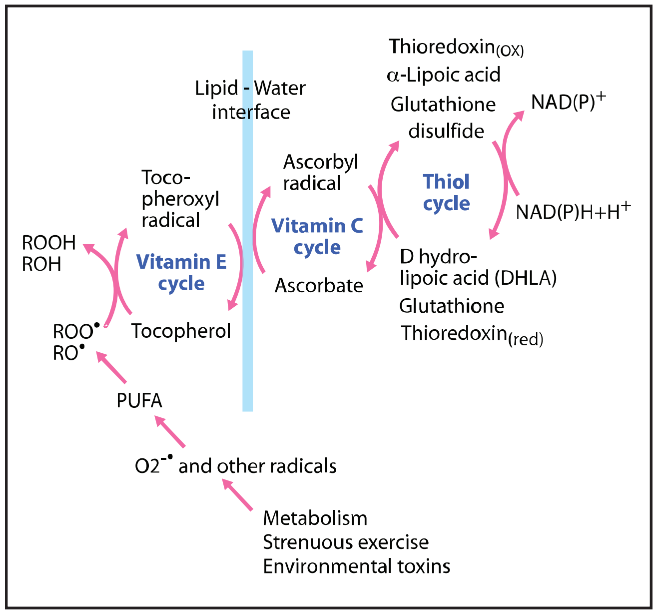

Figure 7-4. An antioxidant network to detoxify free radicals.

First, the superoxide free radical is simultaneously reduced and oxidized (dismutated) by superoxide dismutase to form hydrogen peroxide and oxygen (reaction 1) (**Figure 7-2**). Although hydrogen peroxide is a ROS, it is much less reactive than superoxide. As mentioned above, it may diffuse out of the mitochondria before reacting with another molecule. In the second step, catalase enzymes convert hydrogen peroxide into water and oxygen (reaction 2). Ironically, the hydroxyl (OH) free radical, the most mutagenic of the ROS, is generated when superoxide is converted to hydrogen peroxide. Peroxide readily reacts with ferrous iron (Fe^{2+}) or other transition metal ions (Fenton reaction) to produce hydroxyl radicals (reaction 3). Ferric iron (Fe^{3+}) can accept an electron from superoxide and cycle it back to the ferrous state where it is available to react with another peroxide molecule (reaction 4). Trace amounts of ionic iron can potentially catalyze formation of large quantities of hydroxyl free radicals.

A more dynamic metabolic picture of potential pathways emerges when these individual reactions are linked together in a biologic system (**Figure 7-3**). Thus, free radical production depends on multiple pathways and the availability of detoxification mechanisms vs. reactive materials. Overproduction of oxidative/reactive materials vs. detoxification mechanisms is called oxidative stress.

Hydroxyl radicals are highly reactive and oxidize most organic compounds at almost diffusion controlled rates (K >10/molar/sec.) (Dorfman and Adams, 1973). Due to their high reactivity, hydroxyl radicals are indiscriminate, reacting with the first substrate available. Therefore, hydroxyl radicals are highly destructive and have mutagenic potential. Mitochondrial membranes and DNA are particularly susceptible because ROS are formed in close proximity.

Redox reactions are complicated and involve multiple reactions for completion. As mentioned above, antioxidants may require several steps, cellular components or both to successful-

ly detoxify oxidizing agents. **Figure 7-4** demonstrates the production and the stepwise detoxification of an oxidant.

NUTRITIONALLY EFFECTIVE ANTIOXIDANTS

Theoretically, adding antioxidants to a biologic system should positively affect the aging process (**Box 7-1**). However, many interventional studies designed to prove this hypothesis have produced limited or contradictory results.

Distribution and availability of antioxidants are important determinants of biologic outcome. For example, several plant flavonoids and other polyphenols have limited solubility and absorption in the gut compared to other water- or fat-soluble compounds (Carbonaro and Grant, 2005). Physiologic factors such as food intake and composition may markedly influence the effects of antioxidants considered to be easily absorbed and distributed (Hacquebard and Carpentier, 2005; Leonard et al, 2004). One study showed that vitamin E absorption was least effective from gel capsules given without a meal and variably effective when given with a meal. However, vitamin E adsorbed onto a cereal provided consistently higher rates of availability.

Metabolic transformation may alter biologic activity and distribution of orally administered antioxidants between species. Cats lack β-carotene 15,15'-dioxygenase that cleaves β-carotene (provitamin A) into two retinal molecules, whereas herbivores have relatively high activity of this enzyme (Combs, 1998). Thus, cats (and possibly other carnivores) are more likely to absorb carotenoids intact, whereas carotenoids serve relatively more of a pre-vitamin A function for herbivores.

Cats metabolize and eliminate α-lipoic acid at a much slower rate than other species (Hill et al, 2004). Age is another functional consideration. Although vitamin C is not considered essential for rats, as rats age the metabolic enzymes responsible for recycling and transporting vitamin C in hepatocytes become impaired which, if severe, may impart a conditionally essential status for vitamin C to older rats (Lykkesfeldt et al, 1998; Michels et al, 2003).

NON-CLASSIC ANTIOXIDANT MECHANISMS

Many "antioxidant" molecules have other important physiologic functions, including regulating second messengers, cell cycle signaling and controlling gene expression. These cellular redox functions are well regulated and coordinated and are probably inherent rather than random.

Resveratrol, a polyphenol from red grapes, activates sirtuin 2, a member of the sirtuin family of NAD^+ dependent de-acetylases, which mimics the effects of caloric restriction and prolongs cell life (Howitz et al, 2003). Hydrogen production mimics insulin signaling and is now recognized as a component of insulin signaling physiology (Goldstein et al, 2005). Nuclear factor kappaB (NF-κβ) signaling of apoptosis is activated by an alternative pathway via hydrogen. Furthermore, antioxidants that specifically target mitochondria alter this signaling pathway (Hughes et al, 2005; Kutuk and Basaga, 2003; Haddad, 2002). NF-κβ is not the only redox-sensitive transcription factor; several other factors have been characterized with these properties over the past several years (Azzi et al, 2004; Haddad, 2002). Antioxidant molecules are far reaching and go beyond the understanding of classic chemistry.

Box 7-1. Free Radical Theory of Aging.

Denham Harman first proposed the free radical theory of aging in 1956. His theory postulates that reactive oxygen species (ROS) damage cells with resulting age-dependent pathology. Today, it is generally accepted that mitochondria, through aerobic respiration byproducts, are the primary source of ROS in mammals. Accordingly, slowing or reversing the effects of ROS may slow aging.

The free radical theory of aging hypothesis has produced many strategies to mitigate the effects of ROS. One highly touted strategy is to suppress ROS effects with antioxidants or antioxidant defense mechanisms through nutritional supplementation. The effectiveness of this strategy depends on a wide range of different biologic factors.

The Bibliography for **Box 7-1** can be found at www.markmorris.org

MEASURING OUTCOMES OF ANTIOXIDANT STUDIES

Interpreting the vast number of studies involving antioxidant supplements is challenging. The biologic effects of antioxidants may occur by multiple divergent or convergent pathways, thus making interpretation difficult. The effects of ROS are considered insidious and temporally delayed, thus, predicting long-term outcomes from short-term experiments is another challenge to interpretation. Finally, determining the outcome event is also problematic because of the variety of endpoints that have been developed to measure the effects of antioxidants. Some outcomes discussed below highlight potential pitfalls of current methodologies.

Antioxidant Concentrations in Foods, Supplements and Tissues

Oral antioxidant administration as a supplement or in combination with food does not ensure absorption and distribution into tissues. Some antioxidants are more readily absorbed than others. Species differences may further affect absorption. Vitamin E is usually easier to absorb than water-insoluble plant phenols; however, variable absorption and distribution may occur depending on several factors. Vitamin E was more efficiently absorbed when administered with a meal (Leonard et al, 2004). Vitamin E depletion and repletion also appears to have different kinetic parameters depending on tissue type (Pillai et al, 1993, 1993a). Absorption and distribution of oral antioxidants must be relevant to the target tissue and the intended bio-

Table 7-1. Examples of biomolecules and specific markers.

Molecules	Markers

Dog	25	7 to 9 kg	Approx. 0.02

logic outcome. Variabilities in bioavailability and distribution have not limited the number of studies attempting to link either increased ingestion or increased serum values of antioxidants to a variety of health outcomes in target tissues. If absorption and distribution fail to prove causality, what measurements are available for developing arguments about biologic efficacy?

Decreased Markers of ROS Damage

ROS are short-lived and difficult to measure as their native species. Several laboratory methods have been developed to measure biologically stable molecules as markers of ROS production in a biologic system. Presumably, if levels of these markers increase in serum or tissue, then more ROS are being produced and more damage results. If marker levels decrease, production of ROS has presumably also decreased. These markers are specific for different biomolecules (**Table 7-1**). The utility of these measurements has been debated because they indirectly measure presumed ROS reactions, sometimes in distant tissues. As such, they are responses to oxidative events, but do not provide direct mechanistic effects of antioxidant action in target tissues.

The next investigative modality is to look directly at target tissue effects of orally administered antioxidants. These studies can provide biochemical information about tissue mechanisms compared to indirect measures. Several interesting results have emerged with a variety of antioxidants. For example, aged rats, a vitamin C independent mammal, have decreased ability to recycle vitamin C in their hepatocytes, which may be restored by administration of lipoic acid and acetyl-carnitine (Lykkesfeldt et al, 1998). As mentioned above, aged rats had increased oxidative damage to hepatic proteins, which decreased enzymatic activity and increased susceptibility to protein degradation (Starke-Reed and Oliver, 1989). Finally, oxidative damage increases in the brains of aging beagles and rats; the damage was correlated with memory loss in rats (Head et al, 2002; Liu et al, 2002). Intervention with acetyl-carnitine and lipoic acid partially reversed the memory loss in older rats (Liu et al, 2002).

Biologic Outcomes of Antioxidant Interventions

Intervention studies are much more difficult to perform because of their greater expense, length of time required for intervention and the inability to control dietary intake of individuals. However, animals that have shorter lifespans are useful for developing strategies that may benefit people and other animals with longer lifespans. Models with shorter lifespans and/or accelerated aging, attributable to more rapid ROS damage, may; therefore, be more translucent to interventions and assessed more quickly for efficacy (Magwere et al, 2006). In addition, specific genetic models such as the senescent accelerated mouse, which overproduces free radicals, and transgenic models are becoming more available. These models may provide insight into efficacy and modes of action of supplemental dietary antioxidant regimens.

VETERINARY APPLICATIONS

The science of nutritional antioxidants has advanced over the past several years. Numerous studies have revealed biologic benefits to supplementing foods or dietary regimens with oral antioxidants in a variety of species. A review of mainstream antioxidants and their application to canine and feline nutrition follows.

Vitamin E

Dogs

Requirements for vitamin E in dogs and cats were suggested as early as 1939 and modified based on selenium and polyunsaturated fatty acid (PUFA) content of foods in the 1960s (Anderson et al, 1988; Harris and Embree, 1963; Hayes et al, 1969). From published research, the National Research Council (NRC) recommends that dogs receive 22 IU vitamin E per kg/food dry matter (DM) (based on a food containing 0.1 ppm selenium, not more than 1% linoleic acid and 3,670 kcal metabolizable energy/kg DM). This results in a range roughly equivalent to 0.4 to 1.4 IU/kg body weight for maintenance (lower number) up to pregnant/lactating dogs (upper number) (2006).

Effects of vitamin E on other biologic outcomes have been tested in dogs. Investigators found that levels higher than the requirement may confer targeted biologic benefits. Increasing dietary intake of vitamin E up to 2,010 mg/kg DM in geriatric beagles improved immune function (Hall et al, 2003; Meydani, 1998). Increased intake of vitamin E in food is related directly to increased vitamin E content of skin, which may provide health benefits for dermatologic disease processes (Jewell et al, 2002). Vitamin E concentrations in blood decrease with exercise, whereas higher levels have been associated with improved performance (Piercy et al, 2001; Scott et al, 2001). Finally, vitamin E protects from ischemic damage in a variety of tissues (Jorge et al, 1996; Sebbeg et al, 1994; Fujimoto et al, 1984).

There are no published toxicity data for vitamin E in dogs; however, concentrations exceeding 2,000 IU/kg DM of food have been fed for 17 weeks without observable negative reactions (Hall et al, 2003). Although an upper limit of toxicity has not been documented, a level of 1,000 IU/kg DM of food, or 45 IU/ kg of body weight, has been suggested (NRC, 2006).

Cats

Cat foods are often higher in fat and PUFAs than dog foods, which may provide a different matrix for determining requirements. Nonetheless, several studies have shown that the amount of vitamin E needed to support growth and reproduction in cats is approximately in the same general range as that for dogs, when accounting for adequate selenium and excessive PUFAs. Thus, a range of 0.5 to 1.7 mg of vitamin E/kg body weight has been suggested by NRC (2006) for maintenance and pregnancy/lactation, respectively.

Food supplemented with vitamin E at 272 and 552 IU/kg DM food improved immune function in aged cats (Hayek et al, 2000). Supplementation with 1,000 IU D-α-tocopherol enhanced neurologic recovery in a spinal cord compression model (Anderson et al, 1988). Vitamin E supplementation at 800 IU/day via gel caps did not protect better than placebo for preventing onion powder or propylene glycol induced Heinz body anemia in cats (Hill et al, 2001). Food supplemented with vitamin E and cysteine (2,200 IU vitamin E + 9.5 g cysteine/kg food DM) protected against acetaminophen-induced oxidative production of methemoglobinemia (Hill et al, 2005). Also, pretreatment of cats with vitamin E and selenium (200 IU vitamin E + 50 μg selenium) for five days delayed motor nerve degeneration in a model of axonal degeneration (Hall, 1987). A presumed safe upper level for oral administration has not been established; however, administration of vitamin E parenterally at 100 mg/kg body weight to kittens resulted in significant mortality (Phelps, 1981).

Vitamin C

Dog and Cats

Dogs and cats are capable of synthesizing required amounts of vitamin C by de novo mechanisms (Innes, 1931; Naismith, 1958). One group of investigators showed that hepatic in vitro synthesis of vitamin C in dogs and cats was much less (i.e., 10 to 25%) than in other mammals leading to speculation that ability to synthesize vitamin C may be limited in these species; however, no followup work has been performed (Chatterjee et al, 1975). In dogs, both ascorbic acid and ester-C are rapidly absorbed, possibly by use of an active transport mechanism in the gastrointestinal tract (Wang et al, 2001).

The subchronic intravenous toxicity (i.e., LD_{50}) dose for vitamin C has been reported to be greater than 500 mg/kg/day and 2,000 mg/kg/day for cats and dogs, respectively (Körner and Weber, 1972). Supplementation of vitamin C (0, 200, 400 or 1,000 mg/day) to cats resulted in a small progressive reduction in urinary pH (Kienzle and Maiwald, 1998). In people, intake of ascorbate at the upper recommended limit of 2,000 mg/day increased urine oxalate excretion and risk of kidney stone formation (Massey et al, 2005). However, moderate supplementation of vitamin C in healthy cats (i.e., up to 193 mg/kg DM food, approximately 2 mg/kg body weight), did not appear to increase the risk of oxalate stone formation (Yu and Gross, 2005). Supplementing rats with vitamin C at 1,500 mg/kg DM food may decrease erythrocyte fragility when vitamin E is near the requirement level in food (Chen, 1981). Additionally, oral vitamin C supplementation at 1 g/day may slow racing times in greyhounds (Chapter 18) (Marshall et al, 2002).

β-Carotene and Other Carotenoids

The carotenoids, predominately β-carotene, have been subjected to preliminary studies in canine and feline nutrition. β-carotene can serve as a precursor to vitamin A in dogs, but not cats. Although carotenoids possess antioxidant properties, most of the research in dogs and cats has focused on immunomodulatory benefits.

β-carotene supplementation increases concentrations of β-carotene in canine and feline plasma and white blood cells (Chew et al, 2000, 2000a). However, the concentrations reached in feline plasma are approximately 50-fold higher than those in canine plasma at the same approximate time and dose rate, indicating that most of the β-carotene administered to dogs is probably converted to vitamin A rather than absorbed directly as b-carotene. People convert approximately 60 to 75% of β-carotene into vitamin A and absorb approximately 15% intact. From this, the mean concentration of serum β-carotene in people is approximately 0.3 μmol/l, which is approximately 10-fold greater than concentrations found in dogs receiving supplements. Nevertheless, supplementation with β-carotene reportedly improves immune function in young and aged dogs (Kearns et al, 2000; Chew et al, 2000b).

Supplementation with the carotenoid lutein increases plasma and leukocyte concentrations in dogs and cats. Food supplemented with lutein improves immune function in both species (Kim et al, 2000, 2000a). A novel form of astaxanthin provides cardioprotection from vascular occlusion in dogs (Gross and Lockwood, 2005).

β-carotene has been evaluated in beagles at very high doses (i.e., 50 to 250 mg/kg/day as an oral dose in beadlets) (Heywood et al, 1985). Although coat discoloration and liver vacuolization were noted at all dose levels, no consistent findings of toxicity were found. Carotenoid safety is not well evaluated in cats; however, it may be presumed to be very safe based on wide margins of safety in other mammals and lack of conversion to vitamin A in this species. Canthaxanthine supplementation in cats for six months induced retinal pigment epithelial changes that included some vacuolization but no functional electroretinogram changes (Scallon et al, 1988).

Selenium

Selenium was first recognized as an essential nutrient in 1957 based on its ability to spare vitamin E in exudative diathesis in chicks (Schwarz et al, 1957). The metabolic basis for selenium's nutritional function remained unclear until it was discovered in

1973 (Rotruck et al, 1973) that selenium was a component of glutathione peroxidase. Subsequently, investigators discovered several selenium-dependent glutathione peroxidase isoforms (phospholipid, cytosolic, plasma and gastrointestinal). In addition, other selenoproteins were discovered including (three iodothyronine 5'-deiodinases [types I, II and III]); two thioredoxin reductases and four other selenoproteins (in plasma [P], muscle [W], liver and prostate) (Combs, 2001).

Glutathione peroxidase primarily defends against oxidative stress by catalyzing the reduction of hydrogen peroxide and organic hydroperoxides, which react with the selenol group of the active center of selenocysteine. As a constituent of 5'-deiodinases, types I to III, selenium combats oxidative stress by deactivating large amounts of hydrogen peroxide produced by the thyroid gland, which is used for iodination of thyronine residues. The activity of phospholipid and cytosolic glutathione peroxidase protects the thyroid gland from oxidative damage.

Glutathione peroxidase and thioredoxin reductase activities are involved in a variety of key enzymes, transcription factors and receptors. Thioredoxin reductase's involvement in the modulation of redox-regulated signaling including ribonucleotide reductase, prostaglandin and leukotriene synthesis, receptor-mediated phosphorylation cascades (i.e., activation of NF-κβ) and in apoptosis is of great interest (McKenzie et al, 1998; Neve, 2002).

The selenium requirement of most animals is similar and based on maximization of glutathione peroxidase in plasma and red blood cells. The estimated selenium requirement for kittens and adult cats is 0.15 and 0.13 mg selenium/kg food, respectively (Wedekind et al, 2003, 2003a) and 0.10 mg selenium/kg food for adult dogs (Wedekind et al, 2002). Recommended allowances of selenium in pet foods, which account for bioavailability, for dogs and cats are 0.35 and 0.30 mg selenium/kg food, respectively (NRC, 2006).

Animal studies and clinical intervention trials involving people have shown selenium to be anticarcinogenic at intakes 5- to 10-fold greater than recommended daily allowances or minimum requirements (Combs, 2001; Neve, 2002). Several mechanisms have been proposed to account for selenium's anticancer effects: 1) antioxidant activity through glutathione peroxidase and thioredoxin reductase, 2) enhanced immune function, 3) altered carcinogen metabolism, 4) inhibited tumor proliferation and enhanced apoptosis and 5) inhibited angiogenesis (Neve, 2002). Studies indicate antioxidant protective ranges for selenium would be approximately 0.50 to 1.3 mg selenium/kg food DM for dogs and cats. Interestingly, the complementary nature of antioxidants such as vitamins C and E and selenium suggests that one "spares" the need for the others in protecting against lipid peroxidation. In the case of all of these antioxidants, effective levels necessary to reduce disease risk are much higher than levels needed to merely prevent nutritional deficiency.

Safe upper limits for selenium for most species are similar (Koller and Exon, 1986), approximately 2 mg selenium/kg food, although neither the Association of American Feed Control Officials (AAFCO, 2007) nor NRC (2006) suggests a safe upper limit for cats (Wedekind et al, 2003). Cats have approximately fivefold higher serum selenium concentrations compared to other species (Foster et al, 2001). This is probably attributed to the fact that selenium intakes are higher for cats than for most other species. For example, fish and other seafood, which are highly concentrated sources of selenium, are fed much more widely to cats than dogs. However, studies show that even when dogs and cats are fed foods containing the same selenium concentration, serum selenium concentrations are 40 to 60% higher in cats. Cats have significantly higher selenium concentrations in blood even when fed similar dietary selenium intakes compared to most other species including dogs. It is unclear whether cats have a higher tolerance for selenium; however, the literature suggests that diets containing similar sources and levels of selenium were more toxic for swine (Kim and Mahan, 2001) than for cats (Wedekind et al, 2003). AAFCO (2007) suggests a safe upper limit of 2 mg selenium/kg diet for dogs (Wedekind et al, 2002).

Thiols: S-Adenosyl-L-Methionine, α-Lipoic Acid, N-Acetylcysteine

Thiol metabolism has gained research momentum as redox chemistry has matured. Thiols are capable of redox reactions similar to those of oxygen and have many metabolic correlates within cells. Glutathione, S-adenosyl-L-methionine (SAMe), thioredoxin and other sulfur-containing molecules have important roles in metabolism and antioxidant defenses.

SAMe has been used to successfully treat acetaminophen toxicity in cats and dogs (Wallace et al, 2002; Webb et al, 2003). Administration of SAMe to clinically healthy cats improved indices of redox status as indicated by decreased RBC thiobarbituric acid reaction substances and increased hepatic glutathione (Center et al, 2005).

α-Lipoic acid is another thiol that may influence reduced glutathione content of cells. As a food additive, α-lipoic acid resulted in increased ratios of reduced white blood cells to oxidized forms (GSH:GSSG) in dogs (Zicker et al, 2002). Administration to cats prolongs elimination of α-lipoic acid compared to that of other species; therefore, administration rates should be adjusted accordingly (Hill et al, 2004).

N-acetylcysteine increases reduced glutathione in cats challenged orally by onion powder compared to values in controls (Hill et al, 2001). N-acetylcysteine combined with ascorbic acid inhibits virus replication in cell lines infected with feline immunodeficiency virus (Mortola et al, 1998). Cysteine in combination with vitamin E also protects cats from acetaminophen-induced oxidative damage (Hill et al, 2005).

Fruits and Vegetables

Fruits and vegetables are often rich in flavonoid, polyphenol and anthocyanidin ingredients that may possess antioxidant properties. Exhaustive research of the effects of these ingredients in dogs and cats is unavailable; however, a few studies have tried to evaluate some potential benefits of adding fruits and vegetables to dietary regimens. Oral administration of a bioflavonoid complex reduced the extent of Heinz body anemia caused by acetaminophen administration to cats (Allison et al,

2000). A combination of fruits and vegetables in a supplemented food increased selected flavonoids in the blood of aged dogs (Zicker, 2005). Although effective doses and safety of fruits and vegetables are not well evaluated, administration of onion powder to cats can result in Heinz body anemia, perhaps through increased oxidation, although it has purported antioxidant benefits in some species (Robertson et al, 1998).

Combination Therapies

Because many antioxidants work in networks, several studies looked at complex mixtures of these compounds. Physiologic outcomes are variable, but generally, effects on immune function have been positive (Devlin et al, 2001) and markers of antioxidant status or damage from oxidative stress have been reduced (Baskin et al, 2000; Jewell et al, 2000; Piercy et al, 2000; Wedekind et al, 2002a; Yu and Paetau-Robinson, 2006). Long-term supplementation with a complex mixture of antioxidants slowed cognitive decline in aged dogs and resulted in improved behavioral correlates in an in-home study (Roudebush et al, 2005). The contribution to the final results of each individual compound is unknown in any of these studies; thus, this remains an area of future research.

chews. About half of these dog owners give their dogs treats every day; on average, these respondents provide treats for their dogs five to six times per week. The pet typically receives two treats per treating occasion. Providing pets with treats continues to increase significantly; 88% of dog owners, 65% of cat owners and 73% of bird owners provide their pets with treats (PetPlace.com, 2006).

Pet owners and those taking and interpreting a dietary history can easily ignore the variable contribution of treats to the daily nutrient intake. As a generalization, dietary balance is maintained when less than 10% of the daily intake consists of table scraps or treats and the remainder is a prepared food that is complete and balanced. At low levels, treats can be considered nutritionally trivial except in certain medical conditions. Excessive feeding of treats interferes with normal appetite and dietary balance and can contribute to obesity. Inappropriate use of treats might include when: 1) the quantity consumed exceeds the manufacturer's recommendation, 2) the pet has a high intake of cream, meat, organ tissues and processed human foods and 3) up to 20% of the daily energy requirement is provided by treats used for dental benefits.

An increasingly popular treat form is dried animal tissues (e.g., bovine penis, tail, tendon or hoof and pig's ears) (**Figure 8-5**). Dried animal tissue treats are more than 85% protein, which often are characterized by a high-collagen content of low biologic value.

Treats can be part of the dietary management of obesity, diabetes mellitus, urolithiasis, cardiac failure, renal failure and adverse reactions to foods when used under medical supervision and when the nutrient profile of the treats is compatible with the appropriate veterinary therapeutic food.

Supplements

Supplements are different from treats, although the terms are sometimes used interchangeably. Treats are nutritionally trivial, but supplements are very concentrated nutrient modules. The proper role of a supplement is to correct a diagnosed nutrient deficiency. Unfortunately, many supplements are overused and present some risk for abuse and toxicosis.

The most common form of veterinary supplements is a wide variety of vitamin and vitamin-mineral combinations that are used by 10% of animal owners (Slater et al, 1995). Mineral and electrolyte supplements include calcium, phosphorus, sodium, potassium, magnesium, iron and zinc. Protein and amino acid supplements (including taurine) are also common but should only complement the base food in situations of repletion feeding.

Routine use of vitamin-mineral supplements is not needed when a dog or cat eats typical commercial pet food. One study evaluated the daily calcium and phosphorus intake of adult dogs and cats consuming an average dry commercial pet food compared with the daily-recommended allowances for these animals (**Table 8-1**) (Kallfelz and Dzanis, 1989). In dogs, average calcium and phosphorus intakes were almost three times the daily allowance, whereas in cats, intakes were 65 to 75% above the allowance. This finding suggests that supplementation of normal commercial foods with calcium and phosphorus is unnecessary. The study also found that dogs and cats consuming commercial dry rations were ingesting from two to five times the daily allowance of vitamins (**Table 8-1**). Thus, the need for routine supplemental vitamins is questionable at best when dogs and cats eat a typical commercial pet food. For pregnancy, lactation and growth, all-purpose or specific-purpose growth pet foods contain adequate nutrient levels; supplementation for these physiologic conditions is unnecessary.

Table 8-1. Daily intake of calcium, phosphorus, vitamin A and vitamin D by an adult dog or cat consuming a typical commercial dry pet food.*

Dog	**MDR****	**Average intake**
Calcium (mg/kg/day)	25	74
Phosphorus (mg/kg/day)	19	54
Vitamin A (IU/kg/day)	23	67
Vitamin D (IU/kg/day)	2.3	11
Cat		
Calcium (mg/kg/day)	41	70
Phosphorus (mg/kg/day)	36	67
Vitamin A (IU/kg/day)	46	121
Vitamin D (IU/kg/day)	4.5	9.1

Key: MDR = minimum daily requirements.

**From Nutrient Requirements of Dogs and Nutrient Requirements of Cats. National Academy of Sciences, Washington, DC: National Academy Press, 1985, 1986.

Fat supplements provide a concentrated source of calories and essential fatty acids. Corn, safflower, canola and sunflower oils mix easily with food and provide a cost-effective source of additional linoleic acid. Commercially available fatty acid supplements emphasize linoleic acid, gamma-linolenic acid and mixtures of various omega-3 fatty acids (eicosapentaenoic and docosahexaenoic acid). The usual objective for fat or fatty acid supplementation is to increase caloric intake or to improve a pet's coat. However, specific fatty acids are beneficial in certain disease conditions and are used in foods designed for those diseases.

Various herbs and yeasts have been advocated for flea control but these products have no demonstrated efficacy (Baker and Farver, 1983). Human health foods are also used to supplement pet foods. These items include sea salt, kelp, algae, lecithin, chelated minerals, enzymes and probiotic digestants of enteric microorganisms (Chapter 5). These items are sometimes used in homemade foods or provided by owners who take these supplements themselves.

The correct use of supplements is based on a diagnosis of a nutrient deficiency. Unfortunately, supplements are commonly used as "insurance" against suspected deficient intake. They may also be used when super-supplementation of a particular nutrient is perceived as a need. In the first case, a more effective, less costly and safer approach is to simply exchange the suspect food and its corrective supplement for a food that is nutritionally adequate. The super-supplementation approach creates risk for toxicosis or dietary imbalance and can violate the treatment principle of "Above All, Do No Harm."

Table 8-9. Common pet food additives.*

Antioxidant preservatives
Butylated hydroxyanisole (BHA)
Butylated hydroxytoluene (BHT)
Ethoxyquin
Propyl gallate
Rosemaric acid/rosmarequinone
Tocopherols
Antimicrobial preservatives
Calcium propionate
Citric acid
Fumaric acid
Hydrochloric acid
Phosphoric acid
Potassium sorbate
Propionic acid
Pyroligneous acid
Sodium nitrite
Sodium propionate
Sorbic acid
Humectants
Cane molasses
Corn syrups
Propylene glycol
Sorbitol
Sucrose/dextrose
Coloring agents/preservatives
Aluminum potassium sulfate
Artificial color(s)
Azo dyes (tartrazine [FD&C yellow No. 5], sunset yellow [FD&C yellow No. 6], allura red [FD&C red No. 40])
Caramel color
Iron oxide
Natural color(s)
Nonazo dyes (brilliant blue [FD&C blue No. 1], indigotin [FD&C blue No. 2])
Sodium erythrobate
Sodium metabisulfite
Sodium nitrite
Titanium dioxide
Flavors/flavor enhancers
Artificial flavors
Citrus bioflavonoids
Dehydrated cheese/dried cheese powder
Digests
Liver meal
Monosodium glutamate
Natural flavors
Natural smoke flavor
Palatability enhancers
Acidified yeast
Digests
Garlic powder/oil
Hydrochloric acid
L-lysine
Meat extracts (beef, chicken, turkey)
Onion powder/oil
Phosphoric acid
Spices
Sucrose, dextrose, cane molasses
Water (moisture)
Whey
Emulsifying agents, stabilizers and thickeners
Diglycerides (of edible fats and oils)
Glycerin
Glyceryl monostearate
Gums (hydrocolloids)
  Seaweed extracts (carrageenan, alginates)
  Seed gums (guar gum)
  Microbial gums (xanthan gum)
  Chemically modified plant materials
Modified starch
Monoglycerides (of edible fats and oils)
Miscellaneous
Charcoal
Mineral oil (reduces dust)
Polyphosphates (dental calculus prevention)
  Sodium tripolyphosphate (dough conditioner)
  Disodium phosphate
  Tetrasodium pyrophosphate
Yucca schidigera extract (flavor, odor control)

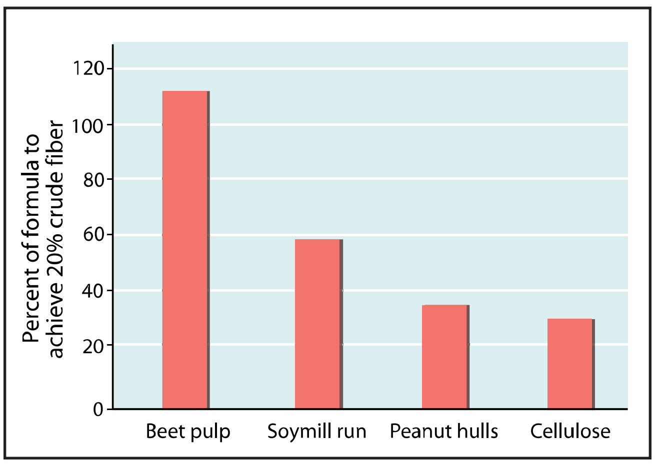

Figure 8-11. The amount (% of formula) of a particular fiber ingredient necessary to produce a product containing 20% crude fiber. Note that it is impossible to achieve 20% crude fiber in the finished food using beet pulp because the percentage exceeds 100.

Additives

Since 1920, legally sanctioned food additives have been used commonly in human and animal foods. Pet food manufacturers use various additives to generate products with visual appeal, prolonged nutritional quality, palatability and a long shelf life.

Because most commercial pet foods are designed as complete foods, nutrient enrichment with vitamins and minerals is the most important and beneficial use of pet food additives. Most ingredients with unfamiliar, chemical-sounding names are, in fact, nutrients. In general, additives other than vitamins and minerals are found least often or in smallest amounts in moist foods, and most commonly or in largest amounts in dry foods, semi-moist foods, treats and snacks.

The term "additive" is inclusive for anything imparting increased nutritional, gustatory or cosmetic appeal. Additives commonly used in prepared human and pet foods include colors, flavors, flavor enhancers, emulsifying agents, gelling substances, stabilizers, thickeners and processing aids. The terms preservative and additive are often used synonymously, but they are distinctly different. Preservatives are substances added to foods to protect or retard decay, discoloration or spoilage under normal use or storage conditions. Thus, all preservatives are additives, but not all additives serve a preservative function.

Many additives have multiple purposes in pet foods as outlined in **Table 8-9**. A few additive categories are described here in more detail.

Antioxidant Preservatives

See the shelf life and antioxidant sections in this chapter.

Antimicrobial Preservatives

Because semi-moist pet foods and treats have a high moisture content and are not maintained in a sterile environment, they often contain antimicrobial preservatives. These compounds

inhibit bacterial putrefaction, mold formation or both. Examples include acids, propylene glycol and propionate and sorbate salts.

Humectants

Humectants reduce water activity and prevent loss of water after processing. See the soft-moist manufacturing section in this chapter for more details.

Coloring Agents/Preservatives

Natural and synthetic colors are often added to pet food products to enhance consumer appeal. Examples of natural colors include the carotenoids. Synthetic colors used in pet foods include iron oxide; coal tar derivatives (azo dyes) such as tartrazine (Food, Drug & Cosmetic [FD&C] yellow No. 5), sunset yellow (FD&C yellow No. 6) and allura red (FD&C red dye No. 40) and none-azo dyes such as brilliant blue (FD&C blue No. 1) and indigotin (FD&C blue No. 2). An artificial color may only be used in a pet food in the United States if it is listed as safe in the United States Food and Drug Regulations (21 CFR 73 and 74). Several additives are not colors themselves but are used to prevent discoloration of products. Examples of color enhancers or preservatives are the nitrites and bisulfites.

Emulsifying Agents and Stabilizers/Thickeners

Gums (hydrocolloids), glycerin, glycerides and modified starch are used to prevent separation of ingredients and create the gravy, sauce or jelly portion of moist pet foods. These additives allow manufacture of high-moisture foods that are highly palatable to pets, but that do not have an excess of free water.

Gums are long-chain, high molecular weight polysaccharides that dissolve or disperse in water to build viscosity in or thicken products. Gums also are used for secondary effects that include stabilization of emulsions, suspension of particulates, inhibition of syneresis (release of water from fabricated foods) and formation of films or gels. Gums frequently used in pet foods include seaweed extracts such as alginates (brown seaweed) and carrageenan (red seaweed), seed gums such a guar gum (ground endosperm of guar plants), microbial gums such as xanthan gum (bacteria originally isolated from the rutabaga plant cultured on carbohydrate media) and chemically modified plant materials such as sodium carboxymethylcellulose (cellulose chemically modified to become water soluble). Modified celluloses and vegetable gums are frequently sprayed on the surface of commercial dry foods with digests. Water mixed with these dry foods creates a gravy.

Miscellaneous Additives

Polyphosphates are frequently used as additives in baked treats and moist pet foods. These additives serve as dough conditioners and help to improve texture, retain natural moisture and protein in meat ingredients, reduce oxidation and allow better color development.

Extracts of *Yucca schidigera* are marketed in pet foods as a means of reducing fecal odor. Yucca extracts, in higher concentrations, reduce atmospheric ammonia in livestock and poultry confinement units. Saponins or other active compounds in the extract appear to reduce levels of free ammonia by binding ammonia or converting ammonia to other products. Some yucca extracts may also inhibit urease enzymes. Whether binding or preventing free ammonia is an effective way of reducing pet fecal odor has not been proved. Yucca extract is not officially approved for odor reduction use in pet food, although it is approved as a flavoring agent for pet and human foods.

Palatability Enhancers

Pet food companies have done a great deal of work in the area of palatability enhancement. In general, dogs like fats, sugars, meat ingredients and digests, which are animal tissues that have been chemically or enzymatically altered. The digestion process from which digests are made releases amino acids, such as lysine, and dipeptide combinations that enhance palatability for dogs. Cats strongly prefer meat ingredients and inorganic acids such as phosphoric acid to fats and sweet ingredients such as whey and sugar. Cats also strongly prefer the amino acids cystine and glycine. Feline digests generally have a low pH, which also aids in preservation. Digests are available in dry and liquid forms to best accommodate the manufacturer's application process.

Formulating dry pet foods with wet meat ingredients combined with fat (up to about 25% of the product) also improves palatability (**Box 8-6**). In this process, a liquid mixture of meat, water and fat is pumped into the extruder raising the overall moisture, which is then driven off during the drying process. The palatability of the finished product is enhanced because the wet meat ingredient is cooked once in the extruder, as opposed to meat meals, which are rendered first then extruded.

Palatability enhancers are less effective in a canned matrix because of the high-moisture environment and deactivation from high processing temperatures. Therefore, meat selection becomes the most important factor in improving the palatability of a moist product. In addition, a higher moisture content can increase the palatability of moist foods. **Table 8-9** lists some palatability enhancers commonly used in the pet food industry.

COMMERCIAL PET FOOD MANUFACTURING

Principles of Extrusion/Dry Manufacturing

Most commercially prepared dry pet food is manufactured using a batch system (**Figure 8-12**). This system grinds and blends raw ingredients in predetermined amounts ranging from 1,000 to 5,000 kg, depending on capacity, then transports the resulting matrix to an extruder where it is cooked and formed into kibbles. After extrusion, the kibbles are transported to a dryer where they are dried to target moisture, and then transported again by air or vibratory or conveyor belts to sites where fat and flavor enhancers are sprayed or dusted on the surface. The kibbles may or may not be sent through a cooler. The finished product is then transported to packaging machines that place it in containers for shipment and distribution. The entire process is usually automated and computer controlled.

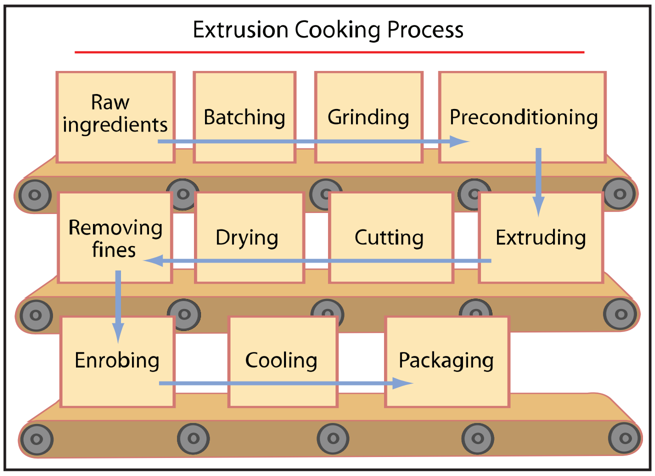

Figure 8-12. Process flow diagram for dry commercial pet food production.

Raw Materials

Ingredients used to manufacture pet foods often are received in bulk (90,000 kg by train cars; 25,000 kg by truckload) as in the case of grains or meat meals, which are the primary ingredients of any dry product, or in 25- to 50-kg bags for ingredients used in small proportions (e.g., trace minerals, crystalline amino acids and vitamins). Ingredients received in bulk are usually stored in silos until needed. Generally, the form in which a manufacturer receives ingredients depends on the physical makeup of the manufacturing plant and how much and what kind of storage units are available. Most ingredient suppliers offer multiple shipment options to best suit the needs of the manufacturer.

Grinding

Ingredients supplied as large particles may need to be ground before mixing (pregrinding) to enhance their nutritional and process characteristics. Generally, the larger the particle size, the more likely that pregrinding is necessary. A good example of this type of ingredient is whole yellow corn. A milling device known as a hammer mill is most often used to grind raw materials and the final dry mix. The hammer mill is a large capacity-milling machine that contains multiple free-swinging steel hammers and a sieve or screen that can be changed to create the desired particle size. Centrifugal force spins the hammers against the screen, pulverizing whole grains to 1,000 microns or less (Rokey, 1995).

The entire dry mix is usually ground to achieve the desired uniform particle size (e.g., usually the consistency of coarse flour). A uniform size is critical for proper water absorption, optimal passage through the extruder and thorough cooking by the extruder (Rokey, 1995). Large uncooked particles may clog the extruder die and may reduce palatability, product appearance and digestibility.

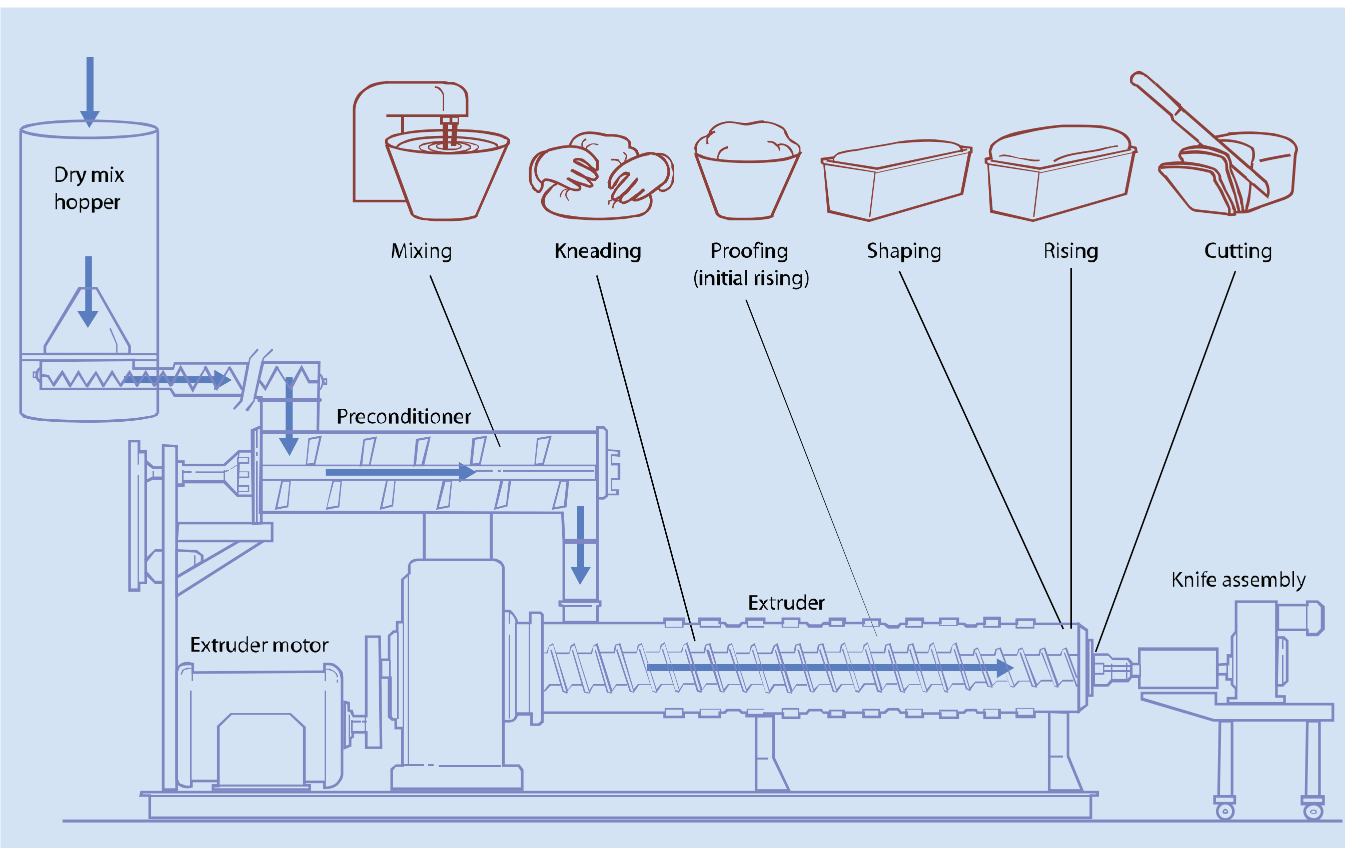

Figure 8-13. The same steps are used in bread baking and extrusion cooking: 1) mixing (preconditioner), 2) kneading (extruder barrel), 3) proofing (extruder barrel), 4) shaping (die plate), 5) rising (die plate) and cutting (rotating knives).

Compounding and Mixing

Good compounding (physically combining all of the dry mix ingredients) and mixing are essential to delivering a consistent, nutritionally adequate product. Improper compounding will result in unequal distribution of essential nutrients or lack of key ingredients in a product.

Ground bulk ingredients are usually stored in large bins. From here, they are blown, via negative airflow, into mixing hoppers. Ingredients that form a smaller percentage of the product can be added by hand and combined with bulk ingredients. Computer-controlled scales weigh dry mix ingredients to ensure they are present in desired quantities.

After a "batch" of dry mix is compounded it must be properly mixed. Mixer types and times are carefully selected based on the flow characteristics of the ingredients that compose the mixture. Because particle size, density and shape influence flow characteristics, a ribbon blender is often used for thorough mixing (Harnby, 1993). A ribbon blender is a horizontal blending machine that has a shaft running through the middle of the mixer. A ribbon of steel attached to the shaft is the mixing element. A ribbon blender is able to thoroughly mix large quantities of dry ingredients (up to 5,000 kg) and is the most commonly used mixing device. After the finished dry mix is ground for the last time, it is transferred to the extrusion process area and stored in a bin.

Extrusion

Extrusion is the primary processing method for commercially prepared dry and semi-moist pet foods. The process itself can be thought of in terms of bread making: mixing, kneading, proofing (rising of the dough), shaping, rising and slicing (**Figure 8-13**). The first step in extrusion cooking is proper preconditioning of the dry mix to start gelatinization of the starches.

The dry mix is fed into the preconditioner by a weighing system that accurately maintains a constant feed rate. The preconditioner contains mixing/conveying paddles (**Figure 8-14**) that mix the dry mix and liquid additions (fat, meat slurries, etc.), along with water and steam to increase the moisture content and prepare the mixture for cooking and forming. Generally, the dry mix and any liquid additions are retained in the preconditioner for about 45 seconds. The preconditioner achieves a 20 to 25% cook of the starch (a measure of the completeness of extrusion cooking). Extrusion provides much more flexibility in processing different formulations than do pelleting or baking technologies (**Box 8-7**).

SINGLE-SCREW EXTRUDERS

Single-screw extruders were originally used in the plastics industry and later converted to all types of food applications and are used by approximately 90% of pet food manufacturers (Rokey, 1995). Extruders come in a variety of sizes from pilot plant prototype machines to large volume machines capable of extruding 12 to 15 tons of food per hour. Single-screw extruders consist of a cylindrical multi-segmented barrel with a single screw that propels, mixes and cooks the material and forces it through a multi-holed die where it is cut to the desired length by a rotating knife (**Figures 8-15** through **8-17**). This type of extruder operates on the principle of friction. The desired cooking of the dough is achieved when the material comes in contact with the barrel wall (Johnson, 1993). The most common type of single-screw extruder used in the pet food industry is called a high shear cooker extruder (Dziezak, 1989).

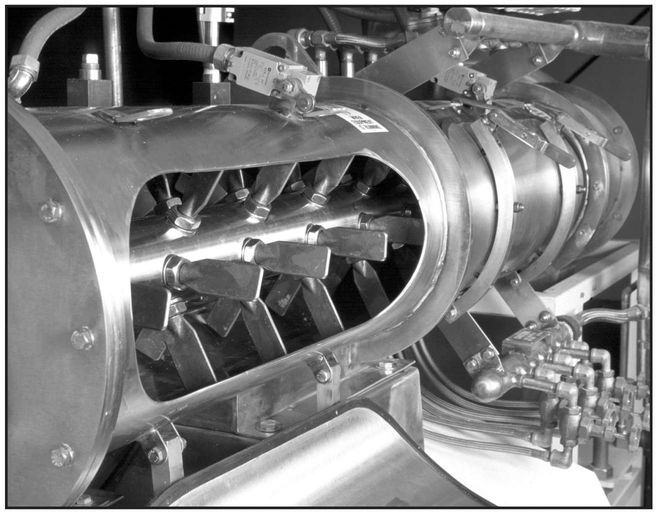

Figure 8-14. Extruder preconditioner used in commercial pet food production. The mixing and conveying paddles shown here initiate starch gelatinization and move the dry mix toward the extruder for cooking.

The process conditions of the single-screw extruder can be adjusted to produce different types of products. For example, a high-fiber, low-fat formula produces significantly more friction, and is therefore more prone to overcooking than more conventional formulas. Reducing the screw speed, screw profile, feed rate or amount of preconditioning, increasing the fat, which helps lubricate the extruder barrel or a combination of these factors will compensate for this processing challenge by reducing the cook time (residence time). Residence times can be varied from 10 to 270 seconds with temperatures ranging from 80 to 200°C (Dziezak, 1989). Because of the ingredient matrix used in pet foods, a high-temperature, short residence time (HTST) approach is used. The benefits of HTST extrusion include: 1) complete cooking, 2) destruction of microorganisms and 3) denaturing of anti-nutritional factors such as trypsin inhibitor and hydrolytic enzymes that lead to rancidity (Dziezak, 1989). Nutrient losses, however, are also incurred because of the high temperatures and shear forces (**Box 8-8**). Vitamin A and E losses of 21 to 26% and thiamin losses of 12% may occur (Frye, 1995). Adding higher levels of these vitamins compensates for losses during extrusion.

TWIN-SCREW EXTRUDERS

Similar to the single-screw extruder, the twin-screw extruder was borrowed from the plastics industry and introduced to the food industry in the early 1970s (Dziezak, 1989). As their name implies, twin-screw extruders have components similar to those of single-screw extruders, except there are two screws. These

Box 8-7. Baking and Pelleting Technology.

The first commercial pet foods were produced using baking technology. Currently, the baking process is used primarily for the manufacture of treats. The baking process uses equipment similar to that used for extrusion in the initial phases. Raw materials need to be finely ground and mixed before they are combined with water to form a "dough." Rollers then flatten the dough as it proceeds to the forming stage called a rotary molding. The dough flows along a conveyor belt where it passes underneath a cylindrical rotor that contains the desired product shape outlines, similar to a large multi-shape cookie cutter. As the dough is "molded" into shapes, the rotor turns and releases the product now cut into shapes. An oven then bakes the product and in the final stages cools it so that it can be packaged.

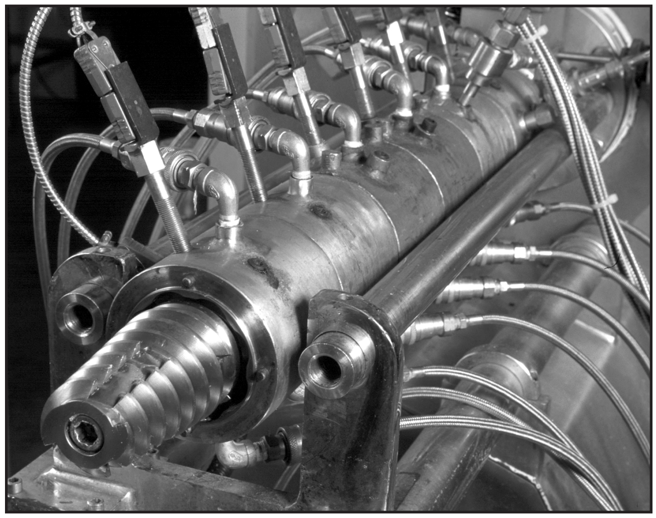
Shape and product definition in baking are almost always superior to that of extrusion. Because the rotor can be tooled to make any detailed outline with little product expansion, the baked treat can have detail that extruded foods cannot achieve. The baking process, however, is less flexible than extrusion. High-wheat formulations (and, therefore high gluten) are necessary to provide product shape and rigidity. Fat levels must be contained in a relatively small range. Too much fat will inhibit the molding process and too little will cause the newly formed pieces to stick in the rotor. Leavening agents must be used to expand the product and maintain texture.

The pelleting process, which is mainly used to make livestock feeds, is similar to extrusion, but has notable differences. The dry mix must be even more finely ground because the pellet mill has less flexibility in particle size than an extruder. The preconditioning phase is also longer in pelleting because most of the starch gelatinization must occur before product enters the pellet mill. Pressure from pressing the dry mix into the multi-hole die translates to cooking the mix and forming pellets.

The pelleting process is markedly slower and has lower output than extrusion. Ingredient selection and process flexibility are limited in pelleting; the extruder can generate much more cooking energy, thereby allowing addition of internal fat and liquid that is incompatible with pelleting. Because pelleting uses less cooking time than extrusion (two to 16 seconds at 71 to 82ºC vs. 10 to 270 seconds at 80 to 200ºC), there is a greater risk for microbial growth and production of a non-commercially sterile product. In addition, extruded products are more digestible than pelleted products. The benefit of the pelleting process is its lower cost.

screws may be co-rotating or counter-rotating, intermeshing or non-intermeshing. The most common twin-screw extruder is the co-rotating, intermesh design (**Figure 8-15**).

The twin-screw design offers benefits over the single-screw extruder because its intermeshing screws mix more thoroughly, transfer more frictional energy and convey the dough forward more effectively. This allows a shorter residence time distribution (i.e., the amount of time the dough is in the extruder barrel) and more uniform cooking. Certain product formulations benefit from twin-screw extrusion. Products that contain a large percentage of internal fat (25%) can be made in the twin-screw extruder, but not in the single-screw extruder because of the lubricating effects of fat. Other products that are difficult to extrude, such as very sticky mixtures or formulas containing fresh meat, are more readily processed in twin-screw extruders because of their increased pumping action and increased cooking ability.



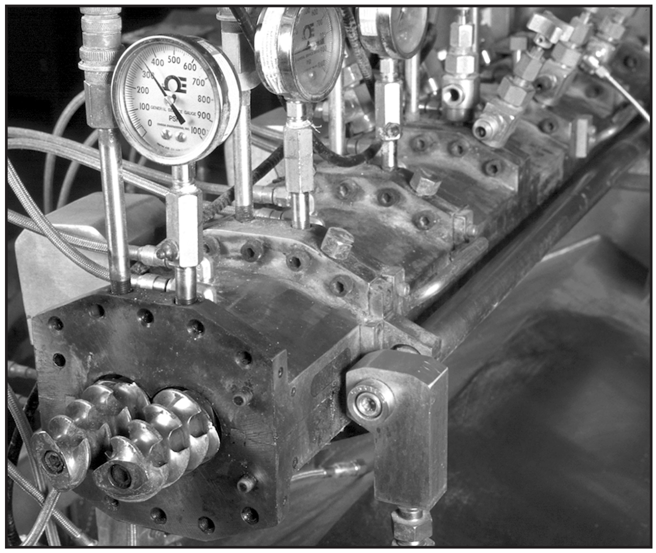


Figure 8-15. Pictures of single- (top) and twin-screw (bottom) extruders. The head of the extruder barrel has been removed showing the screw assemblies. Steam and liquid can be injected directly into the extruder barrel to modify the cooking process.

DIE AND KNIFE

The final stage in the extrusion process occurs when the gelatinized dough-like material is forced through the openings of the die. The die is a removable plate with one or more holes of the desired shape that is bolted to the head of the extruder barrel. Die configuration is an important piece of the process because the shape of the openings in the die contributes to the shape of the finished product (**Figure 8-16**). In addition, the die provides the backpressure required for developing shear. The

Box 8-8. Vitamin Losses During Processing and Storage.

In a study conducted by a major supplier of vitamins to the human and pet food industries, investigators analyzed vitamin-fortified extruded and canned pet foods for vitamin levels. The purpose of the study was to examine the processing losses of vitamins and the recommended supplementation guidelines to offset those losses. The foods were sampled before processing, after processing and after three, six, 12 and 18 months of storage. The results are shown in **Tables 1** and **2**.

In the high-moisture environment of moist pet foods, ascorbic acid (vitamin C) was completely unstable even when bound in the protective polyphosphate form. Typically stable vitamins (e.g., riboflavin, niacin, pantothenic acid, choline, vitamin B_{12} and biotin) had good processing resistance with the exception of biotin in moist dog foods. Heat- and moisture-labile vitamins (e.g., thiamin, folic acid and β-carotene) showed losses during the canning process. The fat-soluble vitamins benefit from research into protective coatings that make them much more resistant to processing losses. Storage losses were minimal due to the protective environment of the can.

Polyphosphate-bound ascorbic acid and the water-soluble B vitamins were more resistant during extrusion than in canning. Thiamin and vitamin B_{12} were lost during storage. The fat-soluble vitamins A and E had processing losses, but vitamin A remained stable, unlike vitamin E, through 18 months of storage.

Pet food manufacturers are aware of processing and storage losses of vitamins and overcome these predictable losses by supplementation. Principles of vitamin supplementation of pet foods include: 1) considering the lifestage of the animals to be fed, 2) understanding that vitamins from natural ingredients may be variable or unavailable, 3) meeting the animal's requirements with the supplemented level, 4) considering total levels from supplementation and natural sources to prevent toxicity, 5) considering the energy density of the product and 6) compensating for processing, storage and compounding losses.

Table 1. Vitamin losses (%) incurred during processing and storage of moist dog and cat foods.

	Moist cat food		Moist dog food	
Vitamin	**Processing**	**Storage***	**Processing**	**Storage***
Vitamin A	0.0	0.0	10.0	0.0
Vitamin E	0.0	9.2	4.3	10.7

die is also the final cooking point in the extruder. The number of holes in the die, the shape of the holes and the thickness of the die all contribute to the density, texture and shape of the extrudate (i.e., the material in the extruder). Generally, several die holes will cause less expansion than a single die hole and thicker dies will produce smoother kibbles.

Figure 8-16. Various die inserts can be fitted into the plate at the end of the extruder barrel. The shape of the die will determine the shape of the dry kibble pieces. The dies shown here will produce oval, round, triangular or fish-shaped pieces.

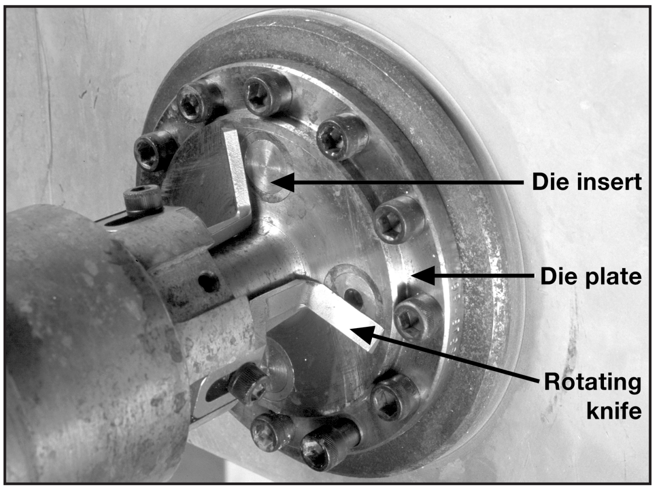

Figure 8-17. Rotating knives fit flush onto the plate at the end of the extruder barrel. The speed of rotation determines the length of the individual food pieces.

The temperature of the extrudate is between 100 to 200°C. It contains approximately 25 to 27% moisture and is under tremendous pressure (i.e., 34 to 37 atmospheres) (Dziezak, 1989). When the extrudate encounters ambient pressure and temperature at the die, moisture is flashed off, expanding the product (i.e., at least 50% greater than the die diameter) and creating the characteristic porous texture of dry pet food. The loss of between 3 to 5% moisture markedly cools the product and helps retain its shape (Colonna et al, 1989).

The extrudate resembles a rope as it leaves the die. A knife assembly on the face of the die is used to cut the extrudate to the desired size (**Figure 8-17**). The design and sharpness of the knife are critical to product appearance and size. The multi-bladed knife assembly rotates at high speed shearing off the "rope," creating kibbles. The speed the knife assembly rotates determines the length of the kibbles.

Drying/Cooling

The high-moisture, soft, spongy kibbles are conveyed by air to the dryer. During this conveyance, the kibbles lose another 2 to 3% moisture. The primary purpose of the dryer is to remove another 10 to 15% moisture from the kibbles. Heated air draws moisture out of the center of the kibble through the external surface where the moisture evaporates into the atmosphere. Reducing product moisture to between 8 and 10% inhibits mold and bacterial growth, thereby improving product shelf life.

Two types of dryers are commonly used in the production of pet foods: horizontal bed dryers and vertical bed dryers. Horizontal bed dryers are usually long rectangular machines that contain an inlet with a swing feeder, a slow-moving conveyor belt and an exit (**Figure 8-18**). Horizontal bed dryers can be single or multiple pass, meaning that the product makes one pass through or, in the case of a double-pass dryer, the product tumbles from one level and doubles back before exiting.

Vertical dryers are typically tall box-shaped machines that contain several levels or "decks" to support the newly extruded pet food as it cascades from the top to the bottom of the unit. These decks separate the product so that the drying profile can be varied to meet the needs of a specific product. Each deck uses a controlled discharge grid that can be cycled to allow all or part of the product on that deck to flow down to the next level using gravity.

Various zones of either type of dryer can be heated to different temperatures to optimize drying. The first zones are usually heated to about 80 to 100°C where the product is warmed and then moved into primary drying zones with temperatures of 120 to 150°C. Finally, the kibbles are cooled to 80 to 100°C before they exit the dryer. The typical retention time in a double-pass dryer with a cooling zone is 15 minutes for drying and seven minutes for cooling (Colonna et al, 1989).

Bed depth (height of the product on the conveyor belt or dryer deck), zone temperature, retention time and humidity all influence drying of pet food products. If the initial zones are too hot, the external surface of the kibble will dry too quickly sealing in moisture, which is known as "case-hardening." As the moisture migrates through the external surface, microfissures can form that will make the kibble more fragile, leading to breakage and excess fine particles (fines) during and after packaging. If the product is too hot as it exits the dryer and is packaged without proper cooling, condensation will occur, creating an environment that encourages mold and bacterial growth.

Enrobing

Enrobing is the process by which coatings, either liquid or dry, are applied to the kibbles in the final step before packaging. For example, coatings may be applied in a rotating drum (**Figure 8-19**) to which liquids (usually fat, flavor enhancers or both) are added in predetermined amounts. Fat is usually added in the enrobing step because it disrupts starch gelatinization and adversely affects expansion of the product. Flavor enhancers have their greatest effect upon palatability when they are applied topically. Three to four times the amount of enhancer may be needed if applied internally to achieve the same effect if

applied topically. As the drum turns, the product tumbles upon itself further coating each kibble. When dry coatings are used, a fat coating is applied first to help the dry mixture adhere to the kibbles, which are then tumbled similarly.

Packaging

Dry pet food packaging increases shelf life, protects the food from infestation and provides product information. Classically, the package of choice for dry pet foods is the bag, which can contain as little as 100 g of product for use as samples or up to 20 kg or more of product for sale in mass merchandising outlets and warehouses. Filling machines come in a variety of sizes and capacities to handle various package sizes and shapes. The process is usually automated and calibrated to ensure that the fill weight matches the guaranteed weight on the package label. An overage of 0.5 to 2% is not uncommon to ensure weight compliance.

An important consideration in choosing packaging is the type and amount of fat in the product to be packaged. As the fat percentage increases, protection from "grease out" must also increase. Grease out is caused by fat leaching out of the kibble through the bag, leaving grease stains on the bag surface. It is, therefore, of cosmetic concern and an indication of packaging integrity, and doesn't necessarily indicate rancidity or compromised product quality. The lamination of a polyethylene, or polypropylene, inner liner at a thickness proportional to the amount of fat, a natural paper middle liner and a clay-coated outer liner protect against grease out. Another consideration is the saturation of the fat used. Vegetable oils, because of their high degree of unsaturation, are liquid even at low temperatures and tend to migrate out of the kibble into the surrounding packaging. This process is accelerated if the kibble has rough or sharp edges that puncture the bag liner. Grease out may also occur more readily in conditions of high temperature during storage and distribution. Failure to compensate for these effects will lead to grease out and unsightly, stained packages.

Dry pet food products are increasingly found in nontraditional packaging. Milk cartons, buckets and jugs are just a few examples seen in retail outlets. A consideration when using alternative packaging is the effect the material has on the flavor or odor of the food. Some plastics used in packaging materials impart "off" flavors that decrease palatability.

Modified atmosphere packaging can be used to limit oxidation of fats in pet foods. Such packaging materials have a polymer with barrier properties that preclude diffusion of air including oxygen through to the kibbles. The significant reduction in gas exchange also allows for the use of nitrogen as a flushing agent, just before sealing the package, to remove oxygen from the bag, which further reduces product oxidation. This is particularly helpful with dietary fats (e.g., eicosapentaenoic acid and docosahexaenoic acid), which are highly susceptible to oxidation.

Principles of Semi-Moist Manufacturing

Extrusion

The pre-extrusion equipment used to manufacture semi-moist pet foods is very similar to that used in dry product manufacturing. Because of the higher moisture levels and humectants in semi-moist foods, extruders are generally configured to produce lower cooking temperatures and lower die pressures than found in dry product processing. These requirements are ideal for the twin-screw design, but single-screw extruders may be used. Post-extrusion equipment differs because the product does not go through the drying step, but rather goes through low agitation coating drums where water, humectants and acids are added, then through a cooler (refrigerated air) to set the product's structure and retain the high moisture content and spongy texture.

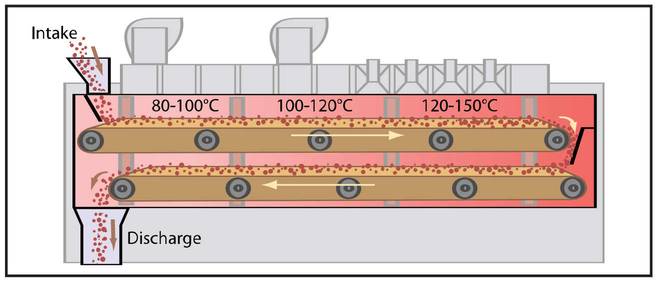

Figure 8-18. Diagram depicting pet food dryer components. Freshly extruded kibbles enter the dryer and pass through heating zones on the upper conveyor, tumble to the next conveyer, pass through the cooler zones and finally exit the dryer. (Adapted with permission, Aeroglide Corporation, Raleigh, North Carolina.)

Figure 8-19. Rotating coating drum used for applying fat and flavor enhancers to dry food. Nozzles (arrows) spray the appropriate ingredient while the product tumbles upon itself further coating each kibble.

Mold Inhibition

Semi-moist pet foods are high in moisture (25 to 35%) and, as such, are more prone to spoilage from mold and bacteria. In addition, semi-moist foods are susceptible to moisture loss leading to loss of product integrity and texture. Semi-moist products are formulated with mold and bacterial inhibitors and humectants to retain moisture and packaged in moisture-proof barrier packaging.

The measurement of how susceptible a product is to mold growth is called a_w, or water activity. It is defined as the amount of moisture available for microbial growth and is calculated

Table 8-10. Relationship between water activity and microbial growth.*

Water activity (a_w)	Phenomenon
0.90	Lower limit for general growth of bacteria (e.g., *Salmonella, Clostridium and Lactobacillus* species)
0.80	Lower limit for most enzymatic activity and growth of most fungi
0.60	Lower limit for osmophilic/xerophilic yeast and fungi
0.55	DNA becomes disordered, no growth possible

*Adapted from Bush A. Encyclopaedia of Food Science, Food Technology and Nutrition, vol. 3. London, UK: Academic Press Ltd, 1993; 1490.

Box 8-9. Maillard Reactions.

The Maillard reactions (nonenzymatic browning reaction) between protein and reducing sugars can deteriorate the nutritional quality of foods during processing or storage by affecting the availability of some amino acids. The reaction occurs when reducing sugars, such as glucose, fructose, lactose or maltose, combine with free amino groups found on amino acids such as lysine. Heat accelerates the reaction. Digestive enzymes cannot cleave the peptide bonds adjacent to an amino acid that has a sugar attached to it. Lysine typically can be made unavailable through Maillard reactions with the reducing sugars found in most pet foods. Maillard products may also increase microbial degradation of taurine in the large intestine. Amino acid and sugar Maillard reaction products are generally not absorbed or if they are absorbed they are typically excreted in the urine and are of no nutritional value to the animal. On the other hand, controlled Maillard reactions can be used during the cooking process to produce desirable flavors, colors or aromas.

In addition to Maillard reactions, heat and alkaline pH may result in unusual cross-linking of certain amino acids and peptides that are not normally found naturally. Examples such as lysinoalanine (lysine linked with alanine), lanthionine (cysteine linked with alanine) or ornithoalanine (ornithine linked with alanine) may be formed. These compounds are not used well by animals, thus they reduce the protein quality of the food. This type of amino acid cross-linking may occur during the processing of dried meat meals, ingredients often used in pet foods. However, Maillard binding of amino acids only becomes a practical nutritional problem when the amino acid is limiting. When lysine is abundant, the protein quality is not significantly degraded.

using the following formula:

a_w = % Equilibrium Relative Humidity ÷ 100.

The value for a_w is a number between 0.0 and 1.0 and is obtained using a glass jar containing the product and a humidity probe. The product is allowed to equilibrate in varying levels of humidity, which are then measured and the a_w calculated. Each strain of mold or bacteria has an a_w value at which growth is no longer possible (Bush, 1993). **Table 8-10** describes the effect of a_w upon microbial growth.

Water activity, not moisture content, becomes more important in semi-moist pet foods. Most semi-moist pet foods have high moisture contents (>30%), but relatively low a_w values because added humectants bind free water making it unavailable for microbial growth. Early preservation techniques such as salting or adding sugar lowered the a_w value of meats and, therefore, increased the shelf life stability of those foods. Common pet food humectants include: 1) high-fructose corn syrup, 2) salt, 3) propylene glycol, 4) glycerol, 5) sorbitol and 6) other polyols. Adding large amounts of humectants results in an a_w value of around 0.70, which will inhibit most microbial growth. In the United States, the Food and Drug Administration has removed propylene glycol from GRAS (generally recognized as safe) status for use in cats (Christopher et al, 1989) because of its potential toxic effects. Manufacturers in the United States have responded by removing propylene glycol in favor of glycerin or polyols. To add a margin of safety, antimycotic agents (e.g., sorbate, propionate salts or both) are added in small amounts to inhibit growth of resistant organisms. In addition, acids (phosphoric, hydrochloric, etc.) may be added to lower a food's pH to maximize antimycotic effects.

Semi-Moist Packaging

Exposure to ambient air markedly increases moisture loss in semi-moist foods. About 50% loss occurs over a 24-hour period and much of that in the first four hours. Moisture loss affects product plasticity, and therefore palatability, creating a hard, crystalline structure considerably tougher than that of dry products. Barrier packaging retains moisture that is critical to maintaining shelf life.

Most feline semi-moist products are packaged in a polypropylene inner layer bound to an aluminum foil layer that inhibits diffusion of water molecules. Most manufacturers use this type of inner layer regardless of the type of outer packaging (pouch, canister, etc.). Canine products usually contain less moisture (around 25%) but contain large amounts of sugars to control the water activity. Because the a_w value and moisture are lower in these products, the packaging can be less stringent. Nonpermeable polypropylene pouches without the foil membrane are often used.

Principles of Canning

The Frenchman Nicholas Appert invented canning as a method of food preservation in 1810 in response to the French government's need for preserved foods to support its military campaigns (Lopez, 1987). Later work by Louis Pasteur showed the relationship between processing and the reduction of food spoilage. In the 1920s, the toxic effects of mesophilic bacteria such as *Clostridium botulinum* (anaerobic spore-former) were documented and the importance of controlling these species with heat and pH was first understood.

Canning is a time/temperature-dependent process that can be adjusted to create different textural results with the ultimate goal being to achieve commercial sterility. Lower temperatures

will require more time to attain proper core temperatures; conversely, higher temperatures require less time to achieve sterilization. Because of high process temperatures and vacuum conditions in cans, canning destroys aerobic and anaerobic bacteria, making it the best method to preserve high-moisture foods for extended periods.

One newer method is the increasing use of foil pouches that most often contain a single serving of food. Products packaged in pouches usually contain increased moisture levels compared to that of loaf style cans. The high moisture content allows foods to be poured from the package into the feeding bowl. Pouches meet the needs of consumers who desire easy to store foods and single serving freshness. However, pouches increase the cost of feeding compared to dry or conventionally canned foods.

Product Form

Several types of moist pet food products and various sizes and shapes of packaging materials exist. Early canned dog foods were composed primarily of ground offal and horsemeat as by-products of the human food industry. These products were high in protein, fat and moisture and were similar in appearance to pâté. More contemporary forms include chunk and gravy, flaked, ground meat and shredded, all of which mimic foods consumed by people.

"Loaf" products contain some carbohydrate sources (corn, rice, etc.) that balance the amount of protein and fat. These products are usually lower in moisture, and because of the structural properties that starch imparts, are found in finely formed loaves. Vegetable gums and other hydrocolloid thickeners are used to create a firmer texture in canned products that contain little carbohydrate. A popular form for moist dog and cat foods is pieces of meat or fish in jelly. These products may range in form from a finely ground pâté in jelly to large chunks of meat suspended in aspic (e.g., jelly mold). A hygroscopic medium is used to create a two-phase food texture: a "piece" suspended in a medium. The viscosity of the suspension medium can vary from a semi-liquid gravy, to a jellied, savory coating to a solid, suspending jelly.

In manufacturing, the viscosity of the suspension medium is selectively regulated by using different combinations and ratios of hygroscopic sucroglycerides, starches, gums, pectins and alginates. (See Additives.) Many gums and starches are functional food "thickeners" for binding free water into semi-liquid gravies or soft jellies at room temperature. Carrageenan, carboxymethylcellulose, agar, carob, guar, acacia and xanthan gums are examples of thickeners. Pectin and alginates (seaweed derivatives) create more "solid" jellies, suspend pieces and conform to the container to form a loaf. Jellies are often golden and translucent to reveal the internally embedded pieces. Gravies are frequently opaque due to the inclusion of animal tissue meals, caramel coloring or both.

In addition to the water-binding capacity of the jellying agents, the viscosity and specific gravity of the suspension medium should approximate the density of the pieces at processing temperatures. Parity in density will help prevent separating during processing, so the pieces remain suspended.

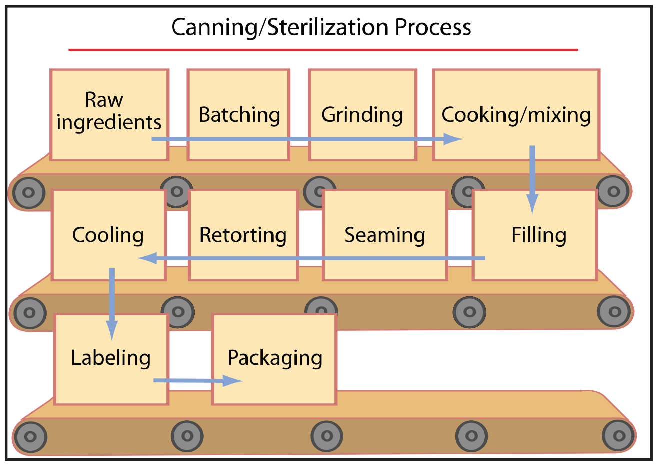

Figure 8-20. Process flow diagram for moist commercial pet food production.

The food pieces may be natural tissues or extruded vegetable and meat proteins. In some pet food markets, intact vegetable matter such as peas and carrots have consumer appeal. These elements can be natural or made from textured vegetable protein. Diced pieces can originate from large, flat cakes made from dough premix.

Canning Process

The canning process is usually continuous flow, highly automated and carefully controlled. Fresh and/or frozen meats are: 1) ground, 2) may or may not be mixed with grains, 3) subjected to steam and water, 4) filled into cans, 5) sealed and sterilized with a pressure cooking device, 6) cooled, 7) labeled and 8) put in cases (**Figure 8-20**).

MEATS/ANIMAL PROTEIN GRINDING

One of the major ingredients of any moist pet food is the animal protein component. Fresh meats and meat by-products require frequent shipments, a large refrigerated area for storage and a system of "just-in-time" manufacturing that uses the ingredients quickly to reduce waste and spoilage and assure freshness. Frozen meats require a very large freezer storage capacity and specialized grinding equipment, but offer the manufacturer flexibility in ingredient use.

Generally, meats, whether fresh or frozen, require grinding before canning and sterilization. In a continuous canning process using frozen ingredients, a predetermined sequence and amount of meat is fed into a machine that chips the frozen blocks of meat into smaller portions. The chipped meat is then conveyed to the final grinding step where it is forced through a plate that contains many one-fourth- to three-fourth-inch openings. The mechanical shear grinds the frozen meats and begins the thawing process. If multiple meat sources are used, meats may require mixing to create a homogeneous blend. The meat mixture then proceeds to a cooking step that increases the temperature of the product to a level appropriate for processing.

In a batch process, the ingredients are measured by weight, ground and placed into a cooker/mixer in one large batch. The

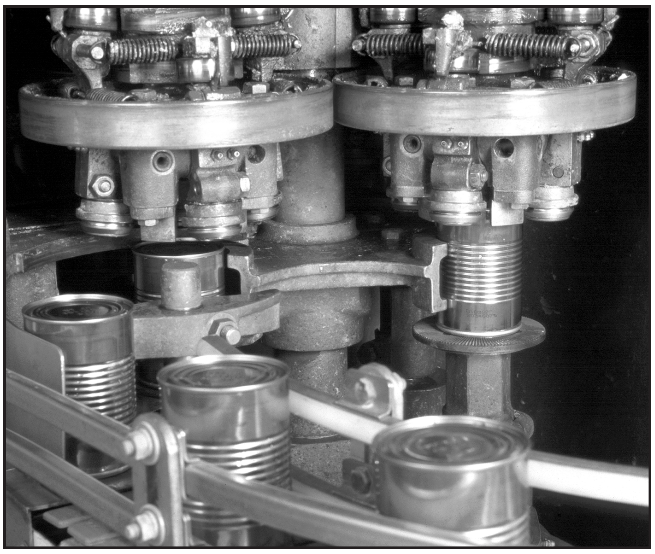

Figure 8-21. As individual cans rotate, the filler/seamer fills the can and then places and seams the lid.

process is repeated as necessary to achieve the desired amount for the manufacturing run.

COOKER/MIXER

The cooker/mixer plays a critical role in the processibility, texture and flavor of the final product. In this step, the meat mixture can be blended with pre-ground or blanched grains, starches, gums, vitamin and mineral premixes and water to complete the formulation. In addition, the entire mixture is heated to specific temperatures (25 to 85°C) to gelatinize starches and begin protein denaturation, which affects the texture, flowability and flavor of the product (**Box 8-9**). The ingredients are mixed and propelled forward in the cooker/mixer by a screw that controls the speed at which the mixture travels, and therefore, the degree of cooking.

In general, high-carbohydrate moist products will require higher processing temperatures (>70°C) to fully hydrate the starch component and maintain viscosity. When the mixture does not attain appropriate viscosity, a condition known as "spin-out" occurs. As the cans are sealed the machine rotates the cans at high speeds developing centrifugal forces. If the viscosity is low, the mixture cannot "hold" ingredients like cracked corn or rice and they will migrate to the edge of the can's contents creating a product with a tough exterior and a soft interior.

Lower temperatures (<55°C) are needed to create the proper viscosity for processing formulations high in animal tissue. Excessive cooker/mixer temperature will ruin the texture of the product after sterilization.

FILLER/SEALER

The hot mixture is usually transported to a heated storage reservoir above the filler/seamer machine. The filler/seamer is a high capacity machine (300 to 1,000 cans/min.) that fills the cans, places a lid on each can and seams the lid (**Figure 8-21**). To create the vacuum necessary for commercial sterility, steam is injected over the product just before sealing. Steam effectively displaces air and after the can is sterilized and cooled, water vapor condenses and contracts, creating a relative vacuum. The steam injection step is not required if the product is hot enough to generate water vapor to displace the air in the can.

The filling/sealing process is precisely controlled to prevent potentially hazardous conditions. The closure step on any moist pet food container is critical to ensure the product's stability. Underfilled cans will be underweight and subject to regulatory action. In addition, vacuum difficulties may lead to increased oxidation resulting in fat and vitamin destruction and product discoloration. Overfilled cans lack sufficient headspace to create a vacuum, thus the lid may improperly seal resulting in product spoilage and distended cans. Cases are stamped with a date code that identifies the year, month, day and time of production. This information may be coded or in "open" form that is easily recognized. Reputable manufacturers will provide decoding information for those who call their toll-free numbers.

STERILIZATION/RETORTING

After filling and sealing is completed, the cans are sterilized in a machine called a retort. The main objectives in retorting products are to preserve the food and achieve commercial sterility. Commercial sterility is defined as the conditions in which heat processing frees a product of microorganisms of public health significance (i.e., pathogens) (Lopez, 1987). This is not to be confused with complete sterility in which all pathogenic and nonpathogenic microorganisms are killed. The main pathogen of concern is *C. botulinum*, a rod-shaped, spore-forming, mesophilic anaerobe that produces a neuroparalytic exotoxin that causes botulism. *C. botulinum* is destroyed by temperatures above 116°C and will not grow in acidic conditions (pH <4.6). In general, process temperatures should be at least 121°C for a minimum of three minutes to kill pathogenic bacteria.

Manufacturers must document process times and temperatures for each formula produced. This time/temperature relationship can be established by process testing using cans of the formula that have thermocouples attached so that internal temperature at the coldest spot can be measured. More time is needed at lower temperatures to kill the same organism. As an example, process temperatures of 121°C for three minutes are equivalent to 100°C for six hours. The relationship is established when the temperature at the coldest spot is greater than 116°C for the required time.

Various pressure-cooking devices (retorts) are available. All retorts follow the same basic process steps, or "phases," that ensure commercial sterility: 1) bring-up phase, 2) sterilization phase and 3) cooling phase. The bring-up phase uses hot water or steam to gradually heat the can contents to 80 to 100°C. In the sterilization phase, pressurized steam or water at temperatures between 116 and 129°C raise and maintain the temperature of the can above 116°C, long enough (60 to 90 min.) to kill all pathogenic bacteria. The cool-down phase (80 to 100°C) starts the cooling process. The cooling phase uses water at a temperature of 18 to 25°C, depending on the retort used. The cans are cooled to between 32 and 40°C to allow non-mechanical drying of the outside of the can and to prevent rusting.

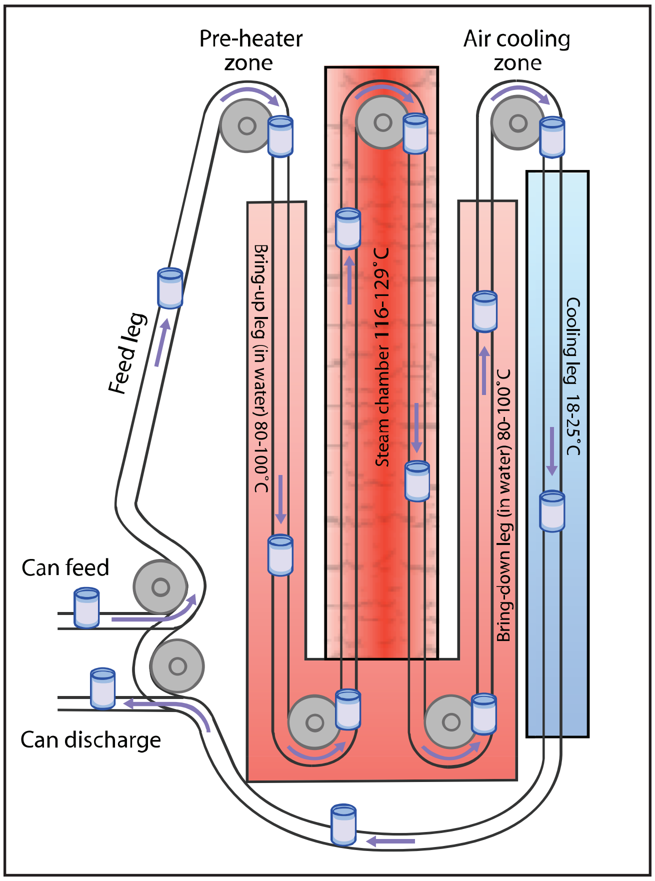

Figure 8-22. A diagram of the continuous process flow of the hydrostatic retort. Cans enter the feed leg and are brought up to temperature in the bring-up leg, then enter the sterilization leg (steam chamber) where the product is sterilized and finally enter the bring-down leg and cooling leg where the cooling process is completed.

These temperatures are not hot enough to continue cooking the cans' contents.

RETORTS

Retorts have been designed to process all types of packages from baby food jars to cans that hold more than 3 kg of fruit or vegetables. Several types of retorts are used by the pet food industry, but hydrostatic and batch retorts are most common.

The hydrostatic retort is a continuous process machine that conveys the cans on carriers that are connected to a chain drive in a tower layout. The cans advance through the various legs of the process in a continuous loop transitioning from water to steam and back to water again (**Figure 8-22**). This type of sterilization method is called hydrostatic because the steam pressure, and therefore temperature, is controlled by water pressure in the water legs. Because the cans slowly rotate on their sides throughout the process, the gas bubble is evenly distributed on the outside surface as the cans' contents. This is evident by the uniform appearance of pâté and loaf-type products produced in this manner.

Batch retort sterilizers, as the name implies, are loaded, processed and cooled in a batch-type manner. These sterilizers can be configured vertically or horizontally; the vertical configuration is used most commonly in the pet food industry (**Figure 8-23**). Some batch retorts have three to four baskets that are filled and lowered into the retort for processing. The baskets must then be lifted out of the retort, the cans cooled and sent for labeling. The benefit to this system is that the headspace is kept constant because the cans are oriented vertically without agitation, resulting in a uniform appearance. The disadvantages are that the system is labor intensive and has a low production capacity. This system works well for test batches and pilot work.

Figure 8-23. In a batch retort sterilizer, cans are loaded, processed and cooled in baskets (batch-type manner) rather than in a continuous process as occurs in hydrostatic retorts.

The automated crateless system is a newer batch retort. In

Table 8-11. Standard accelerated stability tests and their conditions.*

Test	Conditions	Comments
Ambient storage	Room temperature Atmospheric pressure	Too slow
Light	Room temperature Atmospheric pressure	Different mechanism
Metal catalysts	Room temperature Atmospheric pressure	More decomposition
Weight-gain method	30 to 80°C Atmospheric pressure	Endpoint questionable
Schaal oven	60 to 70°C Atmospheric pressure	Fewest problems
Oxygen uptake	80 to 100°C Atmospheric pressure	Different mechanism
Oxygen bomb	99°C 65 to 115 psi O_2	Different mechanism
Active oxygen (AOM)	98°C Air bubbling	Different mechanism
Rancimat	100 to 140°C	Endpoint questionable

*Frankel EN. Trends in Food Science & Technology 1993; 4: 220-225.

this system, cans from the sealer are conveyed to a bank of vertical retorts filled with water and situated over a cooling canal filled with cold water. The first retort loads cans from the top, where they tumble to the bottom and are cushioned by water. When the first retort is filled, the conveyor moves to the next sterilizer and the process is repeated. After the retort is filled with cans, the cushion water removed, the retort vented, the cans sterilized by steam, an unloading valve at the bottom allows the cans to tumble into the cooling canal. The cans are cooled and conveyed forward for labeling and casing. This system has four to five times the capacity of the crate retort system. Product appearance, however, may be inconsistent because the headspace bubble will settle to the top regardless of the can's orientation.

LABELING/CASING

The temperature of cans coming out of the cooling leg will be between 32 and 40°C, which causes rapid evaporation of exterior moisture. The vacuum in the can is a critical quality component that assures seal integrity. Can vacuum is determined with a sensor that scans the tops of the cans just before labeling. If the can lid is convex, the can will be rejected automatically.

The dry cans then proceed to the labeling system, which automatically applies adhesive and the appropriate label at a rate of about 450 to 500 cans per minute.

After labeling, the cans proceed to casing, which is an automated process that orients the cans, prepares the cardboard or paper case from flat stock, loads the appropriate number of cans per case and then seals the case with adhesive at a rate of about 1,000 to 1,300 cases per hour. Date code information is ink-jetted on the case for rapid identification, and the cases are loaded onto pallets for transportation.

QUALITY CONTROL PROCEDURES

Because pet owners depend on people at the distribution outlet (veterinary hospital, pet store, etc.) or word of mouth (breeder, veterinarian, other pet owners) for information about a company or its products, endorsements and company reputation are direct or indirect statements about quality. Quality is a relative term meaning different things to different people.

Quality procedures for manufacture of pet foods are neither required nor regulated. Implementation of a quality program is the sole responsibility of individual pet food manufacturers. Some companies go to the expense of studying and implementing world-class manufacturing processes (benchmarking); others do very little. Some companies use high-quality human and pet food grade ingredients; others purchase the least costly ones. Some companies conduct multiple tests to evaluate the quality of raw ingredients and finished products; others do what is minimally necessary. Some companies submit to voluntary plant inspections; others avoid such evaluations.

The rest of this chapter describes quality-manufacturing procedures that some pet food manufacturers follow in the continuous pursuit of product excellence. The information discussed below should give the reader examples of a quality manufacturing program employed by companies whose reputation is built upon the products and services they provide.

Ingredients and Process

Understanding and controlling raw ingredients and the manufacturing process are the keys to manufacturing a high-quality pet food. A good quality program to ensure raw ingredient integrity is essential. The key elements of such a program include: 1) ingredient specifications, 2) ingredient receiving and testing procedures and 3) ingredient handling procedures at the plant.

The contractual agreement with suppliers should list ingredient specifications including nutrient composition, purity requirements, key analytical criteria and shipping conditions. Receiving procedures at the manufacturing site should include analytical testing of ingredients, physical inspections and checks to ensure raw ingredients are segregated appropriately and maintained properly. Handling procedures after receiving and initial bulk storage are designed to ensure ingredients are not damaged in any fashion. Proper conveyance mechanisms, rodent and insect control procedures and appropriate design of holding vessels to ensure first-in, first-out ingredient flow help eliminate damage and help ensure freshness. Good quality control practices include internal audits of these procedures and systems and audits by a third party, such as the American Institute of Baking.

Attention to the use of high-quality raw ingredients and high-quality processing will ensure a high-quality product. The essential element of a good quality program for the processing of pet foods is a complete understanding of each manufacturing unit's operation and its effect on the attributes of the finished product. Once these effects are understood, critical con-

trol points can be established around unit operations and quality systems set up to monitor and ensure conformance. The manufacturing process of pet foods primarily involves proper compounding of raw ingredients and then working this mixture for moist or dry extruded products. Therefore, quality programs must include: 1) calibration procedures for conveying the individual ingredients, 2) proper time and temperature measuring and 3) calibration procedures for the cooking process. For moist products, the sterilization program must be documented and recorded. Detailed records should be kept for each lot of product manufactured, clearly detailing the processing conditions. Routine, clearly documented calibration and correlation programs must be established for each process variable (i.e., weighing or scaling, temperatures, flow rates, etc.). Analytical and physical testing of finished product is another essential element of a good quality program.

Vendors

Pet foods contain numerous raw materials from many suppliers. A vendor quality control program is critical to ensuring receipt of high-quality raw ingredients.

A good quality vendor control program begins with: 1) testing methods for nutrient levels, 2) microbiologic evaluation and 3) toxicity testing. Defining these test methods ensures that multiple vendors of raw ingredients deliver against the same purchasing specification. A routine calibration and correlation program should be established to minimize method and operator variations. A vendor quality program should establish the frequency of analytical testing; however, each lot of an ingredient must be tested initially for moisture, protein and fat, at a minimum, to see if it adheres to ingredient specifications and for accurate compounding. Ingredients should also be routinely analyzed for other nutrients of concern (e.g., calcium, phosphorus, magnesium and sodium).

Beyond the testing required in a purchasing specification, further quality assurance can be attained through programs the food industry calls vendor self-certification. The objective of these programs is to shift the focus from final ingredient shipment testing to building of quality control procedures upstream in the vendors' process. For example, purchasing specifications for cereal grains would include a target value for percent moisture of the grain. Most certification programs require vendors to keep detailed records on the lots of material they purchase. The intent is to encourage vendors to define, understand and control their raw materials and processes so that they manufacture and supply ingredients that will fall within the pet food manufacturer's specifications.

Product Quality

The quality of the finished pet food product is quantified by how well the product meets the formulated nutrient content as well as other critical parameters, such as: 1) consistent appearance, 2) physical integrity, 3) package integrity, 4) adequacy of sterilization and 5) freedom from toxins and microbiologic concerns.

Sampling frequency should be established to ensure that any nonconforming product is identified and removed. This frequency depends on batch sizes, length of storage and normal ingredient variation history. Sampling every 30 minutes for moisture, protein, fat, calcium, phosphorus, sodium, potassium and magnesium to determine variation in the process is a good starting point. Samples can be analyzed either separately or as a composite sample collected over time if the manufacturing process is well controlled.

For dry pet foods, sampling should include: 1) each lot of raw ingredients received, 2) the mix of raw ingredients once compounded (weighed and mixed), 3) the product leaving the extruder, 4) the product leaving the dryer, 5) after any topical enrobing and 6) finished product in the package. For moist pet foods, samples should be taken from: 1) raw materials, 2) product in the cooker/mixer and 3) sterilized product.

Statistical Process Control

To ensure the most consistent quality of the finished product, modern factories use statistical process control in the manufacturing process. Statistical process control determines normal variation through chemical analysis of the product at various points in the process compared with nutrient specifications of the finished product. It also establishes control limits based on this variation.

Variables analyzed can be moisture, protein, fat or any other nutrient of concern for a particular product where consistency is required. Usually, two to three standard deviations from the mean represent the control limits. Adjustments to the manufacturing process are made only when finished product attributes are outside these control limits.

Analytical Tests

Finished products are analyzed to ensure conformity to formulated nutrient content and freedom from toxins and microbiologic concerns. At a minimum, a good quality program should include routine testing to determine percentages of moisture, protein, fat, ash, calcium, phosphorus, sodium, magnesium, potassium and crude fiber. Additionally, incoming raw ingredients and finished products should be tested for *Salmonella* and *Clostridium* species, aflatoxin and vomitoxin.

Each manufacturing facility should have an in-house laboratory that can run the above analyses as the product is produced. The results help operators adjust the process controls to ensure the finished product meets specifications. Faster analytical methods (e.g., near infrared) that can analyze several nutrients simultaneously with speed and accuracy help operators control the process. In addition to chemical analysis, the physical size, density and color should be part of the finished product specifications. In the case of canned pet foods, can seal, product texture and vacuum should be recorded in addition to chemical analysis results.

Shelf Life

Shelf life is the amount of time a product maintains nutritional, microbial, physical and organoleptic (sensory) integrity. The main cause of diminished shelf life in dry products is oxidation.

Fat, either bound in the ingredient matrix or applied to the surface of dry products is subject to the second law of thermodynamics, which states that a system follows an irreversible cascade toward entropy, or disorder. The double bonds of polyunsaturated fatty acids are particularly susceptible to attack by oxygen molecules to form fatty acid radicals and peroxide byproducts. This process is initiated by oxygen and catalyzed by iron, copper, light and warm temperatures to create a series of chemical reactions called auto-oxidation (Robey, 1994; Pappas, 1991; Halliwell, 1994). Unless checked, auto-oxidation will decrease palatability and destroy fat and fat-soluble vitamins. Oxidation does not occur in an environment lacking oxygen; therefore, moist products have a longer shelf life.

There are no recognized industry standards for shelf life. However, reasonable estimates include up to 36 months for moist foods, nine to 12 months for semi-moist foods and 12 to 18 months for dry foods. Although improved packaging technology and development of natural antioxidants (e.g., vitamins E and C, rosemary and citric acid) have increased effectiveness compared to early methods, they still do not preserve dry foods as effectively as synthetic antioxidants. Dry pet foods preserved with natural antioxidants therefore may have a shelf life markedly shorter than 12 to 18 months. Shelf-life information for products should be available from manufacturers, and can be commonly found on product bags or cans.

Antioxidants

Antioxidants are a class of compounds that function as one or more of the following: 1) electron donors, 2) oxygen scavengers, 3) free radical scavengers or 4) hydrogen donors (Pappas, 1991; Hilton, 1989). **Table 8-9** lists common antioxidants used in pet foods. Antioxidants can be synthetic or natural, used in combination with other antioxidants or alone. They also gain synergism with mineral chelators (e.g., citric and ascorbic acid), and emulsifiers (e.g., lecithin, propyl gallate) and have vastly different potencies depending on the matrix being modified and the antioxidant used. Antioxidants bind with free radicals breaking the cascade of auto-oxidation. Synthetic antioxidants (e.g., ethoxyquin and butylated hydroxyanisole [BHA]) are much more effective than the same quantities of natural antioxidants, such as mixed tocopherols or ascorbic acid. Synthetic antioxidants better resist processing losses and are effective longer, thereby extending shelf life.

Shelf-Life Determination

Shelf life in the pet food industry is usually determined through chemical analysis of oxidation products and by sensory evaluation (palatability testing and olfaction). Some of the chemical methods used for oxidation analysis include oxygen uptake, oxygen bomb, Schaal oven technique, active oxygen method and the Rancimat test (**Table 8-11**).

The methods used must be compatible with the types of fat in the food because different fats will give different results when similar analytical methods are used. In addition, most tests for oxidation rely on high temperatures (80 to 140°C), catalysts or oxygen exposure to simulate the oxidation process. These accelerated methods may produce different results than lower temperature, long-term storage tests because the process of oxidation changes dramatically at temperatures above 100°C, but at lower temperatures the results are less confounded (Frankel, 1993). Many of these tests, however, still have practical value to estimate the antioxidant potential of a given product because they can be conducted rapidly and produce results that correlate reasonably well with ambient storage conditions.

Although there is no standard format for shelf-life evaluation, one study incorporated peroxide value analysis and palatability trials in their assessment of different antioxidant systems in dog foods (Gross et al, 1994). Their design used accelerated storage (16 weeks at 48.8 ± 2.2°C) and ambient storage (12 months at 22.2 ± 1.2°C) methodologies. Peroxide values and proximate analyses were determined monthly, and feeding trials were conducted initially and after 16 weeks of accelerated storage and after five months and 12 months of ambient storage. This method of shelf-life determination was sensitive enough to detect oxidation products (rancidity) through both chemical means and reduced palatability scores.

Nutrient Stability

The oxidation cascade not only creates rancidity with its objectionable odors and flavors, but also destroys the functionality of nutrients. Pet foods contain fat, which provides essential fatty acids and the fat-soluble vitamins A, D, E and sometimes K. These compounds can be markedly reduced by oxidation, possibly leading to a food with vitamin deficiencies.

"Tell me what you eat and I will tell you what you are."
Anthelme Brillat-Savarin, 1825

INTRODUCTION

The pet food label is an important means by which specific product information is communicated between a manufacturer or distributor and consumers, veterinarians and regulatory officials. Commercial pet foods differ from human food products in that the final consumer, the animal, is not the purchaser. Thus, there are two different "customers" with regards to safety, nutritional balance and palatability. Pet food label information is not directed to the final consumer, but to the owner or veterinarian who decides what the animal will be fed.

Implementation of the Nutrition Labeling and Education Act of 1990 and the Dietary Supplement Health and Education Act of 1994 in the United States has led to increased consumer awareness of the contents and effects of various human foods. Consumer interest in human food label information has increased awareness of information available on pet food labels. The regulations governing pet food labeling are similar to human food labeling rules in many respects, but deviate significantly in some important ways. Thus, veterinarians and pet owners need to understand the rules specific to pet food labeling to obtain and best interpret information about a pet food.

The Label as a Legal Document

The pet food label is more than an attractive package cover designed to sell the product; the pet food label is also a legal document. A number of agencies and organizations regulate the production, marketing and sales of commercial pet foods in different countries. Each agency or organization has different responsibilities with varying degrees of authority (**Table 9-1**). Some of these agencies and organizations regulate the information found on pet food labels whereas others influence the regulatory process.

Pet foods are regulated at their point of sale. As an example, pet food manufactured in the United States for sale outside the United States must meet the labeling requirements established by the country in which the food is sold. Conversely, pet foods manufactured outside the United States must conform to Food and Drug Administration (FDA) and state pet food labeling requirements when sold in the United States.

PET FOOD LABELS IN THE UNITED STATES

Regulation in the United States

Association of American Feed Control Officials

Early regulators recognized the need for uniform and consistent regulation of animal feeds by forming the Association of American Feed Control Officials (AAFCO) in 1909. AAFCO is a private organization, not a regulatory body per se. However, all AAFCO members must be state or federal government officials. Members include animal feed control officials from individual U.S. states and territories, federal agencies such as FDA and government representatives from Canada and Costa Rica.

Table 9-1. Major governing agencies and organizations for commercial pet food manufacturers.

Agency	**Key functions**
Association of American Feed Control Officials (AAFCO)	Sets nutrient standards for substantiation of claims Provides model regulations for the states Provides ingredient definitions
U.S. Food and Drug Administration (FDA)	Specifies some label requirements Regulates health claims Ensures food safety Approves food additives
U.S. Department of Agriculture (USDA)	Regulates some pet food ingredients Inspects animal research facilities
State Department of Agriculture (or similar agency)	Adopts and enforces animal food regulations
National Research Council (NRC)	Evaluates and compiles nutrition research Makes nutrient recommendations
Pet Food Institute (PFI)	Trade organization that represents major pet food manufacturers in the United States
Canadian Veterinary Medical Association (CVMA)	Administers voluntary product certification in Canada
European Commission	The main legislative body in the European Union responsible for creating new directives and regulations
European Council of Ministers	Approves directives and regulations Creates basic laws
National Government (Ministry of Agriculture)	Implements European legislation and controls its application Houses national experts
European Federation of the Pet Food Industry (FEDIAF = Fédération Européenne de l'Industrie des Aliments pour Aminaux Familiers)	Trade organization that represents major pet food manufacturers in Europe
Confederation of the Food and Drink Industries of the EU (CIAA = Confédération des Industries Agro-Alimentaires de l'UE)	Trade organization that represents human food manufacturers in Europe Works closely with FEDIAF on matters of mutual interest

Representatives from pet food trade associations such as the Pet Food Institute (PFI) and the American Pet Products Manufacturers Association and professional organizations such as the American Veterinary Medical Association, Canadian Veterinary Medical Association and American College of Veterinary Nutrition cannot be members of AAFCO, but do attend AAFCO meetings and often serve as advisors to various AAFCO committees and investigators.

AAFCO provides a forum for local, state and federal feed regulatory officials to discuss and develop uniform and equitable laws, regulations and policies. In that capacity, AAFCO has developed model laws and regulations, which although are not directly enforceable (because AAFCO is not a government agency), have become the foundation for most state laws and regulations for all animal feeds. AAFCO addressed the need for information about pet nutrition and pet food regulations by forming a permanent Pet Food Committee in 1959. Model regulations applying specifically to pet foods were adopted in 1967. Amendments to the AAFCO Model Pet Food Regulations occur frequently as needed to address new information and issues relating to pet foods and nutrition. They have been adopted in various degrees by approximately two-thirds of the states. Today, individual members look to AAFCO for guidance when establishing and revising state laws and regulations.

In addition, AAFCO remains the recognized information source for pet food labeling, ingredient definitions, official terms and standardized feed testing methodology. The Model Pet Food Regulations include calorie content statement guidelines and definition of the pet food descriptive terms "light," "lean" and "reduced calorie." The Pet Food Committee has also developed criteria for the official definition of product "families" whose lead member has been tested via the AAFCO feeding trial protocol.

Many pet owners recognize the need to feed their animals nutritionally balanced pet foods. As a consequence, consumers usually purchase pet foods that are labeled "complete and balanced." One means of ensuring nutritional adequacy of a food requires that the food be formulated so essential nutrients meet specified levels. Nutrient minimums before the early 1990s were based on the recommendations of the National Research Council (NRC). In 1990 and 1991, AAFCO established the Canine Nutrition Expert (CNE) and Feline Nutrition Expert (FNE) Subcommittees to establish updated practical profiles based on commonly used ingredients. The CNE and FNE Subcommittee reports formed the basis for new dog and cat food nutrient profiles to be used as minimum standards for the formulation of dog and cat foods (AAFCO, 2007). Two separate AAFCO profiles exist for each species: one for growth and reproduction, and one for adult maintenance. Lower amounts of some nutrients were established for adult dogs and cats, eliminating unnecessary excesses. In addition, maximum levels were established for some nutrients in dog foods, including calcium, phosphorus, magnesium, fat-soluble vitamins and many trace minerals. Maximum methionine, zinc and vitamin A and D levels were established for cat foods. The AAFCO Dog and Cat Food Nutrient Profiles have replaced NRC recommendations as the basis for the substantiation of label claims.

AAFCO (2007) also publishes minimum feeding protocols

for dog and cat foods. These are minimum testing protocols used by manufacturers for substantiating the nutritional adequacy of pet foods via feeding trials and determining metabolizable energy of dog and cat foods.

Food and Drug Administration
Under the Federal Food, Drug, and Cosmetic Act, the FDA has broad responsibilities, including authority over pet foods. Today, the Center for Veterinary Medicine (CVM), in FDA, regulates pet foods in cooperation with the individual states. FDA is responsible for: 1) establishing certain animal food labeling regulations, 2) specifying certain permitted ingredients such as drugs and additives, 3) enforcing regulations about chemical and microbiologic contamination and 4) describing acceptable manufacturing procedures. Feed control officials within each state inspect facilities and enforce these regulations. Health claims on pet food labels or literature accompanying the product are subject to regulation by CVM. A health claim is defined as the assertion or implication that consumption of a food will treat, prevent or otherwise affect a disease or condition (Dzanis, 1994).

United States Department of Agriculture
The United States Department of Agriculture (USDA) is responsible for ensuring that pet foods are labeled so they are not mistaken for human foods. The USDA inspects animal ingredients used in pet foods to ensure proper handling and to guarantee that such ingredients are not used in human foods. The USDA also inspects and regulates animal research facilities. All animal research facilities owned and operated in the United States by pet food companies must fulfill USDA requirements for: 1) record keeping, 2) physical structure, housing and care of animals, 3) food and water quality and 4) sanitation. Research facilities are subject to unannounced inspections by USDA officials at least annually.

National Research Council
The NRC is a private, nonprofit organization that evaluates and compiles research conducted by others. The NRC functions as the working arm of the National Academy of Sciences, the National Academy of Engineers and the Institute of Medicine (Phillips, 1992). The National Academy of Sciences was created in 1863 to advise the United States federal government about scientific and technological matters (Phillips, 1992). The NRC was created in 1916 in response to the increased need for scientific and technical services during World War I (Phillips, 1992). The NRC is not part of the United States government, is not an enforcement agency and is not a basic research organization with laboratories of its own.

The NRC includes a Board on Agriculture and Natural Resources. One of the major activities of the Board has been the development of nutrient requirement recommendations for domestic animals. Numerous ad hoc committees have assisted in developing the series, *Nutrient Requirements of Domestic Animals.* As part of that series, a new edition of *Nutrient Requirements of Dogs and Cats* was published in 2006 (NRC, 2006). Before that, the most current NRC recommendations for dogs and cats were published in 1985 and 1986, respectively (1985, 1986). Before the development and acceptance of AAFCO's Dog and Cat Food Nutrient Profiles, the NRC publications on nutrient requirements for normal dogs and cats were the recognized authority for substantiation of label claims on commercial pet foods. The AAFCO Dog and Cat Food Nutrient Profiles have replaced the NRC recommendations as the standard to be used by pet food manufacturers in the United States for formulating foods for normal dogs and cats.

Currently, pet food labels in the United States that make reference to NRC nutritional recommendations are considered to be misbranded. The NRC recommendations are still used by some pet food manufacturers in countries other than the United States and reference to NRC is still found on some pet food labels. With the most recent NRC edition, it is anticipated that AAFCO will reconvene its expert panel to review and update the AAFCO Dog and Cat Food Nutrient Profiles in light of the new NRC recommendations. AAFCO is not expected to reinstate the NRC recommendations as the authority cited on pet food labels.

Pet Food Institute
The PFI was organized in 1958 as the national trade association of dog and cat food manufacturers in the United States. Active members of PFI produce 95% of the total dog and cat food tonnage in the United States (PFI, 1994). Affiliate members of PFI include the leading suppliers of equipment, ingredients, packaging and services to the United States pet food industry.

PFI works closely with veterinarians, humane groups and local animal control officers to sponsor public affairs and owner education programs that encourage responsible dog and cat ownership. It also represents the industry before legislative and regulatory bodies at the federal and state levels. In the past 20 years, PFI has sponsored research on amino acid requirements of dogs and cats, as well as research on the benefits of pet ownership and the beneficial role of pets in society.

Individual States
Each individual state is responsible for adopting and enforcing pet food regulations. Many, but not all, states have adopted pet food regulations that follow the model bill and model regulations established by AAFCO. The State Department of Agriculture, Regulatory Protection Division or State Chemist administers pet food regulation and enforcement in most states.

Label Design
A pet food label is divided into two main parts: 1) the principal display panel and 2) the information panel (**Figure 9-1**). The principal display panel is defined by FDA as "the part of a label that is most likely to be displayed, presented, shown or examined under customary conditions of display for retail sale." The principal display panel is the primary means of attracting the consumer's attention to a product and should immediately communicate the product identity. The information panel is defined as "that part of the label immediately contiguous

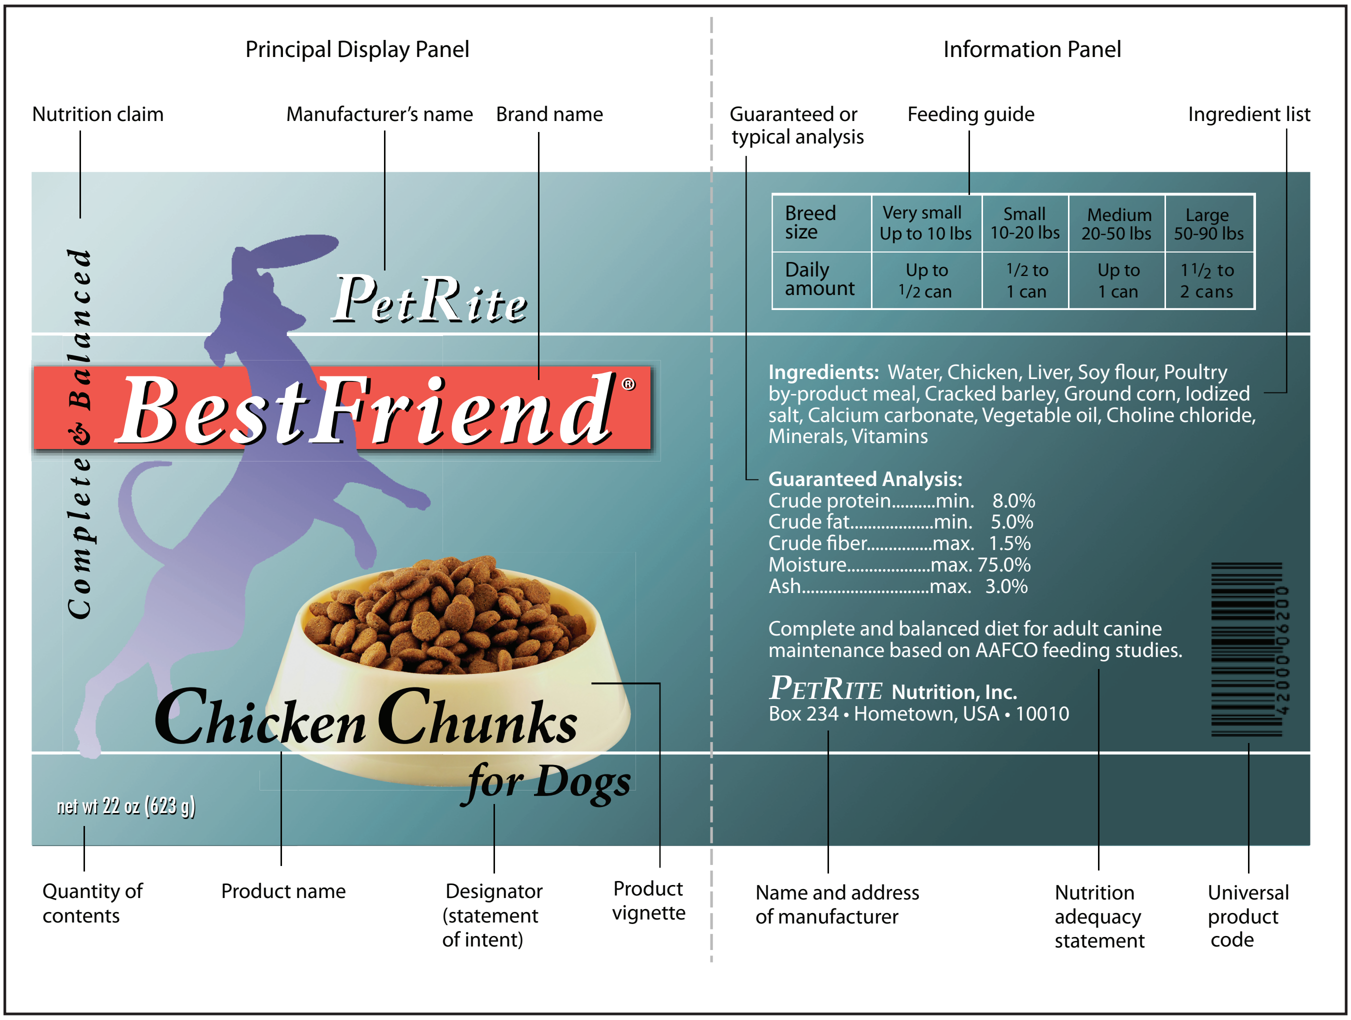

Figure 9-1. Typical pet food label with all elements.

Table 9-2. Key elements found on pet food labels in the United States and Canada.

Principal display panel	**Information panel**
Product identity	Ingredient statement*
Manufacturer's name	Guaranteed analysis*
Brand name	Nutritional adequacy or nutritional purpose statement (product description)*
Product name*	
Designator (intended species)*	Feeding guidelines*
Net weight*	Statement of calorie content
Product vignette	Manufacturer or distributor*
Nutrition claim	Universal product code
Bursts and flags	Batch information
	Freshness date

*Elements required on pet food labels in the United States, on labels certified by the CVMA Program and in some other countries.

and to the right of the principal display panel" (FDA) and usually contains important information about the product. In the United States and some other countries, several items are required by law to be included on the principal display and information panels (**Table 9-2**). The following discussion will focus on the major features found on these two portions of the pet food label.

Principal Display Panel

PRODUCT IDENTITY

The product identity is the primary means by which a specific pet food is identified by consumers. In the United States, the product identity must legally include a product name but may also include a manufacturer's name, a brand name or both. The brand name is the name by which pet food products of a given company are identified and usually conveys the overall image of the product. The product name provides information about the individual identity of the particular product within the brand. The manufacturer or distributor is not required to include its name as part of the product identity on the principal display panel, but must include its name and address on the label.

Initial assessment of pet foods is best determined by looking at the product name on the principal display panel. The product name is usually descriptive of the food and in the United States is subject to AAFCO regulations about composition of ingredients. Percentage rules are important; beef ingredients

Figure 9-2. Examples of pet food descriptor terms.

will be used as an example (**Figure 9-2**): 1) unqualified use of the term "Beef" in a product name requires that beef ingredients be at least 95% or more of the total weight of all ingredients exclusive of water used in processing, but in no case less than 70% of the total product, 2) use of the term "Beef" with a qualifier such as "Beef dinner," "Beef platter," "Beef entree," "Beef formula," or any similar designation requires that beef ingredients be at least 25% of the total weight of all ingredients exclusive of water used in processing, but in no case less than 10% of the total product, 3) the term "With Beef" is intended to highlight minor ingredients and this example requires that beef ingredients be at least 3% of the total product and 4) the term "Beef flavor" does not stipulate a minimum percentage. The beef flavor designation usually indicates that beef is less than 3% of the total product. An ingredient that gives the characterizing flavor (e.g., beef digest, beef by-products) can be used instead of the actual named flavor, beef. In fact, some ingredients may be less than 1% of the total product and still appear in the product name as a flavor. This type of regulation is also found in human foods in which the product names cranberry juice, cranberry juice cocktail and cranberry drink indicate different levels of actual juice in the product.

Percentage rules also apply to product names and moisture content of foods. In the United States, the maximum moisture content in all pet foods should not exceed 78%. However, pet foods can have moisture contents higher than 78% if they are labeled as a stew, gravy, broth, juice or milk replacer. High-moisture pet foods in cans, pouches or tins will contain terms such as "in sauce," "in aspic," "in gravy" or some similar designation in the product name.

DESIGNATOR

The words "dog food," "for cats" or some similar terminology must appear conspicuously on the principal display panel of pet foods sold in the United States. These terms clearly identify the animal for which the product is intended and that the product is not for human consumption.

NET WEIGHT

FDA regulations state that the principal display panel shall bear a declaration of the net quantity of contents. The term "Net Weight" is used most often and must be displayed in conspicuous and easily legible print. Most often, "dual declarations" are made, so that the net weight is stated in avoirdu-

Box 9-1. AAFCO Guidelines for "Natural" Claims.

"Natural" ingredients must be from animal or plant origin or a mined product (e.g., salt). Processes such as extraction, hydrolysis and fermentation are permitted.

Any chemical synthetic process, such as addition of a chemical moiety to a vitamin, is not "natural" under AAFCO definitions.

A pet food bearing an unqualified "natural" claim may not contain ANY ingredients that do not meet the AAFCO definition for "natural."

"Natural" pet foods may contain synthetic nutrients provided a qualifying disclaimer is added, e.g., "Natural ingredients with added vitamins, minerals and taurine," but not other synthetic substances such as artificial preservatives or colors.

The term "natural" may also be used to characterize a single ingredient, e.g., "natural cheese flavor," provided it does not imply that the product itself is "natural."

Table 9-3. Examples of words used on bursts and flags on pet food labels.

5 pounds more

New formula
New pâté style
New recipe
New taste
No artificial colors and flavors
Pleasant aroma
Soy free
Taste preferred 4 to 1 over leading national brand
Taste preferred over leading dog biscuit

pois (pounds and ounces) and metric (kilograms or grams) units. The regulation of net weight declarations is complex. Net weight descriptions must be placed on the principal display panel within the bottom 30% of the panel in lines generally parallel to the base of the package, and they must be separated from all other text above, below and to each side by minimum specifications. The regulations also specify minimum type sizes depending on the square inch area of the principal display panel.

PRODUCT VIGNETTE

The term product vignette refers to a vignette, graphic or pictorial representation of a product on a pet food label. This representation should not misrepresent the contents of the package. This means that a picture or other depiction of the product or ingredients on the label should not look better than the actual product or ingredients.

NUTRITION CLAIM

Nutrition statements appearing on the principal display panel are usually brief. Examples include the terms "complete and nutritious," "100% nutritious," "100% complete nutrition" or some similar designation. A nutritional adequacy statement on the information panel must substantiate nutrition claims on the principal display panel. If the nutritional adequacy statement on the information panel is for a limited lifestage (e.g., for maintenance only), the principal display panel claim must be suitably qualified, such as "100% complete nutrition for adult dogs." Manufacturers can substantiate these nutrition claims by meeting the appropriate AAFCO nutrient profile or successfully completing a protocol feeding trial. Nutrition claims substantiation for "natural" foods is discussed in more detail below (**Box 9-1**).

BURSTS AND FLAGS

Bursts and flags (**Figure 9-3**) are areas of the principal display panel that are designed to highlight information or provide specific information with visual impact. **Table 9-3** lists the type of information often included in bursts and flags. New products, formula or ingredient changes and improvements in taste are most often highlighted. The time allowed for a burst or flag to be on the label varies with the type of information. "New" or "New & Improved" can only appear on the label for six months, whereas a comparison such as "Preferred 4 to 1 over the leading national brand" can remain on the label for one year, unless resubstantiated.

Information Panel

INGREDIENT STATEMENT

Pet foods sold in the United States must list each ingredient of the food in the ingredient statement. Ingredients are listed in descending order by their predominance by weight according to the product's formula. AAFCO has established the name and definition of a wide variety of ingredients. The ingredient names must conform to the AAFCO name (e.g., poultry by-product meal, corn gluten meal, powdered cellulose) or when a suitable AAFCO name does not exist, should be identified by the common or usual name (e.g., beef, lamb, chicken). Ingredients listed as "meat" or "meat by-products" must designate the mammal from which the ingredients are derived unless the meat or meat by-products are derived from cattle, swine, sheep or goats. For example, ingredients derived from deer would be listed as venison or venison by-products. Brand or trade names cannot be used in the ingredient statement and no reference to quality or grade of ingredients can be made. Collective terms (e.g., "animal protein products"), allowed for use on livestock and poultry feed labels, are not allowed on pet food labels in the United States (**Table 9-4**).

The list of ingredients may be helpful, although it has some shortcomings that limit its usefulness for evaluating pet foods. The nutritive value of ingredients can be estimated, but not definitively determined, from the ingredient statement alone. A consumer must rely on the reputation or word of the manufacturer to assess the nutritive value of the ingredients appearing

on the list. A serious limitation of the ingredient statement is that terms such as "meat by-products" are difficult to evaluate. The nutritive value of various meat by-products varies widely. As an example, meat by-products such as liver, kidney and lungs have excellent nutritive value whereas other meat by-products such as udder, bone and connective tissue have poor nutrient availability.

Because individual ingredients are listed in descending order by weight for the product as a whole, careful reading of the ingredient list may be needed to fully understand the true relative proportions of ingredients in the product. A pet food that lists several related ingredients or different forms of the same ingredient separately (e.g., wheat germ meal, wheat middlings, wheat bran, wheat flour) could make wheat-based ingredients appear to be a lower portion of the food than is the fact. Also, because an ingredient's position on the list includes its inherent water content, this allows dry ingredients to appear lower on the list than ingredients that are naturally high in moisture.

This basic principle is commonly used in moist meat-type dog foods in which textured vegetable protein (TVP) is a major portion of the product. The ingredient list may look like this for a food named a "beef dinner:" Water sufficient for processing, meat by-products, beef, soy flour, cornstarch…. In this kind of food, water is typically combined with soy flour to produce TVP. The TVP makes up a predominant portion of the food, but soy flour appears lower on the ingredient statement because it is a "dry" ingredient whereas other components of the food are added as "wet" ingredients. The consumer thinks he or she is purchasing a beef-based food when in fact, there is more soy flour than beef when the two are compared on an equal moisture ("dry matter") basis.

This same principle is used in dry pet foods in which "fresh" meats are highlighted. The ingredient list may look like this for a lamb and rice dog food that claims to provide "real lamb meat:" Lamb, brewers rice, ground yellow corn, corn gluten meal, oat groats, poultry by-product meal, beef tallow…. Lamb appears first on the ingredient list because its moisture content is higher than that of the other dry ingredients. The predominant portion of the food contains a mixture of grains (rice, corn, oats) rather than "real meat."

Pet food additives such as vitamins, minerals, antioxidant preservatives, antimicrobial preservatives, humectants, coloring agents, flavors, palatability enhancers and emulsifying agents that are added by the manufacturer must be listed in the ingredient statement. Pet food additives must conform to the requirements of the applicable regulations in the United States Code of Federal Regulations as food additives (21 CFR 573) or as ingredients generally recognized as safe (GRAS) (21 CFR 582). Some additives are listed only in the sections for human direct food additives or for GRAS substances, but are allowed in pet foods by informal review. With FDA review and concurrence, AAFCO has also established definitions for some additives that are not formally codified in the federal regulations.

Figure 9-3. One label with a flag and one label with a burst.

Table 9-4. Ingredient statement from the same dry dog food as it would appear on pet food labels from selected countries.

United States
Ingredients: Corn Meal, Chicken Meal, Soybean Meal, Animal Fat (Preserved With Mixed Tocopherols And Citric Acid), Natural Chicken Liver Flavor, Vegetable Oil, Dried Egg Product, Flaxseed, Salt, Calcium Carbonate, Minerals (Ferrous Sulfate, Zinc Oxide, Copper Sulfate, Manganous Oxide, Calcium Iodate, Sodium Selenite), Vitamins (Choline Chloride, Vitamin A Supplement, Vitamin D_3 Supplement, Vitamin E Supplement, L-Ascorbyl-2-Polyphosphate [A Source Of Vitamin C], Niacin, Thiamine Mononitrate, Calcium Pantothenate, Pyridoxine Hydrochloride, Riboflavin, Folic Acid, Biotin, Vitamin B_{12} Supplement), Beta-Carotene.

Canada
Ingredients: Grain Products, Poultry Products, Soybean Meal, Stabilized Poultry and/or Animal Fat, Vitamins and Minerals.
CVMA-Certified Product
Ingredients: Corn Meal, Chicken Meal, Soybean Meal, Animal Fat, Dried Whole Egg, Vegetable Oil, Salt, Plus All Necessary Vitamins and Minerals.

Europe*
In Europe there are two options:
1) Ingredient groupings
Ingredients: Cereals, Meat and Animal Derivatives, Vegetable Protein Extracts, Oils and Fats, Eggs and Egg Derivatives, Minerals.
2) Individual ingredient listing
Ingredients: Ground Corn, Chicken Meal, Soybean Meal, Animal Fat, Dried Egg Product, Brewers Rice, Vegetable Oil, Iodized Salt, Calcium Carbonate, Magnesium Oxide.
*Antioxidants, preservatives, vitamins and coloring agents are not listed under ingredients because they are considered additives and are declared elsewhere on the label.

GUARANTEED ANALYSIS

In the United States, pet food manufacturers are required to include minimum percentages for crude protein and crude fat and maximum percentages for crude fiber and moisture (**Table 9-5**). Guarantees for other nutrients may follow moisture, but a nutrient need not be listed unless its presence is highlighted elsewhere on the label (e.g., "contains taurine," "calcium enriched"). Guarantees for substances not listed in the AAFCO Dog or Cat Nutrient Profiles (e.g., vitamin C, L-carnitine, glucosamine, chondroitin sulfate) should immediately

Table 9-5. Guaranteed or typical analysis from the same dry cat food as it would appear on pet food labels from selected countries.

United States (guaranteed analysis)		
Crude protein	Minimum	30.0%
Crude fat	Minimum	18.0%
Crude fiber	Maximum	2.0%
Moisture	Maximum	10.0%
Vitamin E	Minimum	275 IU/kg
Ascorbic acid (vitamin C)*	Minimum	50 mg/kg
Canada (guaranteed analysis)		
Protein	-	30.0%
Fat	-	18.0%
Moisture	-	10%
CVMA-Certified Food in Canada (guaranteed analysis)

Contains EU permitted antioxidant		
Contains EU permitted colorant		

*Not recognized as an essential nutrient by the AAFCO Cat Food Nutrient Profiles.

follow the listing of recognized nutrients and be accompanied by an asterisk referring to the disclaimer "Not recognized as an essential nutrient by the AAFCO Dog (or Cat) Food Nutrient Profiles." The sliding scale method of listing guarantees as percentage ranges (e.g., minimum 15 to 18%) is not allowed. It is important to recognize that these percentages generally indicate the "worst case" levels for these nutrients in the food and do not reflect the exact or typical amounts of these nutrients. This differs from pet food labels in Europe where "typical" percentages are used.

The term crude protein refers to a specific analytical procedure that estimates protein content by measuring nitrogen. Crude protein is an index of protein quantity but does not indicate protein quality (amino acid profile) or digestibility (Chapter 5).

Crude fat refers to a specific analytical procedure that estimates the lipid content of a food obtained through either ether extraction or acid hydrolysis. In addition to lipids, this procedure also isolates certain organic acids, oils, pigments, alcohols and fat-soluble vitamins. Because fats have more than twice the energy density of proteins and carbohydrates, crude fat can be used to estimate the energy density of the food. If the moisture and crude fiber content of two foods are somewhat similar, the food with the higher crude fat guarantee will usually have the higher energy density.

Crude fiber represents the organic residue that remains after plant material has been treated with dilute acid and alkali solutions. It is determined by a specific analytical procedure that was originally developed for the wood pulp industry and then applied to animal foods. Although crude fiber is used to report the fiber content of commercial pet foods, it usually underestimates the true level of fiber in the product. Crude fiber is an estimate of the indigestible portion of the food for dogs and cats (Chapter 5). The crude fiber method typically recovers a large percentage of cellulose and lignin in a sample, and a variable percentage of hemicellulose and even ash.

Moisture is determined by drying a sample of the product to a constant weight. The drying procedure measures water in the product as a whole, but does not distinguish between added water and water in the ingredients. Subtle differences in moisture content of moist products can result in marked differences in dry matter content and therefore the economics of feeding a given pet food. Remember, the dry matter content of the food contains all of the nutrients except water. For example, compare the dry matter content of three different moist cat foods: 1) Food A contains 72% moisture, 2) Food B contains 78% moisture and 3) Food C contains 82% moisture.

Food A   100 - 72% water = 28% dry matter
Food B*   100 - 78% water = 22% dry matter
Food C**   100 - 82% water = 18% dry matter

*28 - 22 ÷ 22 x 100 = 27% more dry matter in Food A (72% moisture) vs. Food B (78% moisture)

**28 - 18 ÷ 18 x 100 = 55% more dry matter in Food A (72% moisture) vs. Food C (82% moisture)

Therefore, what appears to be a small difference in water content of a food produces a marked difference in dry matter content. Guarantees are expressed on an "as is" or "as fed" basis. It is important to remember to convert these guarantees to a dry matter basis when comparing foods with differing moisture content (e.g., moist vs. dry foods).

Although a maximum ash guarantee is not required in the United States, many pet food manufacturers include one on the labels of their foods. In the United States, "low ash" claims are not allowed because "ash" per se is of no true significance. "Low magnesium" claims on cat food labels are allowed if the food meets certain FDA criteria. In such cases, a maximum magnesium guarantee is required. To be labeled as a "low magnesium" food, the product must contain less than 0.12% magnesium, on a dry matter basis, and less than 25 mg per 100 kcal metabolizable energy. Actual analytical values must show that the product consistently meets these levels. The estimation of magnesium content based on calculation from the guaranteed analyses must meet these criteria as well. The only exception occurs when the label bears an AAFCO calorie content statement that is higher than would be estimated from the guaranteed analysis.

Ash consists of all noncombustible materials in the food, usually salt and other minerals. A high ash content in dry and soft-moist foods generally indicates a high magnesium content. However, the ash content of moist cat foods usually correlates poorly with the magnesium content. Excessive magnesium intake may be one risk factor for feline struvite urolithiasis (Chapter 43).

Table 9-6. How to interpret label claims of nutritional adequacy.*

Claim 1: "Good Things Beef Flavor Dog Food is formulated to meet the nutritional levels established by the AAFCO (Association of American Feed Control Officials) Dog Food Nutrient Profiles for maintenance of adult dogs."
Interpretation: This food has been formulated to meet the nutrient levels in the AAFCO Dog Food Nutrient Profile for adult maintenance. This product does not meet the nutrient profile for growth/lactation and has probably not undergone AAFCO feeding tests.

Claim 2: "Good Things Chicken Recipe Cat Food meets the nutrient requirements established by the AAFCO Nutrient Profile for all stages of a cat's life."
Interpretation: This food has been formulated to meet the nutrient levels in the AAFCO Cat Food Nutrient Profile for growth/lactation and adult maintenance. This product has probably not undergone AAFCO feeding tests. The language of the statement is not in compliance with AAFCO regulations.

Claim 3: "Animal feeding tests using the AAFCO procedures substantiate that Good Things Lamb Meal and Rice Formula Dog Food provides complete and balanced nutrition for the growth of puppies and maintenance of adult dogs."
Interpretation: This food has successfully completed an AAFCO minimum protocol feeding trial for growing puppies (10 weeks of feeding) or is a family member of a tested product. It probably, but not necessarily, is formulated to meet the AAFCO Dog Food Nutrient Profiles for maintenance and growth/reproduction.

Claim 4: "Good Things Cat Food with Tuna provides complete and balanced nutrition for kittens and adult reproducing queens as substantiated by feeding tests performed in accordance with procedures established by the Association of American Feed Control Officials (AAFCO)."
Interpretation: This cat food (or a family member) has undergone AAFCO minimum protocol feeding studies for gestation/lactation and growth. This food would be nutritionally adequate for adult cats but is not recommended by this manufacturer for long-term maintenance of adult cats. The language of the statement is not in compliance with AAFCO regulations.

Claim 5: "Complete and balanced nutrition for adult maintenance based on AAFCO protocol feeding studies conducted at the Good Things Nutrition Center."
Interpretation: This food (or a family member) has undergone AAFCO minimum protocol feeding studies for adult maintenance only and has not been tested for gestation/lactation or growth. The language of the statement is not in compliance with AAFCO regulations.

Claim 6: "Complete and balanced nutrition for all lifestages of the dog, substantiated by testing performed in accordance with feeding protocols established by AAFCO."
Interpretation: This dog food (or a family member) has undergone AAFCO minimum protocol feeding trials for gestation/lactation and growth. The language of the statement is not in compliance with AAFCO regulations.

Claim 7: "Meets or exceeds the nutritional levels established by the National Research Council recommendations for all stages of a cat's life."
Interpretation: This cat food has been formulated to meet or exceed the nutrient levels established for growth, gestation/lactation and adult maintenance by the National Research Council (NRC) in the United States. This product has probably not undergone feeding tests. This nutrition statement would be considered misbranded in the United States because the NRC nutrient recommendations have been replaced by AAFCO Cat Food Nutrient Profiles. However, references to NRC are still made on pet foods sold in countries other than the United States.

Claim 8: "Good Things for Dogs: CVMA Certified; Certified by the Canadian Veterinary Medical Association to meet its nutritional standards on the basis of comprehensive feeding trials, chemical analysis and on-going monitoring."
Interpretation: This dog food meets or exceeds the standards established by the CVMA Pet Food Certification Program for adult maintenance. The food meets or exceeds the CVMA standards for nutrient content, digestibility and labeling requirements. Nutrient digestibility is the only feeding test performed after the product is initially certified.

*Claims 2, 4, 5 and 6 appear on pet food labels in the United States market, but Claim 3 is the preferred wording for products that have passed an AAFCO protocol feeding trial, and Claim 1 is the preferred wording for products that meet the profiles.

NUTRITIONAL ADEQUACY STATEMENT

Since 1984, regulations in the United States have required that all pet food labels, with the exception of products clearly labeled as "treats" and "snacks" (and more recently as "supplements") contain a statement and validation of nutritional adequacy. When a claim of "complete and balanced," "100% nutritious" or some similar designation is used, manufacturers must indicate the method and lifestage that was used to substantiate this claim (**Table 9-6**).

AAFCO (2007) regulations allow three basic methods to substantiate claims. The formulation method requires that the manufacturer formulate the food to meet the AAFCO Dog or Cat Food Nutrient Profiles. The feeding trial (protocol) method requires that the manufacturer perform an AAFCO-protocol feeding trial using the food as the sole source of nutrition. The family method allows product analyses to ensure that the pet food is a member of a product family in which the lead member has successfully passed a feeding trial.

AAFCO (2007) nutrient profiles are published for two categories: 1) growth and reproduction and 2) adult maintenance. The formulation method allows the manufacturer to substantiate a "complete and balanced" claim by calculating the nutrient content of a food using standard nutrient information about ingredients or by chemical analysis of the final product. **Table 9-6** lists some of the wording that connotes this type of claim, but the only statement that is acceptable in states that follow AAFCO Model Pet Food Regulations is "(Complete name of product) is formulated to meet the nutritional levels established by the AAFCO Dog (or Cat) Food Nutrient Profiles for (lifestage)." The formulation method is less expensive and time-consuming, but has been criticized because it does not account for acceptability of the food or nutrient availability. A report in 1991 documented that some commercial pet foods that made "complete and balanced" claims by formulation methods alone did not provide adequate growth of normal animals because of poor availability of nutrients in the food (Huber et al, 1991). However, that study was based on the older

NRC recommendations, not the AAFCO Dog Food Nutrient Profiles, which had additional safety considerations built in to help mitigate the potential for these types of deficiencies.

The feeding trial (protocol) method is generally considered the preferred method for substantiating a claim. Feeding tests can be used to support a nutritional adequacy claim for one or more of the following categories: 1) gestation and lactation, 2) growth, 3) maintenance and 4) all lifestages. AAFCO has published minimum testing protocols for adult maintenance, growth and gestation/lactation. A food that successfully completes a gestation/lactation trial followed by a growth trial using the offspring from the gestation/lactation trial can make a claim for all lifestages. The required terminology for labels of pet foods that have passed these tests is: "Animal feeding tests using AAFCO procedures substantiate that (complete product name) provides complete and balanced nutrition for (lifestage)." The wording must appear verbatim. Deviations from the above statement, while occasionally observed on some pet food labels, are currently considered misbranded in the United States (**Table 9-6**).

AAFCO feeding trials are minimum protocols. As an example, the adult maintenance protocol uses eight animals that are fed the food as the sole source of nutrition for six months. A veterinarian examines the animals at the beginning of the study and at the end of 26 weeks for clinical signs of nutritional deficiency or excess. Body weight is recorded weekly and minimal laboratory evaluations (total erythrocyte count, hemoglobin, packed cell volume, serum alkaline phosphatase, serum albumin and whole blood taurine in cats) are performed. This type of protocol will usually detect the vast majority of nutrient deficiencies but might not detect some nutrient excesses that may be harmful when fed over a longer period. In this respect, the AAFCO profiles are better because maximum levels of some nutrients are also established. Growth protocols include feeding the food for a minimum of 10 weeks. Because this test is conducted during the most critical stage of the puppy's or kitten's development, it is very sensitive in detecting deviations from normal growth. The gestation/lactation trial considers factors such as litter size and survivability and health of the dam.

The family method of nutritional substantiation is a combination of the formulation and feeding trial methods. An individual product can be a member of a product family and be nutritionally similar to a lead product that has undergone AAFCO feeding tests. AAFCO (2007) has established clear procedures for establishing pet food product families. To qualify, the family member must be the same processing type as the tested product, sufficiently close to the tested product in metabolizable energy content, analyzed and shown to meet the levels of the tested product for crude protein, calcium, phosphorus, zinc, lysine and thiamin (plus potassium and taurine for cat foods), meet either the tested product or the AAFCO Dog or Cat Food Nutrient Profiles minimums for all other nutrients and meet all established AAFCO Dog or Cat Food Nutrient Profiles maximums. When the calorie content of both the tested product and family members are determined by an AAFCO-sanctioned metabolizable energy feeding trial, the nutritional adequacy statement as used for the tested product may also be used for the family members. Although infrequently observed in the market, labels of family members whose calorie content was determined by calculation methods must state, "(complete product name) provides complete and balanced nutrition for (lifestage), and is comparable in nutritional adequacy to a product which has been substantiated using AAFCO feeding tests."

Pet foods that are clearly labeled as snacks, treats or supplements may make a nutritional adequacy claim but are not required to do so. Pet foods that fail to meet AAFCO requirements by any of the standard methods and are not clearly labeled as snacks, treats or supplements are required to have the nutritional statement: "This product is intended for intermittent or supplemental feeding only."

Veterinary therapeutic/wellness foods are those products that are intended for use by or under the supervision or direction of a veterinarian. These foods may contain the nutritional statement "use only as directed by your veterinarian." In addition to this statement, the label must include the appropriate lifestage AAFCO nutritional adequacy claim or an "intermittent or supplemental" feeding statement.

FEEDING GUIDELINES

In the United States, dog and cat foods labeled as complete and balanced (including snacks and treats) for any or all lifestages must list feeding directions on the product label for all lifestages for which the product is intended. These directions must be expressed in common terms and must appear prominently on the label. Feeding directions should, at a minimum, state, "Feed (weight/unit of product) per (weight unit) of dog (or cat)" and frequency of feeding. These feeding statements are general guidelines at best. Because of individual variation, many animals will require more or less food than that recommended on the label to maintain optimal body condition and health.

There is an exception to this rule for products that bear the "use only as directed by your veterinarian" statement. Because the veterinarian will presumably provide proper instruction about feeding of the product, explicit feeding directions are not required. Many veterinary therapeutic/wellness products, however, may still provide specific directions either on the label or in accompanying product literature.

STATEMENT OF CALORIE CONTENT

The label of a dog or cat food in the United States may bear a statement of calorie content provided the statement is separate from the guaranteed analysis and appear under the heading "calorie content." At this time, it is required for "light" and "less calorie" pet foods, but is voluntary on others. The statement is based on kilocalories of metabolizable energy (ME) on an as fed basis and must be expressed as kilocalories per kilogram (kcal/kg) of product. The statement may also be expressed as kilocalories per familiar household measure (e.g., kcal/cup, kcal/can), in addition to, but in lieu of, the kcal/kg value.

There are two methods for determining calorie content. The

first is the "calculation method," wherein analytical values for the calorie-containing nutrients in the food (protein, fat and carbohydrates) are used to estimate metabolizable energy by the "modified Atwater" formula. This formula is based on average digestibility of these nutrients in commonly used pet food ingredients. As such, it tends to underestimate the true calorie content of very highly digestible foods and overestimate the calorie content of poorly digestible foods.

Calorie content may also be determined by conducting AAFCO-sanctioned feeding trials to obtain a more accurate measurement of digestibility. The most common method is to feed animals the pet food in question for five days, then to very carefully measure food intake and fecal excretion for an additional five days. Comparing "what goes in" to "what comes out," with some additional estimates for nitrogen loss in urine, is a more reliable method for determining metabolizable energy.

To differentiate the two methods on a pet food label, a calorie content statement determined by the calculation method must include the word "calculated."

GENERAL INFORMATION

In the United States, the name and address of the manufacturer, distributor or dealer must be found on the label, usually on the information panel. The phrases "Distributed by...." or "Manufactured for...." or "Imported by...." indicate that a company other than the one selling the product has manufactured the pet food. This is a common practice with private label brand pet foods. The manufacturer in this case is called a co-packer. Regulations require that if the product is manufactured in a country other than where it is sold, the manufacturer's information be accompanied by "Product of (country of origin)."

Although not a legal requirement, most manufacturers include the universal product code (UPC) or bar code on the label. Other information such as batch numbers and date of manufacture are also frequently found on pet food containers or labels. This information is important to know when communicating with a manufacturer about product in a specific container. Some manufacturers will use a freshness date such as "Best before (date)" or list other guarantee policies.

PET FOOD LABELS IN CANADA

Regulation in Canada

The Canadian government has few pet food labeling regulations. The *Consumer Packaging and Labelling Act* specifies that three basic mandatory statements must appear in English and French languages on a pet food label for food sold in Canada: 1) product identity, 2) product net quantity (metric units first) 3) and the dealer's name and principal place of business.

The Canadian government's Competition Bureau has published a "Guide for the Labeling and Advertising of Pet Foods" (2001). This guide provides a voluntary code of conduct setting out best practices for the labeling and advertising of Canadian-produced pet foods. Although these guidelines are not law, the guide is used by the Competition Bureau in evaluating possible violations of Canadian labeling legislation and in assessing complaints about false or misleading pet food labels or advertising. For this reason, most reputable Canadian pet food companies adhere to the Competition Bureau guidelines.

CVMA Pet Food Certification

The Canadian Veterinary Medical Association (CVMA) Pet Food Certification Program was established in 1976 as a voluntary, third-party, quality assurance program for pet foods sold in Canada. The CVMA Program establishes nutrient standards, lifestage feeding protocols and digestibility feeding protocols for dogs and cats (CVMA, 1999; Allard, 1988). Similar to PFI and NRC, the CVMA is not a regulatory agency but provides a method of voluntary enforcement of certain standards for pet foods. Involvement in the CVMA Pet Food Certification Program is not mandatory.

The mission of the CVMA Pet Food Certification Program is:

> "To improve the health and well-being of pets by: 1) providing a nutritional standard for pet foods for manufacturers to meet in order to satisfy the nutritional requirements of a normal pet throughout its life, 2) certifying pet foods that meet the CVMA nutritional standards and monitoring continuously those foods to ensure that they continue to meet the standards of composition, digestibility and palatability, 3) providing the consumer with a quality assurance program and a means of identifying a nutritionally sound pet food in the marketplace, 4) ensuring the CVMA Seal of Certification becomes synonymous in the Canadian public's mind with quality and integrity by assuring that all advertising statements are fairly presented and can be supported by the advertiser and 5) helping pet owners understand the importance of proper nutrition in preventive health care and 6) encouraging the funding of small animal nutrition research" (1999).

All CVMA-certified pet foods are allowed to display the CVMA Seal of Certification on their labels for products sold in Canada. Because of AAFCO restrictions, pet food containers sold in the United States cannot display the CVMA Seal.

Principal Display Panels

Principal display panels on Canadian pet food containers may vary. The Canadian government requires that product identity and net quantity (net weight) be listed on all principal display panels of pet foods sold in Canada. Other elements of the principal display panel described under United States regulations may appear on the container depending on several factors.

The CVMA Pet Food Certification Program requires more extensive labeling requirements than does the Canadian law (Allard, 1988). The CVMA Program labeling requirements include product identity, designator and net quantity, which are usually found on the principal display panel (Allard, 1988). Nutritional claims can be stated but must be substantiated. Product names can contain ingredients (Beef stew, Beef flavor, etc.) as described earlier for United States' labels and follow roughly the same percentage rules. Pet foods that

meet the requirements can display the CVMA Seal of Certification on the principal display panel (**Figure 9-4**) (CVMA, 1999). Requirements dictate the maximum size of the logo for different sizes of containers (CVMA, 1999).

Figure 9-4. The CVMA seal.

The Competition Bureau voluntary guidelines regarding the principal display panel are similar to those for the United States and the CVMA Certification Program. These guidelines require the substantiation of any nutritional claims, and provide definitions for ingredients referenced in the product name (i.e., Beef dog food, Beef dinner etc). The Competition Bureau's guidelines follow similar percentage rules to those of the United States.

Commercial pet foods produced in the United States for sale in Canada will usually contain the elements of the principal display panel legally required in the United States; namely, 1) a product name, 2) designator and 3) net weight. Pet foods produced in Canada that are not CVMA certified are not legally required to conform to the stricter labeling requirements of the United States or CVMA Program, but most Canadian pet foods do follow the comparable guidelines published by the Competition Bureau. Other elements of the principal display panel such as the manufacturer's name, brand name, product vignette and bursts/flags are also found on Canadian labels.

Information Panels

Ingredient Statements

Ingredient statements on pet food containers in Canada also vary. Canadian government regulations do not require an ingredient statement. However, the Competition Bureau guidelines state that ingredients must be listed on the label, that manufacturers should follow the AAFCO feed ingredient definitions and ingredients should be listed in descending order by percentage of weight. The CVMA Program states that ingredients should be listed on the label in decreasing order of concentration in the product. Pet foods produced in the United States and sold in Canada will usually meet the United States regulations for ingredient lists. Pet foods produced in Canada that are not CVMA certified generally follow the Competition Bureau's guidelines even though they are not required to by law (**Table 9-4**).

Guaranteed Analysis

Canadian law does not require guarantees on pet food labels. The voluntary Competition Bureau Guidelines state that a guaranteed analysis must be shown on the label and must include the following on an "as fed" basis: crude protein (minimum %), crude fat (minimum %), crude fibre (maximum %) and moisture (maximum %). Pet foods certified by the CVMA Program must also include the above guarantees. Ash maximums (not more than 6% dry matter) are required for cat foods certified by the CVMA Program, and magnesium maximums (not more than 0.1% dry matter) are required for cat foods that make a "low ash" claim.

Nutritional Adequacy Statements

The CVMA Pet Food Certification Program has published nutrient standards and protocols for digestibility feeding trials for dogs and cats (1989). Nutrient, digestibility, feeding protocol and feeding guideline standards have also been published for "special foods" including light (lite) foods, calorie-reduced foods, geriatric foods, growth foods, gestation/lactation foods and low-ash, low-magnesium cat foods. Feeding trials are incorporated into the standards for geriatric foods (three-month period) and growth foods (weaning to six months). Products that meet these standards can display the CVMA Seal of Certification and use the following words as a nutritional statement: "This product meets nutritional standards established by the Canadian Veterinary Medical Association (CVMA)." In addition to the CVMA certification logo, products certified as special foods may carry language to the effect that: "This product is formulated to provide (claim for level of nutrients)" or "This product meets the CVMA standard for a (type of special food)."

The Competition Bureau Guidelines state that nutritional adequacy claims can be made if they are based on animal feeding protocols and nutrient profile programs such as those administered by the Pet Food Association of Canada, the CVMA or AAFCO. The guidelines further state that products that are formulated for or suitable for only a limited purpose, such as supplemental feedings or that are limited to specific lifestages, must contain a statement to that effect. If a product is intended to be used under the supervision of a veterinarian, the following claim must be included on the product label: "Use only as directed by your veterinarian." The guidelines specifically forbid drug claims (i.e., the words "diagnose," "cure," "mitigate," "treat" or "prevent" disease must not be used on a pet food label).

Some products in Canada will reference the NRC for complete and balanced nutrition claims, although this reference is no longer legal in the United States. Based on published NRC nutrient standards, these claims refer to the formulation/analysis method. **Table 9-6** includes nutritional claims that appear on pet foods sold in Canada.

Other Items on Information Panels

In Canada, pet foods certified by the CVMA must provide feeding instructions on the label if they are sold as light, calorie-reduced or geriatric foods. Pet foods certified by the CVMA Program as light, calorie-reduced or geriatric foods have energy density (kcal/gram of dry matter gross energy) standards, but

caloric density is not required on the label.

Competition Bureau guidelines also require that feeding instructions appear on the product label. The guidelines also cover misrepresentations with respect to business claims (i.e., rank of the company in the industry, length of time in business, etc.) as well as deceptive endorsements or testimonials.

PET FOOD LABELS IN EUROPE

Regulation in Europe

The regulations about pet food labeling for Europe, as discussed in this chapter, apply primarily to the 25 member states of the European Union (EU) and Switzerland. Legislation controlling pet food labels originates in EU institutions and is then implemented into national law. Outside the EU, individual countries have different structures and rules.

European Union

COUNCIL

The Council of the EU is the EU's main decision-making institution. The Council of the European Union is the forum within which the ministers of the EU meet. Depending on the subject on the agenda, each country is represented by the minister responsible for that particular subject (e.g., agriculture, public health etc.) There are nine different Council "configurations."

The Council passes laws, usually in cooperation with the EU Parliament. In principle, the EU Commission proposes laws for the Council, which examines and adopts them or proposes modifications.

EUROPEAN COMMISSION

The Commission acts with complete political independence, and must not take instructions from any member state government. The Commission has the right to propose new EU legislation and ensures that the regulations and directives adopted by the Council and Parliament are implemented. A civil service made up of 36 "Directorates-General" (DGs) and services, based mainly in Brussels and Luxembourg, assists the Commission. Each DG deals with specific matters; DG Sanco (Health and Consumer Protection Directorate General) largely regulates pet food and labeling issues. DG Sanco's work is divided into three main areas: public health, food safety and consumer protection.

In most cases, the various DGs of the European Commission prepare an initial text for adoption as a Commission Proposal. During this preparation phase, national civil servants, the industry, consumers and other interest groups and outside professionals may be consulted.

EUROPEAN PARLIAMENT

The European Parliament is the only supranational institution whose 732 members are directly elected by the citizens of the 25 member states. The European Parliament is involved in legislative activity through its 20 parliamentary committees.

Table 9-7. National member organizations of FEDIAF.

Austria: ÖHTV	Italy: ASSALCO
Belgium: BKVH/CPAF	Netherlands: VKH
Denmark, Norway & Sweden: NPFA	Poland: Polikarma
Finland: Lemmikkieläinruokayhdistys	Portugal: ALIAN
France: FACCO	Slovenia: GIZ_PHMZ
Germany: IVH	Spain: ANFAAC
Greece: GPFMA	Switzerland: VHN
Hungary: HPFA	United Kingdom: PFMA
Ireland: PFAI	

These Committees draw up legislative proposals, and amend and adopt Commission and Council proposals. Two Committees can be involved in pet food legislation: "the Committee responsible for environment, public health and food safety" and "the Committee responsible for agriculture and rural development."

LEGISLATIVE PROCESS

Two kinds of legislative pieces can come forth: a directive or a regulation. A directive must be implemented into national law within a period stipulated in the directive. The national law can be more restrictive than the European directive but must always be within the scope and spirit of the directive. A regulation must be adopted by national law without changes and is applicable almost immediately after publication. The directives for feeding stuffs contain strict provisions and stipulate definitions for ingredients, for methods of sampling and analysis and for types and maximum levels of permitted additives.

NATIONAL AUTHORITIES

The national, regional or local governments in EU countries apply the EU's health and consumer protection laws. Their job is to ensure traders, manufacturers and food producers in their country observe the rules. After a piece of legislation has been published in the Official European Journal, the national government must implement it immediately (regulation) or, in the case of a directive, translate the legislation into national law within the specified time (Borchardt, 1994). The individual countries through their Ministries of Agriculture are responsible for controlling the application of the law by checking labels and taking samples for analysis. National experts, who work closely with the European Commission on legislation, reside under the Ministries of Agriculture of the different member states.

FÉDÉRATION EUROPÉENNE DE L'INDUSTRIE DES ALIMENTS POUR AMINAUX FAMILIERS

Established in 1970, the Fédération Européenne de l'Industrie des Aliments pour Aminaux Familiers (FEDIAF) represents the pet food industry in Europe and unites the national professional organizations of 19 countries, whether they belong to the EU or not (**Table 9-7**) (FEDIAF, 1993; PFMA, 1993). FEDIAF represents approximately 450 compa-

Table 9-8. Product descriptors used in Europe.

Claim/description	Level of the named ingredient
With beef flavor Beef flavor	Greater than 0 but less than 4% of the named flavor should be present
With rabbit Contains rabbit	At least 4% of the named species should be present
High in chicken With extra chicken Extra chicken	At least 14% of the named species should be present
Beef variety Beef dinner Beef recipe Beef menu Beef with cereal	At least 26% of the named species should be present
Brand name rabbit	All contents are of the named origin with no other ingredients present except gravy, jelly, sauce, permitted additives and nutrient supplements

Net weight and/or volume
Reference (batch) number
Registration number of the plant
Species/category
Typical analysis

nies responsible for producing more than 90% of European pet food. The national organizations represent manufacturers, packers and importers of prepared pet food, including foods for dogs, cats, birds and other pets.

FEDIAF's main role is to represent the European pet food industry in all external forums (FEDIAF, Website 2006). FEDIAF cooperates with the European authorities to implement pet food law designed to ensure the manufacture and distribution of healthy, balanced and quality products. New legislation is translated by FEDIAF into labeling guidelines, which in some countries is then implemented into a "Code of Practice" for the members.

Through the nutrition working party, FEDIAF publishes nutrition guidelines as a policy paper for members. To develop these guidelines the group uses NRC recommendations, AAFCO guidelines and studies published by internationally recognized nutritionists, veterinarians and other researchers. These guidelines are updated yearly.

Through their national organizations, FEDIAF also collaborates with local and national authorities to make pet owners more aware of their responsibilities toward their pets and society.

CONFÉDÉRATION DES INDUSTRIES AGRO-ALIMENTAIRES DE L'UE

The Confédération des Industries Agro-Alimentaires de l'UE (CIAA), also known as the Confederation of the Food and Drink Industries, is analogous to FEDIAF for human foodstuffs. Both federations work closely together in matters of common interest that are regulated by the same legislation. Advertising, claims and environmental matters are regulated for human and animal foods by the same law.

Label Design

Pet food labels in Europe are divided into a Principal Display Panel and the Statutory Statement, although the distinction may be less visible than that for pet food labels in the United States. The Council Directive on the circulation of compound feeding stuffs (79/373/EEC, April 1979) regulates the statutory statement. This directive has been updated several times with a major update (Council Directive 90/44/EEC), which has been in force since January 1992. The pet food industry is also protected by Directive 2002/32/EC and amendments, which regulate maximum residue levels of undesirable substances such as heavy metals, mycotoxins and dioxins in feeding stuffs for animals and ingredients for commercial foods/feeds.

Principal Display Panel

As in the United States, this part of the label gives information about product identity, shows graphics and pictures, includes marketing claims to promote the product and contains descriptions of meat types and other information that companies may choose to convey outside of the statutory statements.

No specific rules apply to the principal display panel other than general legislation concerning misleading claims that applies to all advertising (Council Directive 84/450/EEC and amendments). Labels should not mislead the purchaser; the label must not suggest that the product possesses properties that it does not have, nor should the label imply that the product is special when similar properties are found in other products. A pet food label must not claim that the product will prevent, treat or cure disease.

Directive 90/44/EEC, Art. 5.c.4 is the only text directly referring to claims on pet food labels. It allows pet food manufacturers to claim a low or high level of a specific ingredient on the condition that the percentage is specified and that the claim reflects an essential aspect of that particular food. In the absence of more specific legislation and to protect the consumer against unsubstantiated claims, a policy for claiming meat and flavor varieties has been proposed within the FEDIAF (**Table 9-8**). These guidelines serve an advisory role and are currently under discussion. Although they are not official law with force of application, in some countries (e.g., France) the authorities use those guidelines to judge labels for misleading claims.

Statutory Statement

GENERAL

The mandatory and optional declarations are encapsulated in a space provided for that purpose and called "The Statutory

Statement" (United Kingdom) or "Cadre Réservé" (France) (Art. 5 of 90/44/EEC). In addition to being visible, legible and indelible, the statutory statement must be separate from all other information on the label (**Table 9-9**).

Some of this information may be outside the statutory statement, but the statutory statement must indicate where to find the information. Such information as the "best before" date, net weight and the name and address of the company responsible for the product are often found elsewhere on the label.

A pet food label must indicate whether the food is a complete or a complementary pet food (in other words, whether the food can satisfy all nutritional demands without an additional ration [complete] or whether it must be fed with another product [complementary]). For complementary foods, the other food or supplement should be stated (Burger, 1993). The description "complete" or "complementary" must be considered in relation to the intended purpose of the food or to the particular lifestage for which it is defined (e.g., adult, growth or all lifestages).

The species or category of animals must be stated with the indication complete or complementary (e.g., Brand X is a complete food for adult dogs). This statement of intent is often communicated on the principal display panel, but is repeated in the statutory statement.

INGREDIENT LIST

In Europe, ingredients are declared by the individual name or grouped under various categories (**Table 9-4**). These categories are designed to provide consumers with some indication of the source of raw materials used, while allowing the manufacturer some flexibility in the selection of the ingredients within a specific category (Burger, 1993). These categories are well defined and names and descriptions are officially published (**Table 9-10**). Ingredients should be listed in descending order by weight of each individual ingredient or category.

Vitamins are considered additives and are not listed under ingredients. Water does not have to be declared as an ingredient even if added during processing.

TYPICAL ANALYSIS

Contrary to pet food labels in the United States, where minimum and maximum guarantees are stated, the EU regulations dictate that the typical analysis must be declared for: 1) crude protein, 2) crude fat, 3) crude fiber and 4) ash (**Table 9-5**). Moisture must be declared if it exceeds 14%. Typical analysis (percentage) is the average of the nutrient level calculated from several samples and should correspond with the target level of each nutrient for which precise limits of variation are defined.

The typical analysis gives the percentages found in the actual food. Declaration of nutrients such as calcium, phosphorus, sodium, potassium and magnesium is optional. Energy declaration is forbidden in the EU except for some veterinary dietetic pet foods. Other nutrients must be declared if a manufacturer wants to draw attention to them by saying a food is "high in" or "low in" a particular nutrient.

Table 9-10. Common ingredient categories found on European pet food labels.

Cereals	All types of cereals, regardless of their presentation, or ingredients made from the starchy endosperm
Derivatives of vegetable origin	Derivatives resulting from the treatment of vegetable products in particular cereals, vegetables, legumes and oilseeds
Egg and egg derivatives	All egg products, fresh or preserved by appropriate treatment, and derivatives from the processing thereof
Fish and fish derivatives	Fish or parts of fish, fresh or preserved by appropriate treatment, and derivatives from the processing thereof
Meat and animal derivatives	All fleshy parts of slaughtered warm-blooded land animals, fresh or preserved by appropriate treatment, and all products and derivatives of the processing of the carcass
Milk and milk derivatives	All milk products, fresh or preserved by appropriate treatment, and derivatives from the processing thereof
Minerals	All inorganic substances suitable for animal feed
Oils and fats	All animal and vegetable oils and fats
Various sugars	All types of sugars
Vegetable protein extracts	All products of vegetable origin in which the proteins have been concentrated by an adequate process to contain at least 50% crude protein, as related to the dry matter, and which may be restructured or textured
Vegetables	All types of vegetables and legumes, fresh or preserved by appropriate treatment
Yeasts	All yeasts, the cells of which have been killed and dried

ADDITIVES

Five types of substances are commonly declared as additives: 1) vitamins, 2) copper, 3) preservatives, 4) antioxidants and 5) coloring agents (**Table 9-5**).

Vitamins A, D and E must be declared when added by the manufacturer. The added amount should be declared although some countries ask the manufacturer to declare the total amount of the vitamins found in the food. Vitamins are declared in IU or in milligrams per kilogram (mg/kg) of food.

Pet foods are regulated by the same legislation that regulates livestock feed. Although clear exceptions are made for companion animal foods, situations arise in which an unusual nutrient must be declared. This is the case for copper because sheep are much more sensitive to copper toxicity. If a copper salt is added to a pet food, the name of the salt and the total copper content must be declared.

If a container has a net weight of up to 10 kg, the manufacturer can use the following statements: "Contains European Economic Community (EEC) permitted antioxidant(s)," "contains EEC permitted preservative(s)" or "contains EEC permitted colorant(s)." However, if a container has a net weight of more than 10 kg, the name of the additive must be stated in the following way: "With antioxidant X," "with preservative Y," or "preserved with Y" and "with colorant Z," or "colored with Z."

Table 9-11. Indications permitted for dietetic pet foods in Europe.

Support of renal function in case of chronic renal insufficiency
Dissolution of struvite uroliths
Reduction of struvite urolith recurrence
Reduction of urate urolith formation
Reduction of oxalate urolith formation
Reduction of cystine urolith formation
Reduction of ingredient and nutrient intolerances
Reduction of acute intestinal absorptive disorders
Compensation for maldigestion (including exocrine pancreatic insufficiency)
Support of heart function in case of chronic cardiac insufficiency
Regulation of glucose supply (diabetes mellitus)
Support of liver function in case of chronic liver insufficiency
Regulation of lipid metabolism in case of hyperlipidemia
Reduction of copper in the liver
Support of skin function in case of dermatosis and excessive loss of hair
Reduction of excessive body weight
Nutritional restoration, convalescence

Table 9-12. Required information on labels of dietetic pet foods in Europe.

Particular nutritional purpose (**Table 9-11**)
Essential nutritional characteristics
Species or category of animals
Labeling declarations
Recommended length of time for use
Other provisions

Only those additives are declared that have been added during production of the food. Additives (e.g., preservatives or antioxidants) added during rendering to preserve raw materials (e.g., meat or fish meals) do not have to be declared on the label.

Maximum permitted levels of additives are strictly regulated. Additives are only permitted after European authorities accept a dossier that documents efficacy and safety.

BEST BEFORE DATE

The Best Before Date is listed as a day, month and year. The date itself can be found outside of the statutory statement in a place in which it may be more convenient for printing on the container (e.g., the can lid or top of the bag). In this case the statement "Best before..." must appear within the statutory statement with instructions of where to find the date.

FEEDING INSTRUCTIONS

Feeding instructions are compulsory on European pet food labels but are not as strictly regulated as in the United States. The manufacturer will usually list the weight of the food to feed per body weight of the animal.

NET WEIGHT

The "net weight" declaration is regulated by packaged goods regulations. The "e" often seen after the net weight is not specific for pet foods, but indicates that the net weight is an average. Strict rules regulate the limits of variation permitted under or above the declared net weight statement to ensure that the consumer receives the full amount purchased. The net weight declaration is often mentioned on the front of the label but some countries require that the statutory statement declare where the net weight can be found.

OTHER DECLARATIONS

Regulations now incorporate the batch number into the obligatory declarations for pet foods as well as the plant-specific registration number. The name and address of the company responsible for the product must also appear.

Dietetic Pet Foods in Europe

In July 1995, labeling of dietetic pet foods for dogs and cats became strictly regulated. Definitions and scope of the legislation are published in Council Directive 93/74/EC, whereas Commission Directives (i.e., 94/39/EC and 95/9/EC) give the applications (Council Directive 93/74/EC; Commission Directive 93/39/EC; Commission Directive 95/9/EC). Consequently, a number of statements have appeared on the labels of dietetic pet foods. The Commission Directives publish lists (**Table 9-11**) with the permitted indications for dietetic foods ("Particular Nutritional Purposes"), the characteristics of the corresponding foods and specific label declarations (**Table 9-12**). The objective of the legislation is to prevent unsubstantiated and misleading claims on pet food labels.

The term "dietetic pet food," and its official translations, is the only term to be used to indicate that a product falls under this legislation. The new label declarations apply without prejudice to the Council Directive on the circulation of compound feeding stuffs and other provisions regulating nonveterinary medical pet foods.

The legislation considers most indications for nutritional management as "temporary situations" making it mandatory to publish a defined length of use on the labels. This period of time has been determined by the commission and its experts, and does not always reflect the manufacturer's recommendations.

Energy declaration is not permitted on pet food labels other than dietetic foods marketed for obesity and convalescence. The energy density is a calculated value expressed in megajoules per kilogram (MJ/kg) of product.

New nutritional purposes may be accepted when new products are marketed and the manufacturer has introduced a dossier showing sufficient data to support the claims.

Making Pet Foods at Home

"Teach thy tongue to say 'I don't know' and thou shall progress."
Anonymous

CLINICAL IMPORTANCE

Clients are increasingly interested in their own nutrition and that of their pets. Feeding commercially prepared pet foods offers several advantages over feeding homemade foods, including convenience, cost, consistency and better nutritional balance. Nevertheless, a growing number of pet owners prefer to prepare homemade foods. In doing so, they have less guilt, and feel like they are preparing a "real meal" that is "more natural" and "more traditional" (Wolter, 1988).

According to pet owners, veterinarians are the best source of pet health care (Practice Health, 1993); advice about good nutrition is a reasonable extension of this role. Therefore, veterinarians and their health care teams should be able to provide sound and practical advice about home-cooked pet foods. The first part of this chapter gives practitioners more insight into why some pet owners prefer homemade foods, and covers some pet owner concerns about commercially prepared foods because it is possible to provide a balanced homemade food. Veterinarians should not routinely discourage owners who wish to feed such foods. The second part gives practical recommendations for assessing homemade foods. The tables and boxes describe ingredients and methods for formulating homemade foods and resources to correct imbalanced foods.

Nearly all dogs and cats in the United States consume table food at some time in their lives (PFI, 1997). Many dogs fed commercial foods "exclusively" have learned about the availability of table scraps after a meal, garbage on trash day and food from children and generous neighbors. The vast majority of dogs and cats in the United States, however, receive 90% or more of their nutrition from complete and balanced commercially prepared foods (Lund et al, 1996). In one survey, 20% of pet owners answered that they feed their pet candy or table foods every day (AAHA, 1995). The occasional feeding of table foods should not be of concern for healthy pets unless the food composes more than 10% of the daily dry matter intake (Lewis et al, 1987). However, for various reasons, some clients prefer to feed their pets a homemade food exclusively. In the United States, these clients are probably more prevalent in urban areas. Some veterinarians who practice holistic medicine strongly recommend that their clients feed only a home-prepared food. The number of websites offering nutritional consultations about homemade foods by veterinary nutritionists is increasing.

In the United Kingdom and northern European countries, pet owners provide a high proportion of their pets' diets in the form of commercial pet foods. In countries with a longstanding tradition of gourmet cooking, such as France, Italy, Spain and Belgium, many pets receive a portion of the family meal as the cultural norm. In 1987, about 13% of the dog and cat owners in France fed table foods exclusively to their dogs and cats, and another 15% purchased traditional food for home cooking (Pibot, 1989). In 1987, 62% of French dog owners and 79% of cat owners professed to feed commercial pet foods regularly (Bonnavaud, 1989). However, this does not mean pet owners

Table 10-1. Common Reasons Pet Owners and Veterinarians Want to Use a Homemade Food.

They want to use ingredients that are fresh, wild-grown, organic or natural.
They want to avoid additives that are present in some commercial pet foods.
They want to avoid contaminants thought to be present in prepared foods.
They are concerned that the ingredient list is an indecipherable list of chemicals.
They fear an ingredient in a commercial food such as a "by-product."
They wish to maintain adequate food intake in a finicky pet through exceptional palatability.
They desire to personally cook for the pet.
The pet is addicted to table foods or a single grocery item.
They wish to feed major quantities of an ingredient not found in commercial pet foods.
They hope to construct a nutritional profile for dietary management of a disease for which no commercial food is available.
They hope to restrict the allergens/causative substances during an elimination trial or for long-term feeding of animals with adverse reactions to food.
They wish to support a sick or terminally ill animal through home cooking and hand feeding.
They wish to provide food variety as a defense against malnutrition, or because of the popular idea that pets need variety.
They wish to lower feeding costs by using significant quantities of table food and leftovers.
They wish to feed a pet according to human nutritional guidelines (e.g., low fat, low cholesterol, etc.).

feed commercial pet foods "exclusively." One survey estimated that commercial dog foods only provided 27% of the dogs' nutrient needs (Bonnavaud, 1989). In the same period, pet owners spent about one-third of their pet food budget for commercial pet foods and two-thirds for homemade foods (Kieffer, 1989).

In Europe, moist pet foods often are considered a meat source (protein source), rather than a complete pet food. Consequently, some pet food companies have developed a concept that is intermediate between homemade and commercially prepared foods: moist foods, high in protein and fat. To balance the diet, the food's feeding guide recommends supplementing with a specific amount of rice or pasta. A cereal-based mixer is often sold as an alternative to rice and pasta. These latter modules contain carbohydrate and fiber ingredients that are often fortified with calcium, vitamins and trace minerals. When proper ratios are used, the meal provides adequate mineral balance and appropriate protein-to-energy ratios. This may not be the case, however, when the mixer is combined with fresh meat instead of the complementary moist food. Combining, mixing, cooking and serving the modular components fulfills the owner's expectation of "proper" feeding.

RATIONALE FOR CHOOSING HOMEMADE FOODS

When a client wants to prepare pet foods at home, it is important for veterinarians to understand the client's reasons and motivation (**Table 10-1**). In many cases it is possible to address their concerns and to recommend an appropriate commercial food. In one survey, at least 25% of pet owners said they would be influenced to purchase a specific brand of pet food based on a recommendation by their veterinarian (AAHA, 1995). However, when owners strongly prefer to cook for their pet, it is better to provide them with a well-designed homemade recipe, rather than allow them to prepare food according to their own or other well-intentioned pet owner's recipes that may have deficiencies and excesses (Donoghue and Kronfeld, 1994).

Appeal of "Natural" and "Organic" Foods

Independent health food stores in the United States sold $25 million of pet foods marketed as "organic" or "natural" pet foods in 1990, which increased to $29.4 million in 2001. Sales of natural pet food in 2005 reached $520 million, and estimated sales for 2010 are $1.042 billion, with the organic segment approaching $100 million (Kvamme, 2007). These sales figures may well represent the value some pet owners place on natural or organic labeled foods. The United States Department of Agriculture (USDA) has developed national standards for organically produced agricultural products to assure consumers that products marketed as organic meet consistent uniform standards (Jones, 2006). In general, all natural (non-synthetic) substances are allowed in organic production and all synthetic substances are prohibited. Under current definitions, it is not possible to formulate a complete and balanced organic pet food because it is not possible to meet the nutritionally complete and balanced claim without adding inorganic trace minerals and vitamins (Dzanis, 2007). Likewise, it is not possible to formulate a complete and balanced homemade food without using inorganic supplements; therefore, it is only possible to offer a homemade food "made with" organic ingredients. It is important to understand that the definition of organic relates only to how a food product is made and does not relate to the quality or safety of the product.

Appeal of Vegetarian and Vegan Foods

Pet owners who want to feed a vegetarian food to their dog or cat may assume they must prepare the food at home. Commercially prepared vegetarian foods exist for dogs, and can be well-balanced using egg and milk products. Vegan foods (no animal products) should be carefully checked because they may be deficient in arginine, lysine, methionine, tryptophan, taurine, iron, calcium, zinc, vitamin A and some B vitamins (Dwyer, 1991; McDonald et al, 1995). People should be discouraged from preparing vegetarian or vegan foods at home for cats, because cats are strict carnivores. Without adequate supplementation using synthetic ingredients, cats fed vegetarian and vegan diets are at high risk for taurine, arginine, tryptophan, lysine and vitamin A deficiencies.

Concerns about Additives, Preservatives and Contaminants

Additives

In one survey that studied consumer understanding of the word "natural," most respondents mentioned freedom from various

types of additives (Miller, 1991). In surveys, additives are always high on the list of food items that consumers feel may damage their health, or are a sufficient reason not to buy a food (Miller, 1991). However, when ranking the known risks of food hazards in people, the relative risk of food-borne disease (microbial contamination) is highest, about 100,000 times the risk associated with additives (Miller, 1991).

Because food technology and additives are a difficult and confusing matter for non-experts, additives often evoke emotional responses from the misinformed (Potter, 1986). For example, minerals and vitamins added to a pet food to complete the nutritional balance are considered additives. In addition, the issue is not always presented correctly; consumer associations and some so-called experts often accuse additives of causing all kinds of disorders in pets. Advertising occasionally abuses the negative image of synthetic additives to promote "natural" or "additive-free" products. However, evidence linking a particular food or food constituent with a particular disease is often circumstantial and great care must be exercised in assessing its significance (Aruoma et al, 1991). Veterinarians do not always have the answers when owners are alarmed by nutrition gossip, but should become more knowledgeable about pet food additives so they can accurately address client concerns.

Additives (e.g., flavorings, colorings, binders and emulsifiers) in pet foods are the same or very similar to those approved for use in human foods. In the United States, no additive may be legally used in foods unless the Food and Drug Administration (FDA) recognizes that the additive is safe at the intended level of use in the intended food. The FDA usually requires at least two-year feeding tests in two species of animals to reveal short- and long-term effects. Additives currently used in human and pet foods are generally regarded as safe (GRAS; 21 CFR 582) and must be removed from human and/or pet foods if there is an indication of harmful effects (Roudebush, 1993). For example, propylene glycol has been removed from the GRAS list for cats.

Clients who want to avoid "additives" as a generic group are often poorly informed about pet food additives and the possible negative consequences of not adding these compounds to foods. Veterinarians should be able to explain the positive aspects of additives to give clients a sufficient comfort level to feed a commercial product instead of a homemade food (Chapter 8).

In general, additives provide three benefits: 1) organoleptic-to provide structure, texture and color, 2) technologic-to serve as binding and gelling agents and 3) nutritional-to serve as vitamins and antioxidants. Clients interested in additive-free products must first specifically identify which additive (intentional vs. unintentional) they wish to avoid. Some commercially available products do not contain artificial colors, flavors and synthetic preservatives. After a pet owner's specific concerns have been identified and discussed, it is likely that an acceptable commercially prepared complete and balanced product can be located.

Preservatives

Consumer research has identified several factors that pet owners associate with natural pet food including freedom from artificial preservatives (Potter, 1986). Veterinarians and their health care teams should become knowledgeable about pet food preservatives so they can accurately address client concerns. A preservative may be defined as "any substance that is capable of inhibiting or retarding the growth of microorganisms or of masking the evidence of such deterioration" (Aruoma et al, 1991). Protection against microbial attack may be achieved by several methods: chemical treatment (semi-moist and some dry foods), dehydration (dry foods), heat (moist and dry foods), irradiation or storage at a low temperature. Preservatives are very important to prevent molding or bacterial deterioration of semi-moist foods. Many preservatives are organic acids and their salts, such as sorbates, and are the same as those used in many human foods and dressings.

ANTIOXIDANTS

Antioxidants function to stabilize fats and fat-soluble vitamins against oxidation. There are two types of antioxidants: natural and synthetic (Hilton, 1989).

Natural Antioxidants

Commonly used natural antioxidants include tocopherols, ascorbic acid (vitamin C) and rosemary. Tocopherols are often referred to as vitamin E. Although vitamin E (alpha-tocopherol) is the biologically active form in the body, it does not effectively stabilize fats in food. The gamma- and delta-tocopherols exert the best antioxidant activity in food, but have very low vitamin E activity. Thus, the term "Preserved with vitamin E" is technically inaccurate, but it is commonly used to assuage client concerns. Instead, the label should indicate whether gamma- or delta-tocopherol was added.

Ascorbic acid and its salts and esters are most effective when combined with other antioxidants. Salts (L-calcium ascorbate) and esters (ascorbyl-5,6-diacetate) of ascorbic acid are synthesized compounds, but may be perceived as acceptable natural alternatives to a "more chemical sounding" antioxidant.

Rosemary has been investigated for use in pet foods. Although always considered a natural antioxidant, rosemary is not used in its original form, but as a refined extract to avoid influence on taste and odor (Löliger, 1991).

Synthetic Antioxidants

The more commonly used synthetic antioxidants are butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA) and ethoxyquin. BHT and BHA have been used in human foods since 1954 and are most effective when combined. Ethoxyquin has been approved for use in animal feeds and pet foods in the United States for more than 30 years. All three antioxidants are considered safe at their recommended levels in the United States and Europe (AAFCO, 2007; Dzanis, 1991; Council Directive 70/524/EEC, 1970; Council Directive 91/248/EEC, 1991).

Synthetic antioxidants are more effective than natural antioxidants and better withstand the heat, pressure and moisture during food processing. In doing so, they also preserve the fat-soluble vitamins A, D and E for activity in the body. Clients

Box 10-1. AAFCO Definitions for Meat Ingredients Commonly Used in Commercial Pet Foods.

MEAT
Meat is the clean flesh derived from slaughtered mammals and is limited to that part of the striate muscle which is skeletal or that which is found in the tongue, in the diaphragm, in the heart, or in the esophagus; with or without the accompanying and overlying fat and the portions of the skin, sinew, nerve and blood vessels which normally accompany the flesh. It shall be suitable for use in animal foods (IFN 5-00-394).

MEAT BY-PRODUCTS
Meat by-products are the non-rendered, clean parts, other than meat, derived from slaughtered mammals. It includes, but is not limited to lungs, spleen, kidneys, brain, livers, blood, bone, partially defatted low temperature fatty tissue and stomachs and intestines freed of their contents. It does not include hair, horns, teeth and hooves. It shall be suitable for use in animal food (IFN 5-00-395).

MEAT MEAL
Meat meal is the rendered product from mammalian tissues, exclusive of any added blood, hair, hoof, horn, hide trimmings, manure, stomach and rumen contents except in such amounts as may occur unavoidably in good processing practices. It shall not contain added extraneous materials not provided for by this definition. The calcium level shall not exceed the actual phosphorus level by more than 2.2 times. It shall not contain more than 12% pepsin indigestible residue, and not more than 9% of the crude protein in the product shall be pepsin indigestible (IFN 5-00-385).

MEAT AND BONE MEAL
Meat and bone meal is the rendered product from mammal tissues, including bone, exclusive of any added blood, hair, hoof, horn, hide trimmings, manure, stomach and rumen contents except in such amounts as may occur unavoidably in good processing practices. It shall not contain added extraneous materials not provided for by this definition. It shall contain a minimum of 4.0% phosphorus, and the calcium level shall not be more than 2.2 times the actual phosphorus level. It shall not contain more than 12% pepsin indigestible residue, and not more than 9% of the crude protein in the product shall be pepsin indigestible (IFN 5-00-388).

should be aware that most canned foods do not contain antioxidants, and that many commercially prepared dry pet foods use vitamin antioxidants. Awareness of these facts may help clients choose a more appropriate commercially prepared food.

Contaminants

Some clients are concerned about compounds that may be present unintentionally or accidentally in pet foods (pesticides, drug residues and heavy metals) (Chapter 11). Analyses have shown that contamination of pet foods with pesticides, polychlorinated biphenyls (PCBs) and heavy metals is insignificant (Mumma et al, 1986). In the late 1990s, the FDA Center for Veterinary Medicine (CVM) developed and used a sophisticated process to detect and quantify minute amounts of pentobarbital in dog food (2002). Upon finding pentobarbital residues in some samples of dry dog food, CVM scientists conducted further tests that led them to conclude that dogs eating dry dog food are unlikely to have any adverse health effects from the low levels of pentobarbital found in the dog food samples tested. CVM scientists also developed a test to detect dog and cat DNA in the protein of dog food. Because pentobarbital is used to euthanize dogs and cats at animal shelters, finding pentobarbital could suggest that pets were rendered and used in pet food. Test results indicated a complete absence of protein derived from euthanized dogs or cats (Bren, 2002). As a result, CVM scientists assumed the source of pentobarbital in dog food was euthanized farm livestock.

Clients may elect to feed a homemade food to avoid all types of contaminants. However, ingredients in homemade foods may also contain contaminants. Therefore, making a food at home does not ensure against unintentional contaminants. For example, mercury may be found in fish-based pet foods, but the same concern is real for pets fed fresh fish (Mumma et al, 1986; Ferrando, 1989).

Inability to Understand Pet Food Labels

The ingredient list on a pet food label often uses language unfamiliar to most pet owners; however, each term has a specific definition. Pet owners can easily be confused by terms such as meat, meat meal, meat and bone meal and meat by-products (**Box 10-1**).

Furthermore, pet owners may be alarmed about what they read in the popular press and on the Internet about ingredients commonly used in commercial pet foods (Stein, 1993; Pitcairn and Pitcairn, 1995; Martin, 1997, 2002, 2007), which are often undocumented material presented as "investigative research." Consequently, pet owners often assume the worst possible composition of pet food ingredients (Phillips, 1990; Remillard, 1994). Veterinarians should encourage pet owners to identify ingredient terms of concern and provide more accurate information about the composition of these ingredients. Regulatory agency descriptions exist for all ingredients commonly used in commercial pet foods; one source is the Official Publication of the Association of American Feed Control Officials (AAFCO). For example, a pet owner who has read that meat by-products include hair and fecal material (Stein, 1993; Pitcairn and Pitcairn, 2005; Martin, 1997, 2002, 2007), should be informed that it is illegal for meat by-products to contain such materials (AAFCO, 2007).

Some pet owners may still find meat by-products objection-

able after learning the AAFCO definition. However, they may be comfortable with the definition of meat as an ingredient and feed a commercially prepared product containing meat instead of a homemade food.

Some pet owners consider the last half of the ingredient list to be nothing more than a list of chemicals and cannot identify the nutrients provided by synthetic sources. Veterinarians should ask pet owners to identify bothersome ingredient terms and then explain to them which essential nutrients are provided by those ingredients. As examples, calcium carbonate provides calcium, zinc oxide provides zinc and sodium selenite provides sodium and selenium. Some vitamin examples are: thiamin mononitrate provides vitamin B_1, calcium pantothenate provides pantothenic acid and D-activated animal sterol provides vitamin D_3. Pet owners may have fewer objections to feeding commercially made products after biochemical names have been translated into more commonly recognized vitamins and minerals.

Other points of concern include whether the ingredients are available to the pet (i.e., whether the animal is able to digest and absorb the nutrients they contain). In the United States, the pet owner's attention should be directed to the AAFCO statement required on every product that claims to be complete and balanced (Chapter 9). The AAFCO statement provides valuable information (i.e., the testing procedures used and the lifestage for which the food has been substantiated). If the complete and balanced claim was not substantiated by feeding tests for the specific lifestage of the pet (i.e., growth, maintenance, reproduction), another more appropriate product should be recommended.

"My dog eats what I eat" is an expression often heard from people who prefer to cook for their pet. Preparing elaborate meals at home gives the owner the feeling of "being involved" and can be an integral part of the human-animal bond. This may be particularly important for elderly, solitary persons who benefit from feeling responsible for somebody and are motivated to remain active. Other people choose to cook simply because they feel guilty, as if they don't care enough. The latter circumstance is a minor concern in the United States, but is more important in countries such as France (AAHA, 1995; Pibot, 1989).

Quite often, the pet that receives home-cooked meals is a geriatric animal with a diminishing appetite, body weight and condition due to a slowly progressive disease (e.g., chronic renal failure, hepatic disease, cancer). Meal preparation and handfeeding allow the owner to participate in the pet's supportive care. Formulating a simple homemade recipe that is approximately balanced for the animal with a chronic, progressive fatal disease is a reasonable, compassionate gesture on the part of veterinarians.

Table Foods Have Become a Bad Habit

Pet owners may begin feeding a young or sick dog or cat from the table only to realize that later the pet will not eat commercially prepared food. Therefore, table food is 100% of the animal's daily intake. There are several methods of weaning pets off one particular food and onto another. However, if the animal is persistent, the owner reluctant to make a change or both, formulating a diet from table foods commonly used in the household may be the only way to ensure the pet receives balanced nutrition. In addition, these animals may have very selective eating habits. In such cases, the veterinarian should inform the owner to thoroughly mix all ingredients of the homemade food to ensure balanced nutrient intake.

may not address a patient's multiple medical problems. Some patients' medical problems may require apparently contradictory dietary management. For example, a patient with little or no pancreatic tissue may require: 1) a highly digestible food because of a deficiency in digestive enzymes but also 2) a food with moderate fiber levels to help manage diabetes mellitus.

A veterinary therapeutic food may be commercially available for a patient with a particular medical problem, but the product may be unacceptable to the patient or owner. Although some veterinary therapeutic foods are even more palatable than many specialty and grocery brands, most commercial veterinary therapeutic foods are not available in a variety of flavors, and the ingredient formulation is usually fixed. If a pet is finicky, the one flavor or formulation may be unacceptable and, the patient may not consume adequate quantities of the food to support body weight and condition.

However, it should be noted that in general, homemade formulas won't be as effective as commercially prepared veterinary therapeutic foods. Also, not all veterinary therapeutic foods can be formulated at home (**Tables 10-2** through **10-6**).

Dietary Elimination Trials

The prevalence of adverse reactions to food (including food intolerances and food allergies) has been roughly estimated at 1% of all hospital cases, or 10 to 20% of cases with allergic dermatoses presented to specialists (Brown et al, 1995; Carlotti et al, 1990). Although adverse reactions to food are a small segment of practice, there is strong evidence that they do occur in pets. Homemade foods may be fed to companion animals as a diagnostic or therapeutic measure in cases in which adverse food reactions are suspected. Veterinarians should investigate possible food reactions in cases in which gastrointestinal or dermatologic signs do not fully resolve with standard therapy (Chapter 31).

A dietary history is required to identify ingredients that must be eliminated from the patient's food; however, examining pet food labels rarely ensures that a particular protein is not in the product. For example, the words meat and liver do not specify the species of origin (i.e., cattle, swine, sheep or goats). In Europe, most pet food labels do not list individual ingredients, which makes the dietary history even less accurate. Thus, some sources of protein (and species) cannot be adequately identified from the ingredient list, and so cannot be effectively eliminated from the food. Veterinarians should not hesitate to contact pet food manufacturers for more detailed information.

The recommended protocol for demonstrating a food allergy requires feeding a food composed of protein ingredients not previously fed to the pet or a pet food product containing hydrolyzed protein sources. All protein and carbohydrate sources in a novel food must be changed (i.e., the meat and grain sources). Game meats (venison, bison, elk), rabbit, ostrich and duck are relatively novel meat sources, whereas potato, barley and pea are novel carbohydrate sources in North America. All other possible dietary sources of protein and carbohydrate should be discontinued including treats, snacks, table foods, vitamin-mineral supplements and chewable medications. Patients not successfully managed with a commercially prepared novel food or a food containing protein hydrolysates are often fed a homemade food for four to 12 weeks. Homemade foods may have an advantage because they can be better tailored to the patient's specific needs, but many have been shown to be deficient in essential nutrients (Roudebush and Cowell, 1992).

Homemade foods used in dietary elimination trials can easily be supplemented with calcium, vitamins and microminerals. Most veterinary and children's vitamin-mineral supplements and chewable/flavored medications contain proteins not derived from novel sources. Adult vitamin-mineral supplements without additives are available from health food stores

and pharmacies. Supplements are also available that contain no proteins but complete the nutritional balance for dogs and cats with a variety of concurrent medical conditions (www.balanceit.com).[a] These products are a line of all-in-one patent pending supplements specifically designed to make the preparation of foods for healthy and sick dogs and cats easier and less expensive. Any supplement should be added individually to the homemade food on a trial basis (i.e., one per week) because it may contain an item to which the pet is allergic or intolerant.

COMMON PROBLEMS WITH HOMEMADE FOODS

It is possible to achieve the same nutrient balance with a homemade food as with a commercially prepared food. However, this largely depends on the accuracy and competence of the veterinarian or animal nutritionist formulating the food, and on the compliance and discipline of the owner. Unfortunately, some homemade recipes are flawed even when followed exactly and consistently. In one survey, 90% of the homemade elimination foods prescribed by 116 veterinarians in North America were not nutritionally adequate for adult canine or feline maintenance (Roudebush and Cowell, 1992). Unlike most commercial foods, many published homemade recipes are not complete or balanced to fulfill animal requirements (Roudebush and Cowell, 1992; Kallfez, 1996; Donoghue et al, 1987). Few of the numerous published homemade food recipes for dogs and cats have been tested to document performance over sustained periods (Donoghue and Kronfeld, 1994; Kelly and Willis, 1996). Additionally, making homemade foods requires knowledge, motivation, additional financial resources and careful, consistent attention to recipe detail to ensure a consistent, balanced intake of nutrients.

Very few pet food products sold in the United States are designed to be mixed with another food at home. Some prepared meatless products are available, but the manufacturer clearly instructs the pet owner to feed the food for a limited time or to add a protein source when feeding the product long-term. In North America, homemade foods are more likely to be made "from scratch" than from modules, as in Europe.

Formulations for homemade foods should not be assumed to be complete or balanced for any canine or feline lifestage until sufficiently tested (feeding tests, nutrient analysis, etc.). Most recipes have been crudely balanced using the average nutrient content of specific foods and computer assimilation. The palatability, digestibility and safety of these recipes have not been adequately or scientifically tested (Donoghue and Kronfeld, 1994; Stein, 1993; Pitcairn and Pitcairn, 2005; Martin, 1997, 2002, 2007). Even formulations that are initially complete and balanced put pets at risk when pet owners make their own food substitutions, omit ingredients because of personal preferences or convenience or make preparation errors. Therefore, veterinarians and their health care teams should encourage regular dietary histories and patient monitoring for pets fed homemade foods.

Common Nutrient Problems in Homemade Foods

It is difficult to characterize homemade foods designed by owners because each food and patient is unique. However, many formulations contain excessive protein, but are deficient in calories, calcium, vitamins and microminerals. Commonly used meat and carbohydrate sources contain more phosphorus than calcium; therefore, homemade foods may have inverse calcium to phosphorus ratios as high as 1:10. Most homemade foods for dogs contain excessive quantities of meat, often providing excessive phosphorus and far exceeding the animal's protein requirements.

***Disclaimer for all homemade food recipes:** These are computer-formulated homemade foods that meet current recommended nutrient minimums without exceeding the known maximums for dogs and cats. These foods have never been analyzed for actual nutrient content, nor have they been tested in animals (e.g., AAFCO feeding trial) as are some approved, commercially prepared, pet foods. Likewise, the urinary pH produced by these recipes is unknown, but should be adjusted using appropriate oral medications when indicated in certain medical conditions.
†Nutrients of concern are italicized.

Feline foods designed by clients are commonly deficient in fat and energy density or contain an unpalatable fat source (vegetable oil). Homemade foods are rarely balanced for microminerals and vitamins because over-the-counter veterinary vitamin-mineral supplements are neither complete nor are the nutrients well-balanced within the product. In the United States, there is an all-in-one vitamin-mineral supplement specifically designed to balance homemade foods;[a] this supplement is available to pet owners through veterinarians and nutritionists.

Common Ingredient Problems in Homemade Foods

People are taught that eating a variety of foods is nutritionally sound. Clients often extend this principle to their pet's nutrition. As an example, owners who purchase commercial pet foods may not be brand loyal and often change brands "just in case" one brand is really not complete and balanced. Other pet owners will feed both moist and dry versions of complete and balanced products (of the same or different brands) "just in case there's something in one that's not in the other." Pet owners perceive that feeding a variety of foods is their best defense against malnutrition. Many times pet owners feed a variety of foods because they perceive the pet enjoys the frequent dietary changes.

Likewise, some owners feel a homemade food better meets their pet's nutritional requirements because they use a variety of ingredients. Nutritionally, this may or may not be accurate depending on ingredient substitutions. Inappropriate substitutions are a common error made by owners who design homemade pet foods.

Some owners choose the meat and carbohydrate ingredients for the pet's food based on their own preferences, product availability or affordability. Other pets are fed a variety of "leftover" ingredients such as fat trimmings, bones, vegetable skins, crusts and condiments. Pet food composed of table "leftovers" rarely represents the owner's food and is not complete and balanced for the pet.

On the other hand, some owners mistakenly feed their pet according to current and popular human nutritional guidelines such as avoiding fat, cholesterol and sodium. Such practices do not lead to consumption of a complete and balanced food for the pet. Many owners, who make their pet's food according to published canine or feline recipes, over time, make their own ingredient substitutions that may or may not be correct. Foods made at home, therefore, are typically designed from a variety of table foods, and generally have no consistent ingredient composition. Inconsistency is the rule.

The second most common error made by pet owners who cook for their pets is to eliminate the vitamin-mineral supplement because of its inconvenience, expense or a failure to understand its importance. Foods made from recipes that were once crudely balanced become grossly unbalanced when owners eliminate supplements. Regular veterinary checkups are necessary to monitor the patient's progress and response to the food and to monitor the owner's level of compliance.

Some owners and breeders encourage the use of uncooked meat, liver and eggs in their homemade pet food recipes. This practice can be dangerous because uncooked animal ingredients can harbor pathogenic bacteria that normally would be killed during cooking (Chapter 11).

RECOMMENDING HOMEMADE FOODS

Veterinarians should be willing to: 1) assess an existing recipe, 2) offer nutritionally adequate recipes for healthy pets, if the

client insists on cooking for the pet (**Tables 10-7** and **10-8**) or 3) if necessary, make appropriate formula substitutions for the client when the pet is diagnosed with a medical problem (**Tables 10-2** through **10-6**).

Assessing Recipes

Veterinarians encounter a wide variety of pet food recipes from breeders, chat rooms and the popular press. Improving the ingredients in such recipes is not a simple task. It requires knowledge and good formulation skills, and an up-to-date database of locally available ingredients. The ingredients should be selected on the basis of nutrient content, tolerance, availability and cost. Information about the nutrient composition of commonly available homemade ingredients can be obtained from readily available sources; however, the information is usually presented in an obscure format such as amounts of "nutrient per serving" on an as fed basis (Watt and Merrill, 1975; Carper, 1975; Pennington, 1994; Pitcairn and Pitcairn, 2005). Information in human food tables is not readily converted to common forms used to compare pet food formulations (e.g., percent as fed or dry matter basis). A simpler method to correct an inadequate homemade formulation is to adjust the proportions or change the ingredients in the recipe. Homemade formulations can be checked for nutritional adequacy and adjusted using the "quick check" guidelines below.

1. Do Five Food Groups Appear in the Recipe?

- A carbohydrate/fiber source from a cooked cereal grain.
- A protein source, preferably of animal origin, or if more than one protein source is used, one source should be of animal origin.
- A fat source.
- A source of minerals, particularly calcium.
- A multivitamin and trace mineral source.

2. Is the Carbohydrate Source a Cooked Cereal and Present in a Higher or Equal Quantity than the Meat Source?

The carbohydrate source to protein source ratio should be at least 1:1 to 2:1 for cat foods and 2:1 to 3:1 for dog foods. Carbohydrate sources for dog and cat foods are used for energy and are usually a cereal such as cooked corn, rice, wheat, potato or barley. These carbohydrate sources have similar caloric contributions, but some carbohydrate sources also contribute a significant amount of protein, fiber and fat (**Table 10-9**). A specific carbohydrate may be chosen based on specific changes in the patient's protein, fat and fiber requirements. For example, soybean may be substituted for corn if more protein is needed, or peas may be substituted if more fiber is needed.

3. What is the Type and Quantity of the Primary Protein Source?

The overall protein quality in a homemade food can be improved by substituting an animal-source protein for a vegetable-source protein. Skeletal muscle protein from different animal species has very similar amino acid profiles. The protein content of various mammalian and avian skeletal muscle tissues is generally equivalent on a water-free basis. Thus, there is no great advantage to feeding one meat source over another. Any cooked animal protein source should provide the majority of a dog's or cat's essential amino acids.

The final food should contain 25 to 30% cooked meat for dogs, (one part meat to two or three parts carbohydrate, respectively) and 35 to 50% cooked meat for cats (one part meat to one to two parts carbohydrate).

Providing some liver in the meat portion is recommended once a week or no more than half of the meat portion regularly. Liver corrects most potential amino acid deficiencies in homemade foods for dogs and cats. Liver not only improves the amino acid profile over that provided by vegetable and skeletal meat sources, but also contributes essential fatty acids, choles-

Directions: Bake or microwave meat component and cook starch component separately. Grind or finely chop meat if necessary. Pulverize the bone meal or dicalcium phosphate. Mix with other components except the vitamin-mineral supplement. Mix well and serve immediately or cover and refrigerate. Feed the vitamin-mineral supplement with the meal; give as a pill or pulverize and thoroughly mix in food before feeding.

terol, energy, vitamins and microminerals. If a pet owner requests an ovo-lacto vegetarian food, eggs are the best ingredient. If a vegan food is requested, soybeans provide the next best, but incomplete, amino acid profile.

4. Is the Primary Protein Source Lean or Fatty?

The fat content of different cuts of meat varies. When the specified protein source is "lean," an additional animal, vegetable or fish fat source should compose at least 2% of the formula weight for dogs, and 5% of the formula for cats to ensure adequate energy density and essential fatty acids. If a homemade food lacks sufficient caloric density (fat), the addition of cooked beef or chicken fat, poultry skins, vegetable or fish oils (tuna, mackerel, sardine) can increase the caloric density without adding other nutrients. Changing the cut of meat can also markedly increase the fat content of a food (**Box 10-2**).

5. Is a Source of Calcium and Other Minerals Provided?

A homemade food is almost never spontaneously balanced in minerals; an absolute calcium deficiency is common. Unfortunately, pet owners erroneously assume cottage cheese, cheese or milk added in small quantities to homemade pet foods provides adequate calcium. Most foods require a specific calcium supplement. When the protein fraction equals or is greater than the carbohydrate fraction, usually only calcium carbonate is added to the food (0.5 g/4.5-kg cat/day and at least 2.0 g/15-kg dog/day). Calcium carbonate, containing 40% calcium and less than 1% phosphorus, is available in various size tablets from most pharmacies, health food and grocery stores.

Calcium and phosphorus supplementation may be necessary when the protein fraction is less than the carbohydrate fraction. Steamed bone meal, dicalcium phosphate and certain proprietary mineral supplements contain approximately 27% calcium and 16% phosphorus (about 2:1) and microminerals. These supplements, fed at the same dose as calcium carbonate, usually correct the calcium and phosphorus content.

6. Is a Source of Vitamins and Other Nutrients Provided?

Supplements providing vitamins, microminerals, fatty acids and specific nutrients of concern for cats and dogs can be obtained, but they may be cumbersome to feed and greatly increase the cost of the food. An adult over-the-counter vitamin-mineral tablet that contains no more than 200% of the recommended daily allowances for people works well for both dogs and cats at one-half to one tablet per day. One tablet per day of a human adult product will not oversupplement pets with calcium, phosphorus, magnesium, vitamins A, D and E, iron, copper, zinc, iodine and selenium, according to AAFCO maximum allowances for canine and feline foods (2007). In general, veterinary supplements contribute between 0 and 300% of the vitamin-mineral requirements of dogs and cats.

Specific nutrients of concern for cats-such as arginine, arachidonic acid, L-carnitine and choline-can be purchased as individual nutrient products. However, levels in homemade cat foods are usually adequate when a combination of animal proteins is used. Cats fed a homemade formula exclusively should receive 200 to 500 mg taurine daily, depending on the calculated taurine content of the food. Iodized salt should be used whenever salt is added to the food. It is difficult to meet the iodine requirement without using the iodized form (400 µg of iodine/6 g [1 tsp] sodium chloride). The alternative is to prescribe the canine or feline supplement designed for homemade foods.[a]

Making Ingredient Substitutions

When formulating a homemade recipe, proportions of carbohydrate, protein, fat and fiber must be maintained. **Table 10-10** suggests starch, meat, fat and fiber ingredient substitutions and their relative nutrient values. When substituting one ingredient for another, determine the relative nutrient value of the old ingredient and that of the replacement ingredient. If the old

Table 10-9. Nutrient profiles of cooked grains and vegetables for homemade foods.

*Expressed on a kcal/100 g dry matter.
**Expressed on a percent dry matter basis.
***Readily available sugars (e.g., mono- and disaccharides).

recipe recommended 75 g of rice, and the owner would like to use pumpkin instead of rice, 200 g of pumpkin will be needed to supply the same amount (15 g) of carbohydrate as 75 g of rice (**Table 10-10**). As fed weights of foods can be found at the USDA National Nutrient Database (www.nal.usda.gov/fnic/foodcomp/search).

Several methods can be used to formulate homemade foods. Veterinary nutritionists in North America commonly use nutrition software programs such as those listed in Chapter 1. Most practicing veterinarians in North America either contact a veterinary nutritionist directly or use one of these software programs. A third method is to hand calculate the formulation using these steps: 1) determine the ingredients to be used from each food category (**Table 10-10**) and 2) determine the appropriate amount of each ingredient that will supply the needed amount of nutrient for the dog or cat. Each ingredient supplies more than just one nutrient (e.g., rice supplies carbohydrates and some protein). However, this simplified method of formulating a homemade food minimizes nutrient deficiencies by providing overlapping sources of nutrients.

Nutritionally Adequate Recipes

Tables 10-7 and **10-8** are homemade food recipes for healthy adult dogs and cats, respectively. These recipes should be considered all-purpose foods. It should be noted that all-purpose foods do not provide the ideal nutrient profile for most dogs and cats. All-purpose foods, however, provide excess nutrients to adult and older cats and dogs (Chapters 13, 14, 20 and 21).

There are also homemade food recipes for clinical patients. **Table 10-2** contains recipes for reduced protein/low-phosphorus foods for dogs and cats with kidney disease. **Table 10-3** contains recipes for low-fat/high-fiber foods for overweight dogs and cats. **Table 10-4** contains recipes for low-sodium/low-mineral foods for dogs and cats with heart disease. **Table 10-5** is a recipe for a low-protein/low-purine food for dogs with urinary calculi. **Table 10-6** is a recipe for a low-residue food for dogs with gastrointestinal disease.

Because these foods are for clinical patients, it is imperative that clients follow these recipes meticulously. Well-intentioned but ill-informed substitutions or other modifications could result in ineffective, or even counterproductive, nutritional therapy. Furthermore, it is unlikely that these recipes will be as effective as commercial foods in managing clinical patients, even when followed closely.

Box 10-2. Effect of Meat Substitutions on Fat and Energy Levels in Homemade Recipes.

The fat content of the animal protein source in homemade pet food recipes can greatly affect the energy density of the food. In general, animal protein sources such as fish, beef, turkey, chicken and mutton or lamb have similar protein and amino acid contents (**Table 1**). As a result, they can usually be substituted for one another on an as fed basis in most typical homemade food recipes. On the other hand, the fat content and therefore the energy density can increase greatly depending on whether the cut of meat is regular (typical), lean or extra lean (**Table 2**). See **Table 10-10** for more information about ingredient substitutions.

Table 1. Protein and energy content of interchangeable protein sources for a homemade cat food recipe (as fed).

Protein/energy	Lean beef	Chicken	Tuna
Protein	28	28	29
kcal ME/g	4.5	4.4	4.4
kJ ME/g	18.7	18.5	18.2

Table 2. Protein, fat and energy density of ground beef (30 g) with varying fat levels (as fed).

Protein/ fat/energy	Extra lean (>90%)	Lean (>80%)	Regular (<80%)
Protein (g)	7	7	7
Fat (g)	3	5	8
Energy (kcal)	55	73	100
Energy (kJ)	230	305	418

The Bibliography for **Box 10-2** can be found at www.markmorris.org.

Table 10-10. Cooked ingredient substitution lists.

Ingredients	Major nutrient	18-kg (40-lb) dog	4.5-kg (10-lb) cat
Starch, cooked	Carbohydrate	60 g	12 g
Meat, cooked	Protein	28 g	9 g
Fat	Fat	10 g	10 g
Fiber	Dietary fiber	10 g (max)	5 g (max)

Starch: These foods in these amounts yield 15 g carbohydrate with 3 g protein, trace fat and 80 kcal

Bread	25 g	Breadsticks, raisin, rye, whole wheat, white
	30 g	Bagel, English muffins, buns, rolls, pita, tortilla
Cereal	20 g	Ready to eat cereals
	25 g	Bran cereals, shredded wheat
	30 g	Bran flakes, Chex
	100 g	Cooked cereals and grits
Grains	20 g	Cornmeal, flour, cornstarch, popcorn, tapioca
	75 g	Rice
	100 g	Barley, pasta
Vegetables	50 g	Baked beans, sweet potato
	75 g	Beans, peas, lentils, plantain
	80 g	Corn
	100 g	Corn on the cob, lima beans, green peas, potato, yam
	150 g	Squash, parsnips
	200 g	Pumpkin

Protein: Should be weighed after cooking and after bone, skin and excess fat have been removed

Low fat: These foods in these amounts yield 7 g protein with 3 g fat and 55 kcal

Beef	30 g	Baby beef, chipped beef, flank tenderloin, plate ribs, round (bottom, top), all rump cuts, lean spareribs, tripe, ground beef (>90% lean) and USDA good and choice
Dairy	30 g	Cottage cheese
	45 g	Cheeses (low fat 3 g or less/oz.)
Fish	30 g	Any fresh or frozen, tuna or mackerel canned in water
Mixed meats	30 g	Low-fat luncheon meats with 3 g fat or less /oz., >90% lean
Pork	30 g	Leg, tenderloin, ham, Canadian bacon
Poultry	30 g	Chicken or turkey meat without skin
	90 g	Egg whites
Seafood	30 g	Clams, crab, lobster
	50 g	Scallops
	60 g	Shrimp
	90 g	Oysters
Veal	30 g	Leg, loin, rib, shank, shoulder
Wild game	30 g	Venison, rabbit, squirrel, pheasant, goose without skin

Medium fat: These foods in these amounts yield 7 g protein with 5 g fat and 73 kcal

Beef	30 g	Ground beef (>80% lean), corned beef, ribeye
Dairy	30 g	Cheese: mozzarella, ricotta, farmer
Fish	30 g	Tuna, salmon canned in oil, drained
Lamb	30 g	Leg, rib, sirloin, loin, shank, shoulder
Mixed meats	30 g	Low-fat luncheon meats with 3-5 g fat/oz., 85-90% lean
Organ meats	30 g	Liver, kidney, heart, sweetbreads
Pork	30 g	Loin, shoulder arm and blade, butt
Poultry	30 g	Chicken or turkey meat with skin, duck and goose well-drained of fat
	50 g	Egg whole
Veal	30 g	Cutlet
Vegetable	120 g	Tofu

High fat: These foods in these amounts yield 7 g protein with 8 g fat and 100 kcal

Beef	30 g	Ground beef (<80% lean), brisket, chuck, ribs, USDA prime
Dairy	30 g	Cheese spreads, all regular American, blue, cheddar, Monterey, Swiss
Lamb	30 g	Breast, ground
Mixed meats	30 g	Cold cuts, sausages
	45 g	Frankfurter
Pork	30 g	Spareribs, back ribs, ground, country style and deviled ham, sausage
Veal	30 g	Breast
Vegetable	30 g	Peanut butter

Fats: These foods in these amounts yield 5 g fat with 45 kcal

Monounsaturated	5 g	Margarine with soybean, cottonseed, partially hydrogenated oils, peanut oil, olive oil
Polyunsaturated	5 g	Soft tub margarine, oil (safflower, corn, sunflower, cottonseed, sesame)
	15 g	Diet margarine with safflower, corn, sun–flower oil
Saturated	5 g	Chicken fat, beef fat, bacon fat, lard, butter, shortening
	15 g	Heavy cream, cream cheese
	30 g	Sour cream, nondairy substitutes, gravy
	45 g	Light cream, half & half

Fiber: Grams of dietary fiber per 100 g of these foods

Low (0-2 g)	Asparagus, cucumber, lettuce, zucchini, alfalfa sprouts, eggplant, mushrooms, celery, green pepper, tomatoes
Medium (2-4 g)	Bamboo shoots, carrots, peas, string beans, bean sprouts, chickpea, pinto beans, summer squash, broccoli, cauliflower, pumpkin, turnips, cabbage, kidney beans, spinach, watercress
High (5 g or more)	Beans (white, red, lima, black, broad, soy)

Additional Instructions

Specific instructions for preparing, storing and feeding of homemade foods should be given to pet owners. Explaining the importance of a balanced food and providing practical recommendations about how to mix and cook the food will increase compliance. Some owners may even prefer a commercially prepared food when they realize what is involved in preparing a balanced homemade recipe.

Some owners and breeders encourage the use of uncooked meat and eggs in their homemade pet food recipes. Pet owners should be informed that uncooked meat and eggs can harbor pathogenic bacteria that are normally killed during cooking (Chapter 11). Animal ingredients (meat and eggs) should be cooked for at least 10 minutes at 82°C (180°F). Vegetable ingredients should be washed or rinsed and cooked if increased digestibility is desired. Owners can make homemade foods that lack preservatives and antioxidants in three- to seven-day batches but must refrigerate the food in airtight containers between meals (0 to 4°C [32 to 40°F]). Larger quantities of food can be frozen (-20°C [<0°F]). Because homemade foods

are relatively high in moisture and lack a preservative system, they are highly susceptible to bacterial and fungal growth when left at room temperatures for more than a few hours. Pet owners who feed homemade foods must also check the food daily for color and odor changes that may indicate spoilage or deterioration. Clients should be advised of these food safety issues when feeding homemade foods (Chapter 11).

Pet owners should be encouraged to use a dietary gram scale to weigh ingredients. Later, they can convert weights to volumes for easier compounding. Ingredient compositions are published in different ways. For example, some recipes specify cooked rice, whereas others specify rice to be weighed as purchased. Formulation must take this variability into account, and the owner should be informed about it.

Cooking is necessary to improve the digestibility of starch in carbohydrate sources (Walker et al, 1994; Wolter, 1982). Cooking also destroys anti-nutrient factors that may be present (e.g., anti-trypsin in soybeans, thiaminase in some fish). However, carbohydrate and animal protein sources should be cooked separately. Carbohydrate sources need a longer cooking time to increase digestibility, due to swelling and gelatinizing of starch granules. Meat and liver, on the other hand, should not be overcooked to avoid protein denaturation. Cooking vegetables may increase starch digestibility, but does not decrease the value of vegetables as a source of fiber. Longer cooking times, however, may increase vitamin losses (Meyer, 1990).

After cooking, all ingredients should be thoroughly mixed in a blender to prevent the animal from picking out single food items. An unbalanced intake of nutrients may occur if ingredients of a nutritionally balanced homemade food are allowed to separate and the animal does not consume the entire mixture. Be sure the owner understands the dietary formulation only approximates the recommended nutrient intake of the pet at a given weight for a certain number of days.

Owners should be warned that although vitamins and minerals are present in only small quantities, they are very important and are not optional. Vitamin-mineral supplements should not be cooked or heated or stored with the food. Vitamins may be destroyed by heat or oxidation. The vitamin-mineral supplement should be kept separate from the food, and administered just before, during or after a meal to ensure proper dosing. Overall digestibility and availability of vitamin-mineral supplements are improved when using USP labeled products and when these nutrients are present in the small intestine with a meal composed of proteins, fats and carbohydrates.

The food should be warmed to just below body temperature before feeding. Clients should be advised to carefully check for "hot spots" that could burn a pet's mouth after food has been rewarmed in a microwave oven. Wetting the food may improve palatability. Moisture content of homemade foods is approximately 70%, which is more similar to that of moist than dry commercial foods. Animals that favor dry forms of commercial foods may reject homemade foods.

When stored too long, the food mixture may separate and dry out, becoming less palatable. Therefore, it is best not to prepare large amounts of food that cannot be eaten in a few days. Mixing the food before warming will improve palatability.

When choosing the ingredients for specific foods, keep in mind that some ingredients are acceptable for one species, but may markedly decrease the palatability for another. For example, dogs like sugar but cats do not. When formulating a food for patients with diabetes mellitus or colitis, for example, beans and peas may be a suitable carbohydrate and protein source for dogs, but increasing the amount of these ingredients may make a food unacceptable to cats.

Vegetable and meat sources may be substituted for similar ingredients in a recipe (**Table 10-10**). Owners who feed a variety of foods decrease the risk that a particular nutrient might be below requirement long enough to cause clinical signs of deficiency. Clients should receive a list of possible substitutes, and be informed that inappropriate substitutions may jeopardize nutritional balance.

If the patient has a history of food rejection or gastrointestinal upset with food changes, advise the client to feed the homemade food without supplements for a week or so, and then add the supplements one at a time (one per week) to avoid the problem or better identify the source of the problem.

In practices where homemade foods are regularly recommended, the staff should have experience preparing the recipes to become familiar with the preparation of homemade foods. Furthermore, it is worthwhile and probably cost effective to send the most commonly recommended formulas to a food analytical laboratory to confirm the calculated analysis. In the United States, AAFCO provides valuable guidelines for minimum and maximum nutrient allowances within which a food for healthy dogs and cats should be formulated if no feeding tests are done. These guidelines may be a useful target for formulating homemade foods as well.

PATIENT ASSESSMENT/MONITORING

Patients that eat homemade foods should be brought in for regular veterinary examinations (two to three visits per year). Because the nutritional profile of homemade foods is quite variable, a nutritional review is recommended at least twice a year. If a dog or cat eats a homemade food exclusively for more than six months, the veterinarian should ask the client to record and submit a three- to five-day food history so that the nutrient profile and ingredient substitutions can be reevaluated.

The effectiveness of a food can be grossly evaluated by noting the patient's body weight, body condition and activity level. Laboratory data such as albumin level, red blood cell number and size and hemoglobin concentration are gross estimations of the animal's nutritional status and can be used with other clinical observations to evaluate homemade foods.

More specifically, the skin and hair should be examined closely and an ophthalmic examination, including evaluation of the lens and retina, should be performed. These tissues are more sensitive than others to nutritional status (Remillard et al, 1993; Glaze and Blanchard, 1983; Sousa et al, 1988; Harvey, 1994). Stool quality should also be assessed.

Veterinarians should always: 1) offer to have a homemade recipe evaluated by a nutritionist and 2) recommend the feeding of a consistent complete and balanced commercial product as often as possible. This is especially true if the pet has a medical condition for which dietary management depends on the highest level of diet consistency and quality assurance.

CASE 10-1

Lethargy and Vomiting in Three Cats

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
MSPCA Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

Three cats were examined for lethargy and occasional vomiting. Two cats were at their optimal body weight and condition (weight = 4.5 kg, body condition score = 3/5); one cat weighed 5.5 kg and had a body condition score of 4/5. All three cats were icteric, had elevated hepatic enzyme levels and were diagnosed as having hepatic lipidosis.

Assess the Food and Feeding Method

The owners read about pet food manufacturing in a popular cat publication and decided they no longer wanted to feed a commercially produced food to their three cats. They discarded all pet food products in the house, chose a recipe suggested in the text that suited them and began feeding the homemade food exclusively for two weeks. Two cats reluctantly ate a little food almost every day, whereas one cat refused food completely.

Questions

1. How should the veterinarian advise these clients about making food changes in the future?
2. These owners did not want to feed a commercially produced cat food because they were convinced the ingredients used were making their cats subclinically but progressively ill. What food recommendations should be made for these cats?

Answers and Discussion

1. When making food changes for cats, a gradual transition schedule that decreases the old food and increases the proportion of new food is highly recommended (Chapter 1). Generally, cats should eat daily and should not go more than three days without eating a sufficient quantity of food to meet their resting energy requirement. Hepatic lipidosis can occur in normal and overweight cats. The condition occurs more commonly when cats are completely anorectic, but can also occur in cats that have been partially anorectic for weeks to months.
2. Because the owners are convinced they should feed a homemade food, they should be offered a nutritionally adequate generic recipe or should be referred to a nutritionist who could formulate a recipe that takes into consideration their particular concerns.

Progress Notes

The three cats were fed a complete and balanced liquid feline formula for three days (30 ml every three hours) by nasogastric tube. Moist kitten food was offered free choice. Two cats began eating on Days 4 and 5 and were discharged. The third cat progressively deteriorated and was euthanized on Day 5.

CASE 10-2

Weight Loss in an Older Cat

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
MSPCA Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

The owner of a 17-year-old, neutered female domestic shorthair cat with chronic renal failure requested a recipe so she could cook for her cat at home. The owner thought the cat's poor appetite would improve if the cat were fed a food that contained chicken, the cat's favorite ingredient. She asked the veterinarian to review a homemade recipe she obtained from a cat breeder. The cat weighed 3.2 kg (7 lb) and had a body condition score of 2/5.

Assess the Food and Feeding Method

The recipe's nutrient content follows:

Ingredient	(g)	(%)
Meat (chicken, white)	25	25
Rice or pasta	55	55
Vitamin-mineral supplement	13	13
Brewer's yeast	5	5
Spirulina (blue green algae)	2	2

Question

Using the quick check guidelines for homemade foods (See chapter text.), what suggestions should be made about nutrients, ingredient levels and food preparation?

Answer and Discussion

The meat source should constitute at least 30% of the as fed homemade food and contain more fat. The recipe as presented contains virtually no fat. This cat is underweight and has a less than optimal body condition score; it needs a more energy dense food. If the cat prefers white meat then approximately 10 to 20 g of fat is necessary. Chicken skin, beef fat or vegetable or fish oils may be used to constitute at least 10% of the as fed weight of the food.

The food needs a calcium source, such as 0.3 g of calcium carbonate per day. Review the vitamin-mineral supplement label to ensure the supplement contains trace minerals (copper, zinc, manganese, iron, iodine and selenium), B vitamins, vitamin A and taurine. Encourage the owner to use a dietary gram scale to weigh and blend all ingredients to prevent the cat from picking out the chicken, but administer the vitamin-mineral supplement with the meal. The revised recipe follows:

Ingredient	(g)	(%)
Meat (chicken, white)	35	31
Rice or pasta	60	52
Fat (chicken skin)	15	13
Vitamin-mineral supplement	4	3
Calcium carbonate	0.3	0.25

The client was advised to feed chicken liver once a week in place of the chicken meat. The vitamin-mineral supplement recommended was one-half of an adult vitamin-mineral tablet. Brewer's yeast adds magnesium, B vitamins, microminerals and fiber; however, nutritional yeast is fortified and has a better nutritional profile of B vitamins and microminerals. The *Spirulina* is of questionable nutritional value, but probably causes no harm.

CASE 10-3

Understanding Pet Food Labels

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
MSPCA Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

A dog owner recently went to a local kennel club meeting and heard that synthetic preservatives in pet foods should be avoided. She was especially concerned about a preservative with a long name that begins with an "e." Because she didn't know which pet foods in the grocery store contained the compound, she preferred to make her dog's food at home. She asked her veterinarian to review the ingredient list and specifically asked if the ingredient called "ethylenediamine dihydroiodide" is the preservative she should avoid.

Questions

1. What is ethylenediamine dihydroiodide?
2. Where or how can this information be found?
3. What should be the recommendation to the dog owner?

Answers and Discussion

1. Ethylenediamine dihydroiodide is a source of iodine in pet foods in the United States. It is not the preservative ethoxyquin.
2. The Association of American Feed Control Officials (AAFCO) manual provides this information. Alternatively, the pet food company could be contacted directly.
3. The owner need not be concerned about feeding ethoxyquin; however, if she wishes to avoid this preservative, she could choose a commercial pet food product preserved with other antioxidants (e.g., a natural preservative). A commercially prepared complete and balanced pet food is preferable to a homemade food.

CASE 10-4

Back Pain and Weakness in a Springer Spaniel

Rebecca L. Remillard, PhD, DVM, Dipl. ACVN
MSPCA Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

A 13-month-old female English springer spaniel was examined for chronic small bowel diarrhea of seven months' duration. The dog weighed 5.5 kg and had a body condition score of 2/5.

Assess the Food and Feeding Method

The owner was unwilling to feed any commercially produced dog food because "he had tried them all and none of them ever worked." According to the client, the dog does well and had normal stools when fed a homemade food containing only one part boiled white chicken and two parts instant rice. The pet owner would like for the veterinarian to balance this food.

The veterinarian gave the client the following recipe:

Ingredient	(g)	(%)
Chicken, dark meat with skin	80	24
White rice, cooked	250	74
Calcium carbonate	0.6	0.2
Vitamin-mineral supplement	8	2
Salt (NaCl), iodized	0.4	0.1

The owner was also given a printed complete set of instructions and cautions.

Reassessment

Six months later the dog presented with severe back pain, rear leg weakness, inappetence, depression and lethargy. The dog ate the homemade food exclusively for six months and had few episodes of diarrhea. The dog's serum calcium concentration was 8.9 mg/dl (reference range = 9 to 11 mg/dl). The dog's serum albumin concentration was normal.

Questions

1. What additional information would be important to obtain about feeding the homemade food?
2. What is the most likely food-related problem given the clinical signs of generalized muscle weakness and lethargy?
3. What common omission do clients who feed a homemade food often make?

Answers and Discussion

1. The recipe should be checked item by item to ascertain whether the owner is following the recipe and then the instructions for mixing and feeding the food should be reviewed with the client.
2. Long-term feeding of a calcium-deficient food can result in marked muscle weakness, lethargy and osteoporosis.
3. Omitting the vitamin-mineral supplement is a common error made by owners who feed a homemade food.

Progress Notes

After reviewing the food formulation with the owner, he admitted that he had not been giving calcium carbonate supplementation because it was inconvenient to give the dog one (0.5 g calcium carbonate) tablet per day. Ten percent calcium gluconate solution was administered intravenously at 15 mg/kg slowly over one hour. Within hours the dog's attitude improved and the dog was able to stand. The dog was apparently difficult to medicate, so liquid or powdered supplements mixed in the food were suggested.

Most foodborne metal toxicities in dogs and cats involve lead, zinc, cadmium and arsenic. These agents cause a variety of clinical syndromes depending on age, dose ingested and length of exposure. The specifics of metal toxicities are well described in several veterinary toxicology textbooks and are beyond the scope of this chapter.

The tendency of metals to accumulate in plants and animals has ramifications for the manufacture of commercial pet foods. Several studies have been conducted to quantify such accumulations. In one study, researchers analyzed 28 brands of commercial dog food and seven brands of cat food and found that average levels of lead, arsenic and cadmium were 1.26, 0.37 and 0.22 ppm, respectively (Edwards et al, 1979). A later study of 35 dog foods and 13 cat foods found the average levels of lead, cadmium and zinc were 0.88, 0.80 and 122.0 ppm, respectively (Mumma et al, 1986). These studies confirm that nontoxic levels of metals may be present in some pet foods; however, their presence at these levels would not support a diagnosis of metal toxicity. Instead, a definite diagnosis must be based upon finding toxic levels in the food that correspond to elevated levels in the patient's tissues, such as blood, liver and kidney.

Other Sources

SUPPLEMENTS

Many people supplement their own food with vitamins, herbal remedies and other items purchased at health food stores. Well-meaning pet owners likewise think that what is good for them is also good for their pets. Unfortunately, this practice fails to consider species and dose differences. Cats, in particular, may be adversely affected by medications considered safe for people. Certainly, vitamin A and D toxicity is well documented. It is also known that many herbal remedies cause adverse effects in people and animals (Poppenga, 1995; Remillard and Wynn, 2005). Therefore, the safety of other "natural" supplements such as aloe, ginseng root, eucalyptus, ginger and oil of wintergreen has yet to be established for dogs and cats. As the investigation of the clinical case proceeds, the veterinarian should ask the owner how and why the animal's food is being supplemented with these substances.

ONIONS AND GARLIC

Owners may also supplement a pet's food with onions or garlic. Onions derive part of their flavor from n-propyl disulfide, which is toxic to the erythrocytes of several species (Jain, 1993). In 1990, a phenolic compound was extracted from onions that increased methemoglobin concentrations and caused the formation of Heinz bodies in canine erythrocytes (Miyata, 1990).

Onions may injure the lipid membranes of erythrocytes and irreversibly denature hemoglobin (Jain, 1993). These changes result in Heinz body formation, hemolytic anemia and hemoglobinuria. The most common cause of Heinz body hemolysis in dogs is related to ingestion of onions. Although the toxicity has been known for more than 50 years, animal owners still unknowingly feed onions to dogs as part of table food or intentionally as a supplement. The hemolytic episode may be difficult to correlate with onion ingestion because it occurs several days postingestion. Clinical signs related to moderate Heinz body anemia have occurred in dogs consuming relatively small amounts (5 to 10 g of onions/kg body weight) of raw, cooked or dehydrated onions (Harvey and Rackear, 1985; Ogawa et al, 1986). In one study, consumption of approximately 30 g of raw onions/kg body weight for three consecutive days produced severe anemia, erythrocyte Heinz bodies and hemoglobinuria in all dogs fed onions (Ogawa et al, 1986). One animal developed severe icterus and died on Day 5.

Cats are prone to developing erythrocyte Heinz bodies after exposure to many chemicals in food (Jain, 1993; Hickman et al, 1990; Christopher et al, 1989). Likewise, Heinz body anemia has occurred in cats after consumption of onions (Kobayashi, 1981). Baby food or other foods containing similar amounts of onion powder should not be fed to cats because of Heinz body formation and the potential for development of anemia, especially with high food intake. Cats with concurrent oxidative diseases may develop additive hemoglobin damage when fed baby food containing onion powder (Robertson et al, 1998).

Garlic (*Allium sativum*) is also a member of the onion family. Long-term exposure to garlic and garlic extracts caused anemia, contact dermatitis and asthmatic attacks in dogs (Poppenga, 1995). Eccentrocytosis appears to be a major diagnostic feature of garlic-induced hemolysis in dogs. The constituents of garlic have the potential to oxidize erythrocyte membranes and hemoglobin, inducing hemolysis associated with the appearance of eccentrocytes in dogs. Thus, foods containing garlic should not be fed to dogs (Lee et al, 2000).

CHOCOLATE

Pets today are often fed "people" food. One delicacy that has potential to cause toxicity is chocolate. Chocolate products contain variable amounts of theobromine, a potent cardiovascular and central nervous system stimulant (Clark et al, 1981). Although pet owners might believe that chocolate is innocuous, one poison control center documented six cases of chocolate poisoning in dogs during a single year (Hornfeldt, 1987). Signs such as vomiting, diarrhea, panting, nervousness, excitement, tremors, tachycardia, cardiac dysrhythmias, coma, convulsions and sudden death may appear in four to 15 hours after ingestion (Hornfeldt, 1987; Gauberg and Blumenthal, 1983; Hooser, 1984; Sutton, 1981). Renal damage may occur in severe cases.

The toxic dose of theobromine has been reported to be greater than 200 mg/kg body weight (Hornfeldt, 1987). However, a springer spaniel died after ingestion of two lb of milk chocolate, corresponding to a dose of only 92 mg of theobromine/kg body weight (Gauberg and Blumenthal, 1983). Based on this case, consumption of one typical 1.55-oz. milk chocolate bar (93 mg theobromine)/kg body weight could produce clinical signs and possibly death (Hooser, 1984). Unsweetened baking chocolate also contains high levels of theobromine (450 mg/oz.) and has been implicated in cases of toxicity (Hooser, 1984). Finally, dogs have also been poisoned by ingesting cocoa powder (1 to 3% theobromine) (Sutton, 1981).

Theobromine is eliminated very slowly in dogs. This metabolic peculiarity prolongs the clinical syndrome and increases the risk of toxicity from repeated ingestion of small doses of theobromine. Because there is no available antidote for theobromine toxicity, symptomatic treatments such as administration of emetics, activated charcoal, tranquilizers, sedatives and lidocaine should be used in clinical cases of chocolate toxicity.

GRAPES AND RAISINS

Acute renal failure has been associated with ingestion of variable amounts of grapes or raisins by dogs; as little as 0.41 oz./kg in one case (Gwaltney-Brant et al, 2001). Vomiting and azotemia are the most consistent findings, occurring in 100% of the cases in a retrospective review (Eubig et al, 2005). Varying degrees of renal tubular degeneration and proximal necrosis also occur (Morrow et al, 2005). A number of etiologies have been proposed, including heavy metals, mycotoxins and pesticide residues, but given the lack of a dose-response relationship, no clear toxic principle has been identified. Suggested therapy includes gastric decontamination protocols to induce emesis followed by activated charcoal administration and fluid diuresis (Mazzaferro et al, 2004).

FEEDING PLAN

If a diagnosis of foodborne illness seems feasible, then the pet owner should be questioned extensively about the animal's food. First, the veterinarian should identify all possible food sources (including commercial foods, home-prepared foods and table scraps) and determine the feeding amounts and the availability of unintentional food sources. Common questions concerning commercial foods should include: 1) brand name, 2) manufacturer, 3) lot or date code, 4) form of food (i.e., dry, semi-moist, moist), 5) feeding method (i.e., meal fed, free choice), 6) the length of time the pet has been consuming the brand of food, 7) the length of time the pet has been fed from the present container of food (i.e., bag or can), 8) whether water is mixed with the food, 9) how long the food is left in the food bowl, 10) the ambient temperature at feeding, 11) the method of storing the food and 12) whether other pets in the household consume the same food.

Questions about home-prepared foods should include: 1) the source of ingredients, 2) storage methods for the ingredients and the food, 3) method of preparation, 4) preparation temperatures, 5) method of measuring temperatures and 6) feeding method. Any recent change in either the food ingredients or preparation methods should be investigated further.

The amount of food consumed should be compared with the calculated amount typically consumed by an animal of similar size. If the amount consumed is markedly less than the calculated amount, it could mean that the animal does not like the food and may be foraging other food sources or garbage. Decreased intake may also indicate food refusal typical of vomitoxin contamination.

Sampling Procedures

Most veterinary diagnostic laboratories can perform the tests necessary to facilitate a diagnosis of foodborne illness. Many investigative tests and techniques are available to the diagnostic laboratory to help assess the case. In fact, the number is so overwhelming that only a few can be used on a particular sample. It is essential that the veterinarian discuss the likely diagnoses with laboratory personnel before test initiation to ensure the tests most critical to a correct diagnosis are performed. Veterinarians also need to determine the laboratory's preferred specimens and methods of specimen preservation.

Sample/specimen collection should follow the rules of physical evidence even if the possibility of litigation seems remote or nonexistent to ensure results are admissible in court if circumstances change. The admissibility of this information in a trial depends on whether: 1) all specimens and/or samples were properly identified, 2) the "chain of custody" (**Table 11-3**) is documented by a specific and detailed description of all events and changes of possession starting at the time of collection, through transportation and transferal to final sample analysis at the laboratory and 3) the evidence is relevant to the case (Grau, 1993). Therefore, it is also important to inform laboratory personnel if there is any possibility of litigation.

The best sources of samples for assessment of the food for possible etiologic agents are: 1) the actual food source, 2) food ingredients (homemade foods), 3) stomach contents, 4) intestinal contents and 5) feces. The following procedures and methods relate primarily to assessment of the food but also could be used to evaluate any previously described specimens (e.g., urine, blood, tissues, etc.).

The pet owner should bring the entire container of food or containers of food ingredients to the veterinarian to ensure that sample collection follows aseptic technique and the rules of evidence collection (Grau, 1993; Edwards, 1989). Sample collection techniques are described in detail in **Table 11-4**. Label all sample containers as space allows with a sample number and a description of the contents, submitter's name, pet owner's name, date, product label information and lot number. Supporting information and descriptions that cannot be written on the sample label because of space constraints should be numbered identically to the sample and submitted with the sample (Osweiler et al, 1985; Edwards, 1989; Galey, 1992).

Detection Methods

Bacterial Isolation and Identification

Pet food ingredients, like most other foods, contain a diverse microbial flora. Therefore, no single growth medium will satisfy the requirements of all organisms that may be present in a sample. The veterinarian should discuss likely pathogens with laboratory personnel so that the best methods, enrichment techniques and selective media can be used (Galey, 1992; Quinn et al, 1994).

Most laboratories will use a variety of direct examination and culture techniques to attempt a successful identification (Quinn et al, 1994). First, smears of the specimens collected by either the veterinarian or laboratory personnel will be stained and

Introduction to Feeding Normal Dogs

Jacques Debraekeleer

Kathy L. Gross

Steven C. Zicker

"What dogs? These are my children, little people with fur who make my heart open a little wider."
Oprah Winfrey

CLINICAL IMPORTANCE

Much has changed in our perception and use of dogs over the past half century. Our society has moved from an agrarian phase into a postindustrial phase with a concomitant shift of the human population into urban settings. Dogs have, by necessity, made the shift to urban living along with us and in doing so we have discovered their remarkable adaptability and versatility.

Dogs have found a job in virtually every niche of society. Dogs have been useful in law enforcement, as nursing home companions, in the military, in drug enforcement, as paraplegic assistants and in search and rescue. The human-animal bond has become a commonly taught subject in veterinary schools, which testifies to the importance of animals, including dogs, for our mental and physical well-being. The Centers for Disease Control and Prevention (CDC) describe some of the health benefits of pet ownership, including decreased blood pressure, cholesterol levels, triglyceride levels and feelings of loneliness and increased opportunities for exercise, outdoor activities and socialization (2006). Many organizations support the health benefits of pet ownership including the American Veterinary Medical Association, The Delta Society and the National Institutes of Health; these organizations and others have issued statements or provided information supporting the health benefits of pet ownership. According to this national poll of working Americans 18 years of age and over, nearly one in five U.S. companies allow pets at work. A majority of those polled believe pets at work provide benefits such as relieving stress, improving relationships with coworkers, making for a happier workforce and creating a happier work environment (CDC, 2006). Another health benefit for both dogs and people is related to exercise and weight loss. When overweight people and overweight pets exercise together, they both have lower dropout rates from their weight-loss programs (Jewell et al, 2004).

The emphasis on dogs as valued members of society (**Box 12-1**) has driven the development of canine nutrition towards the same goals we strive for in human nutrition: long life, high quality life and enhanced performance.

Demographics

Globally, pet ownership has increased, possibly due to reduced human birth rates, changing family structure and aging populations (Anonymous, 1997). Regardless of a pet's size or species, pet owners consider their pet to be a family member. One survey indicated that 63% of the U.S. population own pets. There are nearly 75 million dogs in the U.S. Furthermore, 45% of U.S. households own dogs; this equates to approximately 1.7 dogs per household (AAMA, 2007). **Table 12-1** lists countries with the most prevalent dog ownership. Breed popularity varies from year to year and from region to region; however, some breeds always appear to be more desired than others (**Table 12-2**). Worldwide, mixed-breed and crossbred dogs are most popular.

Box 12-1. People Treat their Dogs like Family Members.

A majority of American households (62%) own at least one pet, but virtually everyone, more than nine in 10, considers his or her pet a member of the family. Here are some other interesting facts about dog ownership.
- 70% of owners said they give their dogs presents at Christmas.
- 22% of owners celebrate their dogs' birthday by giving a special treat, making a special meal, giving their dog a cake, ice cream, a new toy, a new bone, singing happy birthday, throwing a birthday party with other dogs, taking their dog to a favorite place or taking photographs.
- More than 50% of American dog owners are more attached to their pets than to at least one other person; 36% say they are more attached to their dog than their best friend and 12% say they are more attached to their dog than their spouse.
- 25% of owners let their dog sleep either on top of or in their bed.

The Bibliography for **Box 12-1** can be found at www.markmorris.org.

**American Kennel Club Registration Statistics, 2005.

The terms "mixed breed" and "crossbred" have slightly different meanings. Mixed-breed dogs' ancestry might not be discernable, whereas breeders often plan crossbreeding by mating two different purebred dogs.

Coinciding with increasing numbers of pets, from 2001 to 2006, sales of commercial pet foods increased 5.4% in the U.S. and more than 10% worldwide. In the U.S., the trend is for less pet food to be sold through grocery stores and more through specialty and mass merchandisers. Packaged dry dog foods are almost universally fed by dog owners (95% of dog owners) compared to canned food use (34% of dog owners) (Packaged Facts, 2006). This highly competitive market and increased demand, coupled with the importance of nutrition to the health and performance of dogs, make it necessary for practicing veterinarians to understand not only the basics, but also the subtleties of canine nutrition to make knowledgeable recommendations to clients about optimal feeding programs.

Species Diversity

The modern domestic canine species encompasses a vast number of breeds each with its own genetic idiosyncrasies (Fogle, 1997). Using genomic techniques (microsatellite genotyping), the genetic similarities of 85 modern breeds were organized into four distinct groups. The breeds in each of the four groups had similar geographic origins, morphology or role in human activities (Parker et al, 2004). The variety of dog breeds has arisen out of selection efforts by people to produce animals with specific traits that may enhance performance, show or behavioral characteristics (**Table 12-3**). The result is a species that displays a wide variety of morphology; head shape, size, coat characteristics (color, length, etc.) and musculoskeletal structure. By selecting for these traits, we have probably unknowingly selected for variations in metabolism and nutrient usage as has been evidenced in other species. Our knowledge about breed variation in metabolism and nutrient requirements is growing. Furthermore, nutrigenomic technologies create a potential for an even better understanding of breed-specific nutrition (Chapter 4). Nutrigenomics is currently applied to many species including people (Swanson et al, 2003). Because dogs are good models for certain human diseases, the outcome will be an increasing body of knowledge about metabolism and nutrition of the diverse canid species. A common unifying theme is dogs are omnivores.

DOGS AS OMNIVORES

The word carnivore can be used to indicate either a taxonomic classification or a type of feeding behavior. The order Carnivora is quite diverse (**Table 12-4**) and consists of 12 families containing more than 260 species. Omnivorous and carnivorous feeding behaviors are most common among members of the order Carnivora; however, the order also includes species that are herbivores (e.g., pandas) (Corbet and Hill, 1986; Morris and Rogers, 1983, 1989).

Eating Behavior

Several researchers have examined the eating habits of wolves (*Canis lupus*), the nearest ancestors of our domestic dogs, and close relatives such as coyotes (*Canis latrans*). Both are opportunistic predators and scavengers, hunting and eating what is available regionally (Sheldon, 1992). Coyotes eat carrion and hunt rodents, other small mammals, birds, amphibians and other species (Sheldon, 1992; Landry and Van Kruiningen, 1979). Additionally, they have been reported to consume droppings of herbivorous prey; domestic dogs also will readily consume herbivore feces (Lewis et al, 1987). Regional ungulates such as buffalo, deer, elk, moose, wildebeest, antelope and zebra are the natural prey of wolves (Sheldon, 1992; Landry and Van Kruiningen, 1979). Viscera are typically consumed; therefore, partially digested vegetable material is a normal part of the wolf's diet (Beaver, 1981). Both coyotes and wolves also eat plant matter such as fruits, berries, persimmons, mushrooms and melons (Sheldon, 1992; Landry and Van Kruiningen, 1979; Röhrs, 1987). Similarly, dogs are opportunistic eaters and have developed anatomic and physiologic characteristics that permit digestion and usage of a varied diet.

Anatomy and Physiology

Oral Cavity

The oral cavity functions to decrease the physical size of food for introduction into the rest of the alimentary tract. Decreasing the physical size of food creates particles small enough to pass through the esophagus and increases the surface area of the food, which enhances enzymatic digestion in the stomach and small intestine. Dogs have cutting canine teeth for ripping and tearing and molar teeth with large occlusal tables for crushing, which are associated teleologically with the capacity to use plant material (**Figure 12-1**) (Morris and Rogers, 1989). Dogs may fix large pieces of food with their paws to tear off small pieces with their cutting canine teeth, after which the food particle is advanced to the back of the oral cavity where it may be crushed by the molar teeth and mixed with saliva before being swallowed (Meyer, 1990).

Stomach

Wild canids typically eat large meals, usually infrequently, due to intermittent food availability. Dogs may consume their daily energy requirement in one or two large rapidly ingested meals (Ruckebusch et al, 1991). This eating pattern means that the stomach must be able to expand markedly. On average, a medium-sized, adult domestic dog has the capacity to ingest 30 to 35 g of dry matter per kg body weight per day (Meyer, 1990a; Meyer et al, 1980). However, the canine stomach can adjust, within limits, to accommodate the amount of food ingested and can hold 1 to 9 liters depending on the breed (Schummer and Nickel, 1960).

Small and Large Intestine

The characteristics of the canine small intestine are consistent with those of animals that digest an omnivorous diet (Morris and Rogers, 1989). The small intestine composes approximately 23% of the total gastrointestinal (GI) volume of dogs (Ruckebusch et al, 1991) vs. 15% for cats (Wolter, 1982). The ratio of GI tract length to total body length is 6:1 for dogs, 4:1 for cats, 10:1 for rabbits and as high as 20:1 for some herbivores (Morris and Rogers, 1989; Meyer, 1990; Wolter, 1982). This anatomic relationship is consistent with ingestion of an omnivorous diet with intermediate digestibility (i.e., between low digestible herbaceous forages and highly digestible animal flesh). Dogs digest starch effectively via pancreatic enzymes and mucosal disaccharidases.

Nutrient Requirements and Metabolism

Much can be learned about an animal's nutritional requirements simply by analyzing its natural food source. True carnivores, such as cats, are limited to what is available from prey tissues such as skeletal muscle and liver to provide energy and nutrients, including protein, taurine, arginine, arachidonic acid and niacin. Consequently, carnivorous animals (e.g., cats) developed more efficient pathways to use these nutrients, and have lost the ability or have a decreased ability to synthesize them from precursors (Chapter 19). Being omnivorous and feeding on a varied diet of plant and animal tissue, dogs maintained or improved the ability to synthesize nutrients from precursors. These differences lend more evidence to early evolutionary divergence (Martin, 1989) and further support the premise that dogs are omnivores.

Table 12-5 compares the recommendations for daily nutrient intake of adult dogs to the nutrient content of meat (ground beef). This comparison confirms that an all-meat food would be unbalanced for dogs. Specific aspects of nutritional requirements of dogs are discussed in Chapters 5 and 6 and Chapters 13 through 18.

LIFESTAGE NUTRITION

Lifestage nutrition is the practice of feeding animals foods designed to meet their optimal nutritional needs at a specific age or physiologic state (e.g., maintenance, reproduction, growth or senior). The concept of lifestage nutrition recognizes that feeding either below or above an optimal nutrient range can negatively affect biologic performance or health (Chapters

5 and 6). This concept differs markedly from feeding a single product for "all lifestages" (all-purpose foods) in which nutrients are added at levels to meet the highest potential need (usually growth and reproduction). Adult animals at maintenance are always provided nutrients well in excess of their biologic needs when fed all-purpose foods. Because the goals in nutrition are to feed for optimal health, performance and longevity, feeding foods designed to more closely meet individual needs is

preferred. This philosophy is the central tenant to lifestage nutrition and preventive medicine. In addition to providing advice about basic nutritional requirements of their patients, veterinarians should assess and minimize the nutrition-related health risks at each lifestage. For maximal benefit, risk assessment and prevention plans should begin well before the onset of disease.

The value of lifestage feeding is enhanced if risk factor management is incorporated into the feeding practice. In many instances, when the nutritional needs associated with a dog's age and physiologic state are combined with the nutritional goals of disease risk factor reduction, a more narrow, but optimal, range of nutrient recommendations results. For example, essentially all commercial dog foods sold in the U.S. meet or exceed the Association of American Feed Control Officials (AAFCO) minimum nutrient requirements for dog foods. Regulatory agencies such as AAFCO ensure ingredient safety and nutritional adequacy. However, even foods that are nutritionally adequate may have levels of certain nutrients outside a desired range for disease risk factor reduction or optimal performance (these nutrients are nutrients of concern). As mentioned in Chapter 1, besides nutrients of concern, specific food factors such as digestibility and texture can also affect health and modify disease risk. Together, nutrients of concern and specific food factors are referred to as key nutritional factors. The key nutritional factors for commercial foods for different lifestages of healthy dogs will be discussed in Chapters 13 through 18, including those associated with reducing the risk of specific diseases and those involved with optimizing performance during different physiologic states.

Homemade foods, unlike commercial foods, are not regulated. Thus, unless experts in canine nutrition have formulated the recipes from which they are made, there are no assurances that homemade foods will provide adequate nutrition or that the ingredients used to make them are safe for dogs (Chapter 10). However, even if the recipes for homemade foods ensure nutritional adequacy and ingredient safety, key nutritional factors should also be considered, depending on the lifestage of the dog being fed.

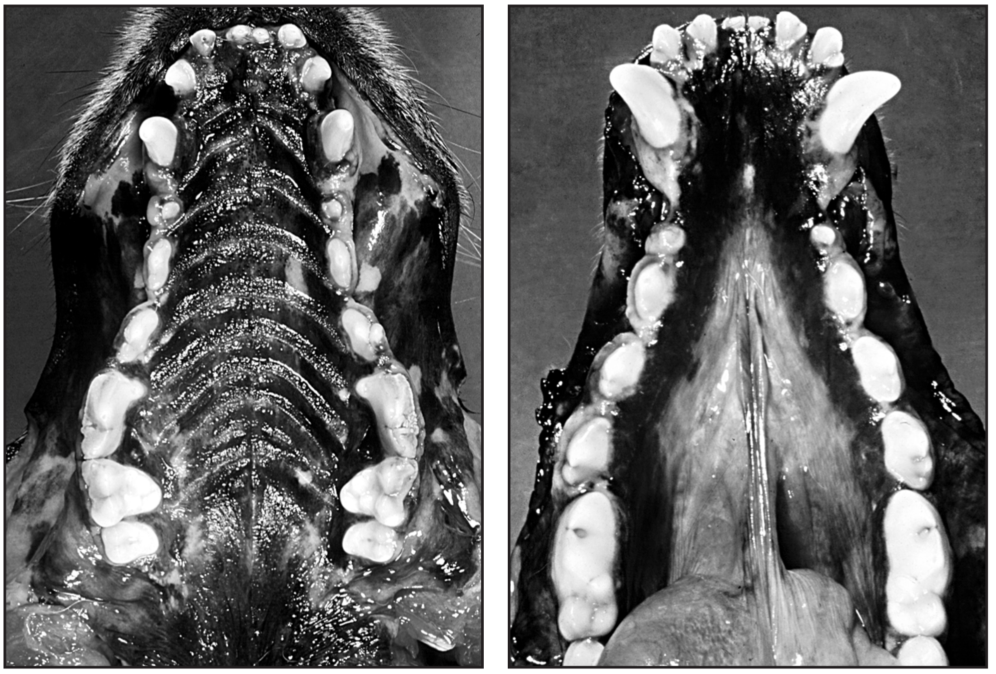

Figure 12-1. Maxillary dentition and palate of a dog (left). Mandibular dentition and sublingual mucosa of the same dog (right). These photographs demonstrate tooth anatomy associated with an omnivorous eating behavior. The cuspid (canine) teeth are long and cutting and are used for capturing and puncturing prey. The maxillary and mandibular premolar teeth interdigitate and provide a shearing action. The carnassial teeth (upper fourth premolar and lower first molar) have broad occlusal surfaces and are used for grinding and chewing. (Adapted with permission from Harvey CE, Emily PP. Function, formation, and anatomy of oral structures in carnivores. Small Animal Dentistry. St. Louis, MO: Mosby-Year Book Inc, 1993.)

In sequence, the chapters that follow cover Feeding Young Adult Dogs: Before Middle Age, Feeding Mature Adult Dogs: Middle Aged and Older, Feeding Reproducing Dogs, Feeding Nursing and Orphaned Puppies from Birth to Weaning and Feeding Growing Puppies: Postweaning to Adulthood. The next chapter begins with feeding young adult dogs because most dogs are adults, and the nutrient needs of adult dogs serve as a good basis for comparing nutrient needs for other lifestages. Chapter 18 covers recommendations for feeding adult working and sporting dogs for optimal physical and olfactory performance.

Feeding Young Adult Dogs: Before Middle Age

Jacques Debraekeleer

Steven C. Zicker

"If you get to thinking you're a person of some influence, try ordering somebody else's dog around."
Will Rogers

INTRODUCTION

Depending on breed, dogs one through five to seven years of age are generally considered young adults. They are usually fully grown (about 12 months old for most breeds) but are not yet middle aged. In people, middle age is often considered to coincide with the third quarter of the average lifespan. Other than obesity and periodontal disease, this age range represents a relatively healthy period in a dog's life. Generally, many of the more common mortal diseases are more often diagnosed in middle-aged or older dogs.

The goals of nutritional management for young adult dogs are to maximize longevity and quality of life (disease prevention). A basic premise is that the foods fed should be nutritious; they should provide the recommended allowances of all known required nutrients. Most regulated commercial foods provide all the necessary nutrients in amounts that avoid deficiencies (Chapter 9). However, to meet the feeding goals described above, nutritional recommendations must exceed simply preventing diseases associated with nutrient deficiencies.

Nutritional recommendations for people living in affluent countries include nutrient and food recommendations that help prevent important diseases such as obesity, diabetes mellitus, cardiovascular disease, cancer, Alzheimer's disease and others. Thus, as in people, optimal feeding plans for pet dogs should include recommendations for specific nutrients and non-nutrient food ingredients (key nutritional factors) that influence important canine diseases. **Table 13-1** lists the important health concerns that may be positively affected by proper nutritional management in this age group of dogs. To achieve these feeding goals, besides selecting the best food, the food needs to be properly fed (amounts and methods).

PATIENT ASSESSMENT

Patient assessment should be a structured process that includes: 1) obtaining accurate and detailed medical and nutritional histories, 2) reviewing the medical record, 3) conducting a physical examination and 4) evaluating results of laboratory and other diagnostic tests. During assessment, the feeding goals should be established and explained, risk factors for nutrition-related diseases considered and key nutritional factors identified.

History and Physical Examination

Often, in a typical busy clinical setting, the time available to obtain a dietary history and conduct a physical examination is limited. However, a minimum dietary database for all canine patients should be obtained and include: 1) the type of food fed (homemade, commercial, dry, moist, semi-moist, etc.), 2) recipes if homemade food represents the majority of the diet, 3) brand names of commercial foods, if known, 4) names of supplements, treats and snacks and 5) method of feeding (free

Table 13-1. Important diseases for adult dogs that have nutritional associations.*

Disease/ health concern	Incidence/prevalence/ mortality/pet owner concern
Dental disease	Most prevalent disease; numerous associated health risks (e.g.kidney disease)
Obesity	Approximate 30% prevalence; associated health risks (e.g., diabetes mellitus, musculoskeletal disease); major concern
Kidney disease	Second leading cause of non-accidental death; major concern
Arthritis	6% prevalence; primary concern
Cancer	Primary cause of death; primary concern
Skin/coat problems	Second most common cause of disease (26% prevalence); second most common health concern

choice, meal feeding, etc.). An extended dietary database includes: 6) quantities fed, 7) recent changes in food type, intake and preferences, 8) access to food for other pets or livestock, 9) who in the family buys food for the pet, 10) who in the family feeds the pet and 11) appetite changes with estimates of magnitude and duration. The general type and level of activity (e.g., house pet, confined to kennel, working dog, etc.) and neuter status should be noted because these factors are important determinants of energy requirements. The dietary history should be expanded if nutrition-related problems such as obesity are identified in the initial evaluation of the patient.

Body weight, body condition score (BCS) (Chapter 1), oral health and overall appearance of the skin and coat of all adult dogs should be assessed and recorded in the medical record. These parameters are general indicators of nutritional adequacy. An otherwise healthy young adult dog with normal body weight, skin and coat and BCS (2.5/5 to 3.5/5) and no evidence of significant dental disease is unlikely to need further nutritional assessment. However, for purposes of disease prevention, nutritional intervention, such as switching to a food that matches the recommended levels of key nutritional factors, may be warranted. The health concerns listed in **Table 13-1** are discussed in the risk factor review that follows.

Gender and Neuter Status

No controlled studies have been performed to delineate differences in nutritional requirements of intact male vs. intact female dogs. It may be presumed that, like other mammals, intact females require less caloric intake than intact males. If this assumption is true it is probably because of gender-related differences in lean body mass. Lean body mass accounts for nearly all of an animal's resting energy requirement (RER) (Blaxter, 1989). Women require fewer calories than men because of a lower relative amount of lean body mass than men (Pellett, 1990). One study showed that female dogs had an average of 16% more body fat than male dogs (Meyer and Stadtfeld, 1980). Surveys have found a much higher prevalence of overweight and obese conditions in female than male dogs (**Figure 13-1**) (Edney and Smith, 1986; Mason, 1970). These findings suggest that intact female dogs may need fewer calories than intact males.

Obesity occurs twice as often in neutered dogs than in reproductively intact dogs (**Figure 13-1**) (Edney and Smith, 1986). Very little is known, however, about the pathophysiology of this phenomenon. Neutering does not appear to have a marked impact on the resting energy expenditure of female dogs (Anantharaman-Barr, 1990); however, it may significantly increase food intake (Houpt et al, 1979). The increased food intake in neutered bitches is thought to be a consequence of a reduction of appetite-suppressing estrogen activity (Houpt et al, 1979; O'Farrell and Peachey, 1990). A decrease in physical activity is also assumed to occur in many dogs after neutering and may play a more important role in male dogs because of decreased roaming (Hopkins et al, 1976; Lewis, 1978). The daily energy intake should be limited to prevent rapid weight gain in neutered dogs; 1.6 x RER is a good starting point. For some breeds and individual dogs, it may be necessary to lower the energy intake of neutered dogs to 1.2 to 1.4 x RER (Chapters 1 and 5).

Breed

The breed classification should be determined in the initial assessment. Different breeds may be at risk for specific diseases or metabolic alterations that require nutritional management. As an example, certain canine breeds appear to be predisposed

to obesity (Chapter 27). In addition, daily energy requirement (DER) differences have been delineated among different breeds, possibly because of differences in lean body mass, temperament and activity level. As examples, Newfoundland dogs have energy requirements about 20% less than average (Kienzle and Rainbird, 1991), whereas Great Danes and Dalmatians may have energy requirements up to 60% higher than average (Rainbird and Kienzle, 1990; Kienzle and Rainbird, 1991; Zentek and Meyer, 1992; Männer, 1990). Careful attention to specific local lineage and personal clinical impressions of breed differences may prove useful in food recommendations.

Activity Level

Activity significantly influences the energy requirements of individual dogs and should be taken into account when estimating energy requirements. For example, standing requires 40% more energy than lying down (Meyer, 1983). DER may range from RER for sedentary dogs to almost 15 x RER for endurance athletes under extreme conditions (Hinchcliff et al, 1997). A consistently higher level of physical activity probably would result in a relative increase in lean body mass, which would result in an increase in energy use, even at rest (Blaxter, 1989). However, because the activity of individual dogs often cannot be defined precisely, feeding recommendations should initially be conservative to avoid overfeeding and the risk of obesity. Food intake should be adapted as needed to maintain optimal body weight. Chapter 18 presents more information about the influence of specific nutrients on athletic performance (**Box 13-1**).

SEDENTARY DOGS

Estimations for DER include enough energy to support spontaneous activity, such as eating, sleeping, going outside and up to three hours of play and exercise per day. However, most pet dogs are minimally active (NRC, 2006). Approximately 19% of owners never play with their dogs and 22% take their

Box 13-1. Special Nutritional Considerations for Stressed Dogs.

STRESS

Police dogs, sentry dogs and other working dogs may refuse to eat, lose weight, develop diarrhea or become reluctant to work for inapparent reasons. Physiologically induced weight loss is most common in sentry dogs, in which a combination of mental stress, weather extremes and activity may result in loss of up to 10% of body weight during a six-hour tour of duty. Stress stimulates release of cortisol and induces a discharge of catecholamines. Besides stimulating alertness, catecholamines may depress food intake in stressed animals by activating the β-adrenergic and dopaminergic receptors in the lateral hypothalamus. This is obvious in highly stressed sentry dogs that may be reluctant to eat the volume of food they need to meet energy requirements. Dogs in various stressful situations demonstrate the same behavior. Some show dogs and racing greyhounds eat sparingly when the owner/handler prepares to depart to a show or a competition. A decrease in food intake, a slight increase in energy requirement and the catabolic effect of cortisol justify feeding a food with increased fat content (at least about 15% dry matter [DM]) and a protein level of about 25% DM. This recommendation does not compensate for energy spent for activity in addition to the stress (e.g., long-distance performances in which fat must be further increased to meet additional energy requirements).

Changing environments such as boarding or hospitalization may influence food intake due to stress. Dogs may develop diarrhea or refuse to eat when boarded. Practitioners commonly see dogs that refuse to eat in the hospital, but readily eat at home.

EFFECTS OF THE SHOW CIRCUIT

The success of a show dog is determined by genetics, general health, socialization, training and nutrition. Therefore, the preparation of a show dog starts with the correct choice of parents, sound breeding practices and correct rearing of puppies. Good nutrition allows for optimal expression of inherited qualities of a dog. Nutrition of a show dog involves feeding for correct development of skeleton and dentition, and maintenance of long-term health. More specific to show dogs are the nutritional needs for optimal condition of skin and coat, and the support of stress.

Preparation for the show may require particular attention. Skin health and correct color, length and glossiness of hair are important for adult show dogs. The first requirement for a shiny coat is good overall health and nutrition throughout the year. See Chapter 32 for more information about the nutritional effects on skin and coat.

Some show dogs may be finicky eaters, so they may need to be fed a more concentrated, palatable food, containing 25 to 30% DM protein and ≥15% DM fat. During a show, dogs don't spend much energy for physical activity; the primary increase is probably due to stress. Generally, a food that supports the health of skin and coat will provide all the nutrients needed to counteract stress.

EFFECTS OF MULTI-DOG HOUSEHOLDS

Individually housed dogs with limited exercise may have daily energy requirements (DER) as low as 90 to 95 kcal (375 to 400 kJ) metabolizable energy (ME)/$BW_{kg}^{0.75}$, or 1.3 x resting energy requirement (RER). When housed in kennels with other dogs in situations where much mutual interaction occurs, DER may increase to 130 to 140 kcal (545 to 585 kJ) ME/$BW_{kg}^{0.75}$, or 1.9 to 2.0 x RER or more.

In the U.S., more than a third of dog-owning families have more than one dog and many families own more than one species. Some dogs may increase their interest in food when a new pet is introduced to a household, whereas others may refuse to eat for a day or two. Jealousy may arise over food, bones or toys, or over space in the bed. Dogs may defend their food bowl and raise the hair on their crest, withers and back or growl. Free-choice feeding may have a quieting effect in kennels or multiple-dog households, and less dominant dogs may have a better chance to get their share of the food provided. In some cases, dogs need to be fed in separate places. However, those situations are often created by the owner's intervention in the pecking order.

The Bibliography for **Box 13-1** can be found at www.markmorris.org.

Table 13-2. Influence of age on daily energy requirements of active pet dogs.*

Age (years)	Typical DER ranges** kcal $ME/BW_{kg}^{0.75}$	kJ $ME/BW_{kg}^{0.75}$	x RER
1-2	120-140	500-585	1.7-2.0
3-7	100-130	420-550	1.4-1.9
>7	80-120	335-500	1.1-1.7

Key: DER = daily energy requirement, ME = metabolizable energy, RER = resting energy requirement, kcal = kilocalories, kJ = kilojoules.
*Most pet dogs are minimally active and have a DER of approximately 95 kcal/$BW_{kg}^{0.75}$ or 1.2 to 1.4 x RER.
**The energy requirements indicated in this table are only starting points and should be adapted for individual dogs.

dogs out for exercise fewer than three hours per week (Slater et al, 1995). Solitary dogs are less active than dogs housed as a group (Hubrecht et al, 1992). In one study, large dogs (Labrador retrievers) were active for half as many hours per day as small dogs (Manchester terriers) (Patil and Bisby, 2002). An association was also reported between increasing age and declining activity; older dogs spent less time running and more time walking (Head et al, 1997; Siwak et al, 2002).

ACTIVE AND SPORTING DOGS

Dogs and horses are often regarded as the elite athletes of domesticated mammals (Rose and Bloomberg, 1989). Greyhounds are sprint athletes and can reach average speeds of 56 to 60 km/hour (35 to 37.5 miles/hour) over typical race distances (Tompkins and Heasman, 1988). Sled dogs are endurance athletes and can maintain a trot of about 16 km/hour (10 miles/hour) for 10 to 14 hours per day for several consecutive days (Grandjean and Paragon, 1992). Energy requirements of dogs performing work between the two extremes (i.e., sedentary and sled dogs) need to be tailored to the individual. Chapter 18 describes how to feed active working and sporting dogs.

Age

Age-related changes occur between the onset of adulthood and five to seven years of age. The prevalence of dental disease, obesity, cancer, arthritis and kidney disease generally increases over this time span (Chapters 27, 30, 34, 37, 47). The cumulative effects of oxidative damage can result in beta-amyloid deposition in the brain as early as five to seven years of age, predisposing to cognitive dysfunction (Chapter 35). Furthermore, apart from reproduction and imposed activity during work or sport, age may be the single most important factor that influences the DER of most adult dogs (**Table 13-2**) (Finke, 1994).

Environment

The influence of the environment should not be neglected when evaluating energy and nutrient requirements. Temperature, humidity, type of housing, level of stress and the degree of acclimatization should be considered with respect to breed and lifestage nutrient requirements of dogs (**Box 13-1**). Animal factors including insulative characteristics of skin and coat (i.e., subcutaneous fat, hair length and coat density) and differences in stature, behavior and activity interact and affect DER.

Dogs can tolerate extreme cold. Adult dogs can maintain normal body temperature in ambient temperatures as low as -46 to -50°C (-51 to -58°F) for four to 27 hours and six out of seven dogs maintained normal body temperatures at -75 to -79°C (-103 to -110°F) for three to five hours (Hume and Egdahl, 1959). One study found that an ambient temperature of -160°C (-256°F) was necessary to make a dog hypothermic after one hour (Giaja, 1938). When kept outside in cold weather, dogs may need 10 to 90% more energy than during optimal weather conditions (Meyer, 1983; Durrer and Hannon, 1962). Heat losses are minimal at a temperature called the lower critical temperature (Blaxter, 1989a). This is the environmental temperature at which dogs reach their minimum metabolic rate. It is breed specific and is lower when the thermic insulation (i.e., coat density and length) is greater (Zentek and Meyer, 1992; Meyer, 1983, 1990; Männer, 1991; Kleiber, 1975). The lower critical temperature is estimated at 15 to 20°C (59 to 68°F) for longhaired breeds, 20 to 25°C (68 to 77°F) for shorthaired breeds and may be as low as 10 to 15°C (50 to 59°F) for arctic breeds (Männer, 1990, 1991; Kleiber, 1975; Meyer, 1990).

Energy use by dogs in cold environments is similar to energy use during endurance exercise (Minaire et al, 1973). In part, skeletal muscle is involved in shivering and non-shivering thermogenesis (NRC, 2006). As with endurance exercise, muscle glycogen stores may limit the ability to withstand cold (Minaire et al, 1973). Thus, high-fat foods are probably well suited for cold-acclimatized dogs in a cold environment. No published studies currently exist about the influence of changing the relative proportions of the nutrient composition of a food for improved resistance to cold in dogs. But for long-term exposure to cold, the amount of food fed should be increased to ensure increased energy availability.

Compared to cold ambient temperatures, a relatively smaller amount of energy is expended to dissipate heat at temperatures above the thermoneutral zone; however, increased amounts of water are required (**Box 13-2**). Adult dogs tolerated high ambient temperatures up to 56°C (133°F) for three hours or more in dry air (Adolph, 1947) but became poikilothermic at 33°C (91°F) or higher in moist air after one hour (Lozinsky, 1924). The metabolic rate increased by 10% in adult dogs when ambient temperatures were 35°C (95°F) (Minaire et al, 1973).

Housing conditions may influence energy and water requirements by modifying the immediate environment. Many housing options are possible; however, any shelter with temperatures closer to the thermoneutral zone will decrease energy requirements in cold environments and water requirements in hot environments (i.e., protection from wind chill, excess sun, etc.). Conversely, housing that moves dogs farther away from the thermoneutral zone will have the opposite effects (e.g., closed spaces in hot humid conditions, damp shady shelters in cold weather). The number of dogs in a shel-

Box 13-2. Nutrients Used for Body Cooling.

When ambient temperature exceeds a dog's thermoneutral zone, water and energy are used for heat loss. The ability of dogs (and people) to withstand extremely high ambient temperatures is well demonstrated by a study conducted in 1775 by Blagden. It was reported that Blagden, and a dog in a basket (to protect its feet from being burned), entered a room kept at a 126ºC (259ºF) and remained there for 45 minutes. A steak he took with him was cooked; however, he and the dog were unaffected.

Bodies cool by radiation, conduction, convection and vaporization of water. As the ambient temperature increases, the conditions for heat loss by radiation, conduction and convection become increasingly unfavorable. When the ambient temperature exceeds the dog's body temperature, the dog's entire metabolic heat production and the heat received from the environment by conduction, convection and radiation must be removed by evaporation of water to maintain normal body temperature.

Vaporization of water can occur via insensible perspiration, respiration, panting and sweating. Dogs have few sweat glands and thus must pant to evaporate additional water for cooling. Panting is facilitated by the elastic properties of the thorax and respiratory system. Depending on the size of the dog, the respiratory apparatus oscillates to a natural frequency (the resonant frequency of the chest is proportional to the square root of the body mass). The amount of cooling is regulated by the duration of panting. If not for resonant elasticity, the increased muscular effort of breathing would generate more heat than the total heat that could be dissipated by panting. As a result of these elastic properties, however, panting requires only a small amount of energy.

The amount of heat lost via vaporization of water is approximately 580 kcal (2,426 kJ)/kg water. In hot desert-like conditions, in which the heat gained from the environment can be 10 times the metabolic heat production, the water required for cooling a 15-kg dog may equal 2.5% of its body mass per hour. At this rate, if uncompensated for evaporative water loss, a dog could experience a 10% reduction of its total body water within 2.5 hours. Thus, from a nutritional perspective, dogs in hot environments may have a significant increase in water requirement with only a small increase in energy needs to maintain normal body temperature.

The Bibliography for **Box 13-2** can be found at www.markmorris.org.

ter may also affect the adequacy of the housing; increased numbers of dogs will increase the temperature in the local environment (Blaxter, 1989a; Kleiber, 1975).

Regarding environmental factors, and unrelated to the nutritional needs of dogs, pet food manufacturers develop products to address owner conveniences and concerns. This practice led to the development of specific pet food flavor varieties, kibble shapes, colors and sizes and packaging improvements. In the U.S., products have been introduced for pets that spend the majority of their lives indoors or in high population density urban settings. As an example, these products address the desire by pet owners for a very small stool volume, which makes cleanup easier. In addition, pets fed highly digestible, calorically dense foods eat less, resulting in less food carried home by the owner. Such trends, however, are not new to urban high population density countries such as Japan.

Laboratory and Other Clinical Information

Healthy young adult dogs require few laboratory and other diagnostic tests as part of routine assessment. The most common extended database includes a fecal examination for intestinal parasites, tests for heartworm infection and fundic examination. For dogs older than five years, a urinalysis performed on a fresh urine specimen collected after an all-night fast is added. A complete blood count, serum biochemistry profile and urinalysis should be obtained for ill dogs and those with suspected abnormal nutrition.

Key Nutritional Factors

Table 13-3 summarizes key nutritional factors for young adult dogs. The following section describes these key nutritional factors in more detail. Calcium is also a nutrient of concern for young adult dogs, especially when they are fed homemade foods (**Box 13-3**).

Table 13-3. Key nutritional factors for foods for young adult dogs.

Factors	Recommended food levels* Normal weight and body condition	Inactive/ obese prone
Water	Free access	Free access
Energy density (kcal ME/g)	3.5-4.5	3.0-3.5
Energy density (kJ ME/g)	14.6-18.8	12.5-14.6
Fat and essential fatty acids (%)	10-20	7-10
Crude fiber (%)**	≤5	≥10
Protein (%)	15-30	15-30
Phosphorus (%)	0.4-0.8	0.4-0.8
Sodium (%)	0.2-0.4	0.2-0.4
Chloride (%)	1.5 x Na	1.5 x Na
Antioxidants (amount/kg food)		
Vitamin E (IU)	≥400	≥400
Vitamin C (mg)	≥100	≥100
Selenium (mg)	0.5-1.3	0.5-1.3
Food texture (VOHC Seal of Acceptance)	Plaque	Plaque

Key: DM = dry matter, kcal = kilocalories, kJ = kilojoules, ME = metabolizable energy, VOHC = Veterinary Oral Health Council Seal of Acceptance (Chapter 47).
*Dry matter basis. Concentrations presume an energy density of 4.0 kcal/g. Levels should be corrected for foods with higher energy densities.
**Crude fiber measurements underestimate total dietary fiber levels in food.

Box 13-3. Nutritional Factors of Concern for Homemade Foods Intended for Adult Dogs.

In addition to the key nutritional factors for commercial foods for adult dogs (See Key Nutritional Factors discussion.), calcium is also a nutritional factor of concern for homemade foods for adult dogs.

Commercial foods may contain inadequate, adequate and sometimes excessive amounts of calcium and/or phosphorus and; therefore, should not be supplemented. However, calcium is often deficient and phosphorus may be excessive in homemade foods, especially when most of the diet comes from meat and leftovers from the table (Table 12-5). Existing commercial multiple vitamin-mineral mixes (powders, tablets, etc.) are seldom designed to correct imbalances encountered in homemade foods. When formulating homemade foods, it is better to correct calcium-phosphorus imbalances by adding mineral sources such as calcium carbonate or dicalcium phosphate, both of which are usually available from drug stores (Chapter 10).

Water

Water accounts for approximately 56% of an adult dog's body weight (73% of lean body mass) (Stadtfeld, 1978). The body has a limited capacity to store water, and although healthy dogs can replenish a water deficit of up to 8% of body weight in a few minutes (Anderson, 1982), water deprivation will result in death more quickly than withholding any other nutrient (NRC, 1985). Therefore, it can be argued that water is the most important nutrient.

Total water intake (i.e., drinking and water from food) is influenced by several factors such as environment, physiologic state, activity, disease processes and food composition. Total water intake increases almost linearly with increasing salt levels in food (Anderson, 1982; Burger et al, 1980). Switching from a moist to a dry food and vice versa markedly affects the amount of water taken with the food; however, dogs compensate well for this difference by changing the quantity of water they drink, thus keeping their total daily water intake constant (Burger et al, 1980). Generally, dogs self-regulate water intake according to physiologic need. Healthy adult dogs need roughly the equivalent of their energy requirement in kcal metabolizable energy (ME)/day, expressed in ml/day (Lewis et al, 1987). Dogs should be offered free access to water at rest and before, during and after exercise (NRC, 2006). During warm weather, enough water should be available to compensate for evaporation by panting (Anderson, 1982) **Box 13-2**.

Energy

Domestic canids are the most diverse mammalian species in body weight and size. Therefore, energy requirements are not linearly correlated with kg body weight, but are more closely related to metabolic weight ($BW_{kg}^{0.75}$) (Meyer, 1986; NRC, 2006). DER recommendations of adult, non-athletic, non-reproducing dogs have varied from 85 kcal (355 kJ) ME/$BW_{kg}^{0.75}$ to more than 220 kcal (920 kJ) ME/$BW_{kg}^{0.75}$ (Zentek and Meyer, 1992; Männer et al, 1987; Heusner, 1991). This range may confuse dog owners, but it is not surprising considering that breed, neuter status, age, daily activity, environmental temperature and insulative characteristics of the integument markedly influence the DER of a particular dog (Rainbird and Kienzle, 1990; Kienzle and Rainbird, 1991; Männer, 1990, 1991; Meyer, 1983; NRC, 2006; Gesellschaft, 1989; Burger, 1994; Finke, 1991). Graphically, the DER for a population of dogs results in a bell-shaped curve; therefore, the energy intake of individual dogs may vary by about 50% above or below the average requirements, even within the same age group (Chapter 1). The RER, however, is not markedly influenced by these factors, and is similar for all dogs, independent of breed or age. RER is approximately 70 kcal (293 kJ)/$BW_{kg}^{0.75}$ (NRC, 2006; Kleiber, 1975) (Chapter 1). A simple linear formula can also be used to estimate RER for dogs weighing more than two kg: RER_{kcal} is approximately (30 x BW_{kg}) + 70 (Lewis et al, 1987). To convert from kcal to kJ, multiply kcal by 4.184. Table 5-2 provides RER values for dogs with body weights from 1.5 to 70 kg.

Because DER is the sum of RER plus all the above influences, it is better to use RER as the basis for calculating energy requirements of adult dogs and to assign different multipliers to account for differences in activity, age and environmental influences. When assigning multipliers to RER, it is important to account for neuter status because this variable can be an important factor in determining DER of household dogs. Neutered dogs may have a lower DER than intact counterparts. Surveys have shown that the prevalence of obesity increases progressively and peaks in middle-aged dogs (Armstrong and Lund, 1996; Kronfeld et al, 1991). Thus, prevention of obesity should be an important goal of feeding programs for young adult dogs. Animals benefit more from an appropriate weight-maintenance program than treatment for obesity (Chapter 27).

Three groups of adult dogs can be distinguished based on DER: 1) one to two years old, 2) three to seven years old and 3) more than seven years old (**Table 13-2**) (Rainbird and Kienzle, 1990; Kienzle and Rainbird, 1991; Finke, 1991, 1994). The differences in DER probably reflect an age-related decrease in activity and lean body mass.

Most pet dogs are minimally active and may have a DER that approaches their RER. Such dogs fed caloric intakes recommended for maintenance (1.6 x RER) will be overfed and are likely to become overweight. A recommendation of 1.2 to 1.4 x RER (85 to 98 kcal [355 to 410 kJ] ME/$BW_{kg}^{0.75}$/day) is a good starting point for feeding sedentary dogs (Männer, 1990, 1991; Männer et al, 1987; Heusner, 1991; NRC, 2006).

A good starting point for estimating the DER of more active adult dogs would be 1.6 x RER (115 kcal [480 kJ] ME/$BW_{kg}^{0.75}$). Such dogs between two and seven years of age would probably have a DER between 1.4 to 1.9 x RER (100 to 130 kcal [420 to 550 kJ] ME/$BW_{kg}^{0.75}$) with the higher number used in the lower age group and the lower number applied to the higher age group (**Table 13-2**). All initial estimates of

energy needs must subsequently be evaluated by body condition assessment and adjusted as needed for individual dogs. It has been estimated that sled dogs may require more than 10,000 kcal/day (41.8 MJ/day) (up to 15 x RER) to maintain body weight under racing conditions (Hinchcliff et al, 1997). Active young adult dogs should be fed a food with an energy density range of 3.5 to 4.5 kcal/g dry matter (DM). The energy density range of foods for inactive/obese prone dogs should be lower (3.0 to 3.5 kcal/g DM).

Fat and Essential Fatty Acids

Fats are an excellent source of energy, but the real requirement for fat is to supply essential fatty acids (EFAs). In addition, fat serves as a carrier for the absorption of fat-soluble vitamins (i.e., A, D, E and K). Linoleic and α-linolenic acids are considered essential because dogs lack the enzymes to synthesize them (Watkins, 1997). Linoleic acid (18:22n-6) is the parent fatty acid of the omega-6 (n-6 series), as is α-linolenic acid for the omega-3 (n-3) series. EFAs have structural functions in cell membranes and are precursors of eicosanoids such as prostaglandins, thromboxanes and leukotrienes (NRC, 1985a; Lands, 1991). Linoleic acid deficiency results in two primary skin defects: hyperproliferation and increased permeability to water (Ziboh and Miller, 1990). The epidermal water barrier consists of lamellae of lipids (sphingolipids) in the stratum corneum of the epidermis. Linoleic acid is incorporated into the ceramide-portion of sphingolipids where it provides the specific characteristics needed for barrier function (Ziboh and Miller, 1990). Additionally, linoleic acid plays a role in fertility (Lands, 1991). Ensuring an adequate intake of EFAs is key to maintaining normal skin and coat quality.

Whether omega-3 fatty acids are essential is less certain because of the inability of omega-3 fatty acids to support all of the physiologic functions that are supported by omega-6 fatty acids (Lands, 1991). Nevertheless, a source of dietary omega-3 fatty acids is recommended (Watkins, 1997). The minimum recommended allowance for dietary eicosapentaenoic plus docosahexaenoic acids is 0.044% DM (NRC, 2006). Omega-3 fatty acids may moderate excessively vigorous actions of omega-6-derived eicosanoids (Lands, 1991) and are of value in the management of certain diseases (Chapters 30, 32, 34, 37). The minimum recommended allowance for dietary fat in foods for normal, healthy adult dogs is 8.5%, with at least 1% of the food as linoleic acid (DM) (NRC, 2006). Depending on the type/source of fat, increasing the amount of fat in foods increases palatability and EFA levels; however, energy content also increases. The recommended range of fat for foods intended for young adult dogs is 10 to 20% (DM). Lower levels of dietary fat are recommended for obese-prone adult dogs (7 to 10% DM).

Fiber

The levels of dietary fat and fiber are important determinants of a food's energy density. Fat provides more than twice as much energy on a weight basis than carbohydrate or protein. High-fat foods have increased energy density; conversely, low-fat foods have decreased energy density. Fiber is a poor source of energy for dogs; thus, as the fiber content of foods increases, energy density decreases. Dietary fiber reduces the energy density of the food and helps promote satiety (Chapters 5 and 27). Inclusion of fiber in foods may therefore help maintain ideal body weight in dogs fed free choice. In pet foods, fiber is listed as crude fiber, which is an imprecise measure because most soluble fiber is omitted. A better measure would be total dietary fiber; however, regulations only permit declaration of crude fiber because no method for determination of total dietary fiber is yet officially recognized for pet foods. It is difficult to determine the optimal concentration of crude fiber in a complete food for dogs; however, up to 5% DM seems adequate. Obese-prone dogs may benefit from at least 10% DM crude fiber and DM fat should be restricted to between 7 to 10%. Foods that are low in fat and high in fiber tend to have the lowest energy density and are recommended for obese-prone dogs.

Protein

The amount of protein in commercial foods for healthy dogs varies widely (15 to 60% DM). After the amino acid requirements are met for an individual animal, addition of more protein provides no known physiologic benefit. This fact often runs contrary to the popular belief that more protein is better. Also, the addition of extra protein in commercial dog foods is sometimes marketed as necessary for carnivores and misrepresents the fact that dogs are omnivores. Excess dietary protein, above the amino acid requirement, is not stored as protein, but rather is deaminated by the liver. Subsequently, the kidneys excrete the by-products of protein catabolism and the remaining keto acid analogues are used for energy or stored as fat, or as glycogen in some cases.

The subject of whether excess dietary protein contributes to the progression of subclinical kidney disease has yet to be resolved (Chapter 37). Studies in people suggest that protein restriction may help slow progression of kidney disease (Mitch et al, 1998; NKF, 1998). In addition to any potential aggravating effects excess dietary protein may have on subclinical kidney disease, foods high in protein also tend to contain high levels of phosphorus. As mentioned above, excess dietary phosphorus accelerates the progression of kidney disease in dogs. Minimum protein requirements for healthy adult dogs eating high-quality protein have been determined using nitrogen balance and endogenous nitrogen excretion. A more reliable estimate based on endogenous nitrogen excretion equates to a minimum requirement of 1.7 g metabolizable protein/$BW_{kg}^{0.75}$ for an ideal protein (NRC, 1985a; Kendall et al, 1982; Schaeffer et al, 1989). When protein of average quality is used (biologic value of about 70), the minimum requirements are increased to 2.1 to 2.5 g digestible protein/$BW_{kg}^{0.75}$ (Gesellschaft, 1989b).

The minimum crude protein content of food depends on digestibility and quality. For example, if the digestibility of an average quality protein is 75%, then about 12% DM crude protein is adequate. Foods containing less than 12% DM crude protein must be of higher biologic value. Biologic value becomes less important for healthy adult dogs if foods contain crude pro-

tein levels greater than 12%. A daily protein intake for adult maintenance of 4.3 to 5.0 g digestible protein/$BW_{kg}^{0.75}$ (biologic value = 70) or 4.0 to 6.5 g digestible protein/100 kcal ME is recommended (Gesellschaft, 1989b). The minimum recommended allowance for DM crude protein is 10% for a commercial food with an energy density of 4 kcal/g DM (NRC, 2006). Foods formulated to meet the lower limits in crude protein must also have the recommended allowances for essential amino acids. Thus, the recommended range of DM crude protein for foods for young adult dogs is between 15 to 30%.

Phosphorus

Minimum requirements for phosphorus for adult dogs are not very different from those established for other mammals. Commercial foods contain adequate and sometimes excessive amounts of phosphorus and, therefore, should not be supplemented.

Based on endogenous losses, a daily intake of 75 mg phosphorus/kg body weight is adequate (Gesellschaft, 1989a). At an energy density of 3.5 kcal (14.6 kJ)/g DM this corresponds to an average content of about 0.4 to 0.6% DM phosphorus. These levels are adequate, but not excessive; daily intakes 20 to 30% less are still sufficient (Gesellschaft, 1989a). Therefore, it is unnecessary to feed foods with higher levels of phosphorus, or to add calcium-phosphorus supplements to commercial foods. Moreover, higher phosphorus levels are contraindicated for a substantial part of the dog population; up to 25% of the young adult dog population may already be affected by subclinical kidney disease (Oehlert and Oehlert, 1976; Rouse and Lewis, 1975; Shirota et al, 1979). One clinical study revealed that 22.4% of all dogs over five years of age examined at a European veterinary teaching hospital for a variety of reasons had abnormally elevated kidney function tests (Leibetseder and Neufeld, 1991). Excess dietary phosphorus can accelerate progression of chronic renal disease (Brown et al, 1991), whereas phosphorus restriction may slow the progression of chronic renal disease and improve long-term survival (Brown et al, 1991; Finco et al, 1992). It is therefore prudent to feed foods that contain adequate but not excessive amounts of phosphorus (Chapter 37 contains more information about how excess dietary phosphorus affects progression of kidney disease).

The minimum recommended allowance for phosphorus in foods for adult dogs is 0.3% (DM); this recommendation is appropriate for foods with an energy density of 4 kcal/g (DM) (NRC, 2006). The recommended range of phosphorus for foods intended for young adult dogs is 0.4 to 0.8% (DM) when the energy density ranges from 3.5 to 4.5 kcal/g DM.

Sodium and Chloride

Essential hypertension is not considered a common problem in dogs; therefore, higher intakes of dietary sodium and chloride have not been considered harmful in young, healthy dogs (Bodey and Mitchell, 1996; Bovée, 1990). However, one study suggested that up to 10% of apparently healthy dogs may have high blood pressure (Remillard et al, 1991).

High sodium and chloride intake is contraindicated in dogs with certain diseases that may have a hypertensive component such as obesity, renal disease and some endocrinopathies (Anderson and Fisher, 1968; Cowgill and Kallet, 1986; Rocchini et al, 1987; Littman, 1990; Ross, 1992). Uncontrolled high blood pressure may lead to kidney, brain, eye, heart and cardiovascular damage (Cowgill and Kallet, 1986; Littman, 1990). Dietary sodium chloride restriction is the first step in, and an important part of, antihypertensive therapy (Cowgill and Kallet, 1986; Littman, 1990; Ross, 1992).

It is prudent to meet but not greatly exceed sodium and chloride requirements when selecting foods for adult dogs. The best estimate for a minimum requirement of sodium is about 4 mg/kg body weight/day (Morris et al, 1976). Generally, 25 to 50 mg/kg body weight/day (Gesellschaft, 1989a) is recommended for adult maintenance; these levels are six to 12 times more than the minimum. The minimum recommended allowance for sodium content of commercial foods is 0.08% (DM); this allowance is for foods with an energy density of 4 kcal/g (DM) (NRC, 2006). For risk factor management, the recommended range for dietary sodium is 0.2 to 0.4% (DM), which is more than adequate. Sodium levels in commercial foods for adult dogs range from 0.11 to 2.2% DM and are higher in moist foods than in dry foods. In the absence of studies establishing chloride requirements in dogs, a value 1.5 times the sodium requirement is recommended.

Antioxidants

The consequences of prolonged oxidative stress (i.e., free radical damage) to cell membranes, proteins and DNA may contribute to and/or exacerbate a wide variety of degenerative diseases. A partial list includes cancer, diabetes mellitus, kidney/urinary tract disease, heart disease, liver disease, inflammatory bowel disease and cognitive dysfunction (Ames et al, 1993; Kesavulu et al, 2000; Ha and Le, 2000; Thamilselvan et al, 2000; Freeman et al, 1999; Cheng et al, 1999; Center, 1999; Knight, 1999). The consequences of free radical damage to cells and tissues have also been associated with the effects of aging (Harman, 1956).

The body synthesizes many antioxidant enzyme systems and compounds but relies on food for others. Commonly supplemented food-source antioxidants include vitamins E and C, β-carotene and other carotenoids, selenium and thiols. Fruits and vegetables are good sources of flavonoids, polyphenols and anthocyanidins. The following discussion focuses on vitamins E and C and selenium as antioxidant key nutritional factors because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C regenerates vitamin E after it has reacted with a free radical), 3) they are safe and 4) information about inclusion levels in pet foods is usually available. For improved antioxidant performance, foods for mature dogs should contain at least 400 IU vitamin E/kg (DM) (Jewell et al, 2000), at least 100 mg vitamin C/kg (DM) and 0.5 to 1.3 mg selenium/kg (DM).

VITAMIN E

Vitamin E is the main lipid-soluble antioxidant present in

plasma, erythrocytes and tissues (NRC, 2006). It is transported in plasma proteins and partitions into membranes and fat storage sites where it is one of the most effective antioxidants for protecting polyunsaturated fatty acids from oxidation. It functions as a chain-breaking antioxidant that prevents propagation of free radical damage of biologic membranes. Vitamin E inhibits lipid peroxidation by scavenging lipid peroxyl radicals much faster than these radicals can react with adjacent fatty acids or with membrane proteins (Gutteridge and Halliwell, 1994). Vitamin E plays a dominant role in defending against oxidative damage in cells.

The requirement for vitamin E for foods (DM) for adult dogs is 30 mg/kg (NRC, 2006). Research indicates that a level of vitamin E much higher than the requirement confers specific biologic benefits. One antioxidant biomarker study in dogs indicated that for improved antioxidant performance, dog foods should contain at least 500 IU vitamin E/kg (DM) (Jewell et al, 2000). Besides helping to prevent chronic diseases associated with oxidative stress, increasing dietary intake of vitamin E up to 2,010 mg/kg food (DM) in older dogs improved immune function (Hayes et al, 1969; Hall et al, 2003; Meydani et al, 1998). Furthermore, increased vitamin E intake is also directly related to increased vitamin E content of skin in dogs (Jewell et al, 2002). The skin is uniquely challenged by oxidants due to its role as a barrier. It is exposed to air pollutants, ultraviolet radiation and oxidants released as a result of normal metabolism, parasites and aerobic microbes. An upper limit of 1,000 to 2,000 IU/kg food (DM) has been suggested for dogs (AAFCO, 2007; NRC, 1985). In one study that demonstrated improved immune function associated with ingestion of 2,010 IU vitamin E/kg food (DM) (Hall et al, 2003), dogs had no safety issues at this intake level for one year.[a] A prudent recommendation is that foods for young adult dogs should contain at least 400 IU vitamin E/kg (DM).

VITAMIN C

Vitamin C is the most powerful reducing agent available to cells. As such, it is important for regenerating oxidized vitamin E. Besides regenerating vitamin E, vitamin C: 1) regenerates glutathione and flavonoids, 2) quenches free radicals both intra- and extracellularly, 3) protects against free radical-mediated protein inactivation associated with oxidative bursts of neutrophils, 4) maintains transition metals in reduced form and 5) may quench free radical intermediates of carcinogen metabolism.

Dogs can synthesize required amounts of vitamin C (Innes, 1931; Naismith, 1958; Chatterjee et al, 1975) and they can rapidly absorb supplemental vitamin C (Wang et al, 2001). However, in vitro studies indicated that dogs (and cats) have from one-quarter to one-tenth the ability to synthesize vitamin C as other mammals (Chatterjee et al, 1975). Whether or not this translates to a reduced ability in vivo is unknown. In conjunction with the recommended levels of vitamin E, above, for improved antioxidant performance, foods for adult dogs should contain at least 100 mg of vitamin C/kg (DM).

Excessive supplementation of vitamin C should be avoided. In people, high levels of oral vitamin C increased urine oxalate excretion and stone risk (Massey et al, 2005). Vitamin C supplementation to cats resulted in a small, progressive reduction of urinary pH (Kienzel and Maiwald, 1998). However, moderate supplementation of foods for healthy adult cats with vitamin C (193 mg/kg of food, DM) did not increase the risk of oxalate production in urine (Yu and Gross, 2005).

SELENIUM

Glutathione peroxidase is a selenium-containing antioxidant enzyme that defends tissues against oxidative stress by catalyzing the reduction of H_2O_2 and organic hydroperoxides and by sparing vitamin E. The minimum requirements for selenium in foods for dogs and cats are 0.10 and 0.13 mg/kg (DM), respectively (Wedekind et al, 2002, 2003, 2003a). Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at levels much higher (five to 10 times) than human recommended allowances or minimal requirements (Combs, 2001; Neve, 2002). Several mechanisms have been proposed for this effect, including enhanced antioxidant activity via glutathione peroxidase (Neve, 2002). Therefore, for increased antioxidant benefits, the recommended range of selenium for adult dog foods is 0.5 to 1.3 mg/kg (DM). There are no data to base a safe upper limit of selenium for dogs, but for regulatory purposes, a maximum standard of 2.0 mg/kg (DM) has been set for dog foods in the U.S. (AAFCO, 2007).

Food Texture

Periodontal disease is the most common health problem of adult dogs (Harvey et al, 1994) and may predispose affected animals to systemic complications (DeBowes et al, 1996). Periodontal disease can be prevented in many dogs with routine veterinary care and frequent plaque control at home. Feeding recommendations for oral health commonly include feeding a dry pet food (Golden et al, 1982). However, typical dry dog foods contribute little dental cleansing and the general statement that dry foods provide significant oral cleansing should be regarded with skepticism. Research has demonstrated that maintenance dog foods with specific textural properties and processing techniques can significantly reduce plaque accumulation and maintain gingival health. If the labels of such foods carry the Veterinary Oral Health Council (VOHC) seal, they have been successfully tested according to specific protocols and shown to be clinically effective in reducing accumulation of plaque (Chapter 47).

FEEDING PLAN

Assess and Select the Food

After the nutritional status of the dog has been assessed and the key nutritional factors and their target levels determined, the adequacy of the food is assessed. The steps for assessing foods for normal adult dogs are to: 1) ensure that the nutritional adequacy of the food has been assured by a credible regulatory agency such as the Association of American Feed Control Officials (AAFCO) for foods sold in the U.S., 2) compare the

Feeding Mature Adult Dogs: Middle Aged and Older

Jacques Debraekeleer
Kathy L. Gross
Steven C. Zicker

"Old dogs, like old shoes, are comfortable. They might be a bit out of shape and a little worn around the edges, but they fit well."
Bonnie Wilcox 'Old Dogs, Old Friends'

INTRODUCTION

For a number of reasons, the mature segment (six to eight years of age and older) of the pet dog population is growing. More than 35% of dogs in the U.S. are at least seven years old and, in Europe, the number of dogs older than seven years increased by about 50% from 1983 to 1995 (Lund et al, 1999; Kraft, 1998). In this chapter, mature dogs include dogs that are middle aged and older. In people, middle age is often considered as being approximately the third quarter of the average lifespan.

Aging increases vulnerability (Mosier, 1989; Hayflick, 1994). Aging isn't a disease; however, morbidity increases with age because normal changes make animals more vulnerable to diseases (Hayflick, 1994). The influence of nutrition on vulnerability to chronic or acute disease is difficult to evaluate, and has not been explored thoroughly in dogs. In people and companion animals, nutrition may be one of the more important aspects of geriatric care because delay or elimination of the two or three leading causes of death would profoundly affect life expectancy (Hayflick, 1994a). In dogs, the three leading non-accidental causes of death are cancer, kidney disease and heart disease (Bronson, 1982; MacDougall and Barker, 1984; MAF, 1991, 1998). Other diseases and disorders are also common (Table 13-1). Moreover, older animals seldom suffer from a single disease and one problem may markedly influence the course of another (Mosier, 1990).

The overall feeding goals for mature adult dogs are to optimize quality and longevity of life and minimize disease. To understand the specific nutritional needs of mature dogs, it is necessary to know the major effects of aging on canine body systems (**Box 14-1**). Aging is characterized by progressive and, usually, irreversible change (Mosier, 1988), and its rate and manifestations are determined by intrinsic and extrinsic factors, one of which is nutrition. Because aging is progressive, the point in time at which a food change should be made is arbitrary, and in a way philosophical. Dogs often are considered mature or likely to start having diseases associated with aging between seven and one-half and 13.5 years (Goldston, 1989). Smaller dogs tend to live longer than large dogs (**Table 14-1**). The life expectancy of smaller dogs may be more than 20 years. Because dogs are often considered older when they reach half of their life expectancy (Grandjean and Paragon, 1990), a food change should be considered around the age of five years for large- and giant-breed dogs and around seven years for small dogs (Markham and Hodgkins, 1989).

At these ages, dogs may gradually start to gain weight and develop age-related physical and behavioral changes (Armstrong and Lund, 1996; Markham and Hodgkins, 1989; Landsberg and Ruhl, 1997). Clinical signs of cognitive dysfunction and brain pathology associated with aging begin at about seven to eight years of age (Head et al, 2000).[a]

However, veterinarians should not accept the tenant that poor health and old age are synonymous (Goldston, 1989). There is a real opportunity to improve the quality and possibly

Box 14-1. The Mature Dog.

Aging is the progressive change that occurs after maturity in various organs and leads to decreased ability of an organism to meet environmental demands. This definition underscores two primary aspects of aging. First, aging occurs "after maturity." Although nutrition in young animals will have an affect on longevity and health, changes occurring during growth should not be considered aging. Second, aging results in a "decreased ability to meet the demands of the environment." Although young organisms adapt easily to fluctuations in nutrient intake and quality, mature animals may no longer be able to cope with excesses, borderline deficiencies or changes in nutrient intake and quality. Therefore, foods for mature dogs should meet allowances more rigorously and consistently because of lack of reserve capacity to handle large excesses and deficiencies.

An important feature of aging is that, compared with a group of younger adults, the mature dog population has a "large variation in health status" between individuals. In addition, diseases may be subclinical and not apparent by results of a physical examination; more in depth assessments are necessary, including diagnostic evaluations. Mature animals, therefore, must be evaluated individually rather than as a group and their nutritional needs determined accordingly.

The Bibliography for **Box 14-1** can be found at www.markmorris.org.

Table 14-1. Percent survival rates of mature dogs.*

Age	10 years	15 years
Small-breed dogs	38%	7.0%
Large-breed dogs	13%	0.1%

the length of life of mature dogs through nutritional management. An important example is cognitive dysfunction (Chapter 35). Nutritional intervention in combination with mental stimulation can halt and even reverse its progression.

There is considerable interest in the potential benefits of pet nutrition on the part of pet owners. In one survey, 51% of respondents indicated that they were interested in learning about clinical signs and treatments for older pets and 47% were interested in pet nutrition (MAF, 2005).

PATIENT ASSESSMENT

History and Physical Examination

A thorough history should be taken and a physical examination performed to identify potential areas of nutritional concern. All of the considerations discussed for young adult dogs in Chapter 13 (i.e., breed, gender and health status) should be considered when developing key nutritional factors for mature dogs. Special attention should be directed to physiologic changes associated with aging and diseases that are more prevalent in mature animals such as renal disease, cancer, degenerative joint disease, cardiac disease, endocrine disorders, periodontal disease, cognitive dysfunction and obesity (Harvey et al, 1994; Alexander and Wood, 1984; Hoskins, 1995; Goldston, 1995; Landsberg and Ruhl, 1997). Many diseases may be subclinical, emphasizing the importance of a thorough evaluation.

This chapter builds on many of the recommendations in Chapter 13 for feeding young adult dogs. The minimum nutrient requirements of mature dogs are similar to those of young adult dogs. The few studies evaluating the effect of aging on the nutritional needs of dogs have shown minimal changes in nutrient requirements. Therefore, nutritional recommendations for mature dogs are based on risk factor management, extension of learning from other species and prudence. For several of the key nutritional factors for mature dogs, this results in reducing the recommended upper range of some nutrients, compared to that for young adult dogs. The only nutritional modification known to slow aging and increase the lifespan consistently in multiple species is caloric restriction. Reducing caloric intake by 20 to 30% of normal, while meeting essential nutrient needs, slows the aging process and reduces the risk for cancer, renal disease, arthritis and immune-mediated diseases in several animal models (Sheffy and Williams, 1981; Kealy et al, 2002). This level of restriction seems difficult to achieve in the long term but should be considered for incorporation into mainstream nutritional advice. Carefully monitoring food intake and body condition in mature dogs is important because these parameters may indicate underlying disease processes.

Laboratory and Other Clinical Information

Laboratory analyses become more important in health screening of dogs older than five years. All mature dogs should be screened for renal disease and hypertension. Chronic renal disease is best diagnosed with a urinalysis (i.e., urine specific gravity, urine protein, urine sediment examination) and a serum biochemistry profile, including urea nitrogen, creatinine, electrolyte, calcium and phosphorus measurements (DiBartola, 1995). Additional blood parameters should be evaluated based on historical and physical examination findings. Generally, indirect blood pressure measurements obtained routinely during hospital visits are reasonable estimates of a dog's true blood pressure (Remillard et al, 1991). However, uncooperative, anxious dogs may have elevated blood pressure values in the hospital setting that do not reflect normal values (Littman and Drobatz, 1995). Fundic examination may also detect changes associated with hypertension and other systemic diseases (Littman and Drobatz, 1995). Thoracic radiographs and echocardiography should be performed if a cardiac murmur is detected or if there is a history of coughing or an abnormal respiratory pattern.

Key Nutritional Factors

Veterinarians should appreciate the diversity in health status of

mature dogs and adapt care and nutrition to the specific needs of each patient (MacDougall and Barker, 1984; Knapp, 1964; Kronfeld, 1983). **Table 14-2** summarizes key nutritional factors for mature dogs. The following section describes these key nutritional factors in more detail. Most of these are the same as for young adult dogs. A more thorough discussion of the overlapping key nutritional factors can be found in the key nutritional factors section in Chapter 13.

Water

Mature dogs are more prone to dehydration due to possible osmoregulatory disturbances, medications (diuretics) and chronic renal disease, with compromised urine concentrating ability. Therefore, continuous access to a fresh, clean water supply is very important and water intake should be routinely monitored.

Energy

With increasing age, lean body mass decreases, subcutaneous fat increases, basal metabolic rate gradually declines and body temperature may decrease. As dogs age, they become slower and less active, and their thyroid function may be impaired (Siwak et al, 2000; Armstrong and Lund, 1996; Finke, 1991; MacDougall and Barker, 1984; Mosier, 1990; Meyer, 1990; Sheffy et al, 1985). All these changes result in a 12 to 13% decrease in daily energy requirement by around seven years of age (Chapter 13, Table 13-2) (Kienzle and Rainbird, 1991). For mature dogs, a daily energy intake of 1.4 x resting energy requirement (100 kcal [418 kJ] metabolizable energy/$BW_{kg}^{0.75}$) is a good starting point (Leibetseder, 1989). This amount should be modified if a dog tends to lose or gain weight when fed at the recommended level. Very old dogs are often underweight and may have inadequate energy intake (Armstrong and Lund, 1996; Kronfeld, 1991; Donoghue et al, 1991). Underweight, very elderly people increase body weight when a food of higher caloric density is provided (Olin et al, 1996). Thus, it may be appropriate to feed a more energy-dense food to very old dogs. Because of the potential for mature dogs to have different energy needs, energy densities in foods recommended for this age group may vary from 3.0 to 4.0 kcal (12.6 to 16.7 kJ)/g dry matter (DM).

Fat

A relatively low fat intake helps prevent obesity in healthy mature dogs. However, some dogs may need different foods at seven years of age than they will at 13 years of age. Very old dogs may have a tendency to lose weight (Armstrong and Lund, 1996; Kronfeld et al, 1991). For these dogs, increasing the fat content of the food increases energy intake, improves palatability and improves protein efficiency (NRC, 1985; Schaeffer et al, 1989).

Research in people has indicated that increased energy intake can correct immunosenescence due to mild protein-energy malnutrition (Morley, 1994). The general condition of elderly people improved significantly by increasing the energy density of the food (Olin et al, 1996). Thus, a good balance should be maintained between preventing obesity and providing sufficient caloric intake.

Generally, fat levels between 7 and 15% DM are recommended for most mature dogs. Fat levels for obese-prone dogs should be between seven to 10%. The fat level should be selected as needed to meet the desired energy density to achieve ideal body weight and condition (body condition score 2.5/5 to 3.5/5). Essential fatty acid requirements should also be met as outlined for young adult dogs.

Table 14-2. Key nutritional factors for foods for mature dogs.

Factors	Recommended food levels* Normal weight and body condition	Inactive/ obese prone
Water	Free access	Free access
Energy density (kcal ME/g)	3.0-4.0	3.0-3.5
Energy density (kJ ME/g)	12.5-16.7	12.5-14.6
Crude fat (%)	10-15	7-10
Crude fiber (%)**	≥2	≥10
Protein (%)	15-23	15-23
Phosphorus (%)	0.3-0.7	0.3-0.7
Sodium (%)	0.15-0.4	0.15-0.4
Chloride (%)	1.5 x Na	1.5 x Na
Antioxidants (amount/kg food)		
Vitamin E (IU)	400	400
Vitamin C (mg)	≥100	≥100
Selenium (mg)	0.5-1.3	0.5-1.3
Food texture (VOHC Seal of Acceptance)	Reduced plaque accumulation	Reduced plaque accumulation

Key: kcal = kilocalories, kJ = kilojoules, ME = metabolizable energy, VOHC = Veterinary Oral Health Council Seal of Acceptance (Chapter 47).
*All foods expressed on a dry matter basis unless otherwise noted. If the caloric density of the food is different, the nutrient content in the dry matter must be adapted accordingly (Chapter 1).
**Crude fiber measurements underestimate total dietary fiber levels in food.

Fiber

Mature dogs are prone to develop constipation (Twedt, 1993), which may justify increased fiber intake. Additionally, fiber added to foods for obese-prone mature dogs dilutes calories. Fiber also decreases postprandial glycemic effects in diabetic dogs (Nelson, 1989). Very old dogs that tend to lose weight, however, should be offered a food with increased caloric density. The recommended levels of crude fiber in foods intended for mature dogs are at least 2% (DM).

Protein

Recommendations for protein intake in mature dogs are controversial, which parallels the debate in people (Pellet, 1990). The decrease in lean body mass, seen with age, together with alterations in protein synthesis and turnover have been the basis for the argument that protein intake in mature dogs should be higher than for younger adults (Grandjean and Paragon, 1990; Kronfeld, 1983; Wannemacher and McCoy, 1966). In contrast, other investigators have recommended reduced protein intake because of the increased prevalence of

renal pathology in dogs older than five years of age (Leibetseder and Neufeld, 1991; Lewis et al, 1987).

As with all lifestages, healthy mature dogs should receive enough protein and energy to avoid protein-energy malnutrition. Improving protein quality, rather than increasing its intake, can provide sufficient protein (Sheffy et al, 1985; Leibetseder, 1989; Mundt, 1989). Additionally, data suggest that mild protein-energy undernutrition in older people plays a role in immunosenescence; however, supplementation with calories returned helper T cells and suppressor cells to values seen in younger people (Morley, 1994). Serum protein concentrations, lymphocyte counts and muscle protein-to-DNA ratios have indicated that foods with 18% DM protein are adequate to maintain immunocompetence in older dogs (Finco et al, 1994). These findings confirmed earlier observations that foods with 16 to 20% DM protein are sufficient to maintain nitrogen balance and protein stores in older dogs (Wannemacher and McCoy, 1966). In addition, alterations in protein metabolism and plasma protein concentrations seen in healthy elderly people are unrelated to daily protein intake, suggesting that other factors play a role (Munro et al, 1987).

High protein intake has not been shown to contribute to the development of kidney disease in healthy animals. However, after kidney function is impaired, protein may play a role in progression of renal disease. In a four-year study with uninephrectomized healthy dogs, investigators recognized no difference in kidney function between dogs receiving a food with 34% DM protein and a food with 18% DM protein (Finco et al, 1994). However, histologic examination revealed an increase in mesangial matrix scores and fibrosis in the high-protein group (Finco et al, 1994). Mesangial proliferation has been described in glomerulonephritis and chronic interstitial nephritis in dogs (Müller-Peddinghaus and Trautwein, 1977a; Spencer and Wright, 1981) and may indicate more rapid renal impairment at a higher protein intake (Finco et al, 1994). Moderately reduced protein intake during early stages of canine renal disease improved the subjects' general condition (Leibetseder and Neufeld, 1991). In conclusion, commercial foods containing 15 to 23% DM protein provide sufficient protein for apparently healthy mature dogs.

Phosphorus

Some degree of clinical or subclinical renal disease is often present in mature dogs; as many as 25% of all dogs may be affected (Oehlert and Oehlert, 1976; Rouse and Lewis, 1975; Shirota et al, 1979; Leibetseder and Neufeld, 1991; Bloom, 1954; Crowell and Finco, 1975; Müller-Peddinghaus and Trautwein, 1977). Excessive phosphorus intake should therefore be avoided (Finco et al, 1992). Researchers have observed that dogs with advanced renal disease had slowed progression and reduced severity of renal disease when phosphorus levels in foods were decreased, thereby improving survival time (Brown et al, 1991; Finco et al, 1992; Lopez-Hilker et al, 1990). The minimum recommended DM allowance of phosphorus for foods for adult dogs is 0.3% (NRC, 2006). Therefore, foods for mature dogs should contain 0.3 to 0.7% DM phosphorus.

Sodium and Chloride

There is no nutritional need for the higher levels of sodium and chloride found in some commercial dog foods, especially considering the increased prevalence of heart and renal disease in mature dogs (Detweiler and Patterson, 1965; Whitney, 1974). High sodium chloride intake may be harmful in diseases that have a hypertensive component. Secondary hypertension is associated with obesity, chronic renal disease and some endocrinopathies, which are frequently seen in mature dogs (Anderson and Fisher, 1968; Cowgill and Kallet, 1986; Rocchini et al, 1987; Littman, 1990; Ross, 1992). Mature dogs with heart disease have decreased ability for eliminating excess dietary sodium (Chapter 36). Kidney disease and certain other diseases with a hypertensive component may be subclinical in their early phases. The minimum recommended allowance for sodium in foods for healthy adult dogs is 0.08 % DM; this recommendation is based on foods with a DM energy density of 4 kcal/g (NRC, 2006). For purposes of risk factor management, the recommended range for dietary sodium in foods for mature dogs is 0.15 to 0.4% DM, which is more than adequate. Some commercial all-purpose foods contain more than 2% DM sodium. Although the chloride requirement of dogs has not been established, a chloride level 1.5 times the sodium requirement is a reasonable recommendation.

Antioxidants

The consequences of prolonged oxidative stress (i.e., free radical damage) to cell membranes, proteins and DNA contribute to and/or exacerbate a wide variety of degenerative diseases including those listed in Table 13-1. In addition to these diseases, cognitive dysfunction was shown to affect 28% of dogs between 11 and 12 years of age and 68% of dogs 15 to 16 years old. Cognitive dysfunction is responsive to certain combinations of antioxidants (Chapter 35).

The consequences of free radical damage to cells and tissues have also been associated with the effects of aging. Although aging is a complex, multifactorial process, one explanation for many of the degenerative changes associated with aging is the free radical theory of aging (Harman, 1956). This theory proposes that free radicals produce cell damage and that age-dependent pathologic alterations may, at least in part, be the cumulative result of these changes.

Many phenomena initiate free radical formation within the body. Although environmental pollutants and radiation are direct and indirect sources of free radicals, the primary source is endogenous from normal oxidative metabolism. However, the body defends itself against the effects of free radicals through a complex network of protective antioxidant compounds.

Antioxidants protect biomolecules by scavenging free radical compounds, minimizing free radical production and binding metal ions that might increase the reactivity of poorly reactive compounds. In addition, many antioxidants exhibit second messenger regulatory function, cell cycle signaling and control of gene expression (Chapter 7). Also, combinations of antioxidants are more effective in relieving oxidative stress than are individual antioxidants.

The following key nutritional factor recommendations focus on the antioxidant vitamins E and C and on selenium as an essential component of the antioxidant enzyme, glutathione peroxidase. These compounds make up the list of antioxidant key nutritional factors because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C regenerates vitamin E after it has reacted with a free radical), 3) they are safe and 4) information regarding inclusion levels in pet foods is usually available. For improved antioxidant performance, foods for mature dogs should contain at least 400 IU vitamin E/kg (DM) (Jewell et al, 2000), at least 100 mg vitamin C/kg (DM) and 0.5 to 1.3 mg selenium/kg (DM).

Food Texture

Oral disease is the most common health problem in mature dogs and may predispose affected patients to systemic complications (DeBowes et al, 1996). Both veterinary care and home care are important in the treatment and prevention of periodontal disease. Foods designed to reduce the accumulation of dental substrates (e.g., plaque) and help control gingivitis and malodor are an important part of an oral home-care program for mature dogs (Chapter 47). If the labels of such foods carry the Veterinary Oral Health Council (VOHC) seal for plaque control, they have been successfully tested according to specific protocols and shown to be clinically effective in reducing accumulation of plaque. However, with older dogs, it is best if an adequate periodontal management program is in place (veterinarian/client/patient) so that there is sufficient periodontal health to ensure that the patient can chew the product (Chapter 47).

Other Nutritional Factor

Calcium

Osteoporosis occurs frequently in older people but is not a clinical problem in mature dogs (Weigel and Alexander, 1981). This finding is probably due, in part, to lifetime feeding of calcium-replete commercial foods to most dogs. There should be little concern about calcium deficiency in mature dogs unless unbalanced homemade foods are fed. Foods with 0.4 to 0.8% DM calcium are recommended for mature dogs. The calcium-phosphorus ratio should not be less than 1:1.

FEEDING PLAN

Mature dogs are more prone to obesity, degenerative joint disease, cardiac disease, renal disease, cognitive dysfunction and metabolic aberrations. They also are usually less active than young adult dogs. The feeding plan should be based on potential risk factors and information attained in the assessment. Because of the larger variation in health among mature dogs, more attention should be paid to individual needs. Nutritional surveillance is more important for mature dogs than for young adult dogs; therefore, the number of veterinary assessments per year should be increased. Goals remain the same as listed in the introduction; however, each patient should be evaluated individually.

Assess and Select the Food

Assessment of the food for mature dogs is similar to those procedures outlined for young adult dogs in Chapter 13. Compare the current food's key nutritional factor levels with the key nutritional factors reviewed above, identify discrepancies between key nutritional factor levels and current intake and decide whether food changes are required. **Table 14-3** compares key nutritional factor levels in selected commercial foods formulated for mature dogs to the key nutritional factor recommendations. Check with manufacturers for key nutritional factor content of foods not found in **Table 14-3**. Contact information can be found on pet food labels, websites or published information. Also, as with young adult dogs, the pet food label should indicate that the product has been approved by a regulatory agency such as the Association of American Feed Control Officials (AAFCO) (Chapter 9).

Commercial treats, snacks and table food should also be included in the food assessment step. Excessive feeding of treats and snacks may markedly affect the cumulative nutritional profile (Chapter 13, Box 13-4). The impact of snacks on daily nutrient intake depends on two factors: 1) the nutrient profile of the snack and 2) the number provided. Thus, if snacks are fed, it is prudent to recommend those that best match the key nutritional profile recommended for mature dogs. Because meeting nutrient requirements is not the primary goal of feeding treats, many commercial treats are not complete and balanced. However, a few treats are complete and balanced and are approved by AAFCO, or some other credible regulatory agency. Most table foods are not nutritionally complete and balanced and may contain high levels of fat or sodium and other minerals. If snacks are fed, it is simplest to recommend that they be commercial treats that, if possible, match the nutritional profile recommended for a particular lifestage (see product label). Generally, snacks should not be fed in excessive amounts (<10% of the total diet on a volume, weight or calorie basis). Otherwise, the nutritional composition of the snack and food should be combined and assessed.

Assess and Determine the Feeding Method

It may not be necessary to change the feeding method when managing healthy mature dogs. However, a thorough evaluation includes verification that an appropriate feeding method is being used.

The feeding method should be monitored more closely in mature than in younger dogs. Free-choice feeding should not be used for obese or overweight patients; however, this method may be preferred for thinner, very old animals to allow increased food intake. It is very important to measure food intake of mature dogs; this measurement may be more accurate when dogs are meal fed. Measures to stimulate food intake may be necessary for some very old dogs. Most mature adult dogs adapt well to new foods, but some patients may have difficulty. It is always good practice to allow for a transition period to avoid digestive upsets. This is particularly true when switching from lower to higher fat foods. The new food should be increased and the old food decreased in progressive amounts

Chapter 15

Feeding Reproducing Dogs

Jacques Debraekeleer

Kathy L. Gross

Steven C. Zicker

"Acquiring a dog may be the only opportunity a human ever has to choose a relative."
Mordecai Siegal

INTRODUCTION

The objectives of a good reproductive feeding program are to optimize: 1) conception, 2) number of puppies per litter, 3) the ability of the bitch to deliver and 4) viability of prenatal and neonatal puppies (Grandjean and Paragon, 1986). Appropriate feeding and management will increase the likelihood of successful reproductive performance, whereas improper or inadequate nutrition can negatively affect reproductive performance in bitches (**Table 15-1**).

Females undergo the greatest extremes in nutrient requirements when the entire reproductive cycle is considered. Estrus, pregnancy and lactation are each associated with specific nutrient concerns that must be addressed. The concerns change with intrinsic physiologic alterations and may be influenced by environmental and other extrinsic factors. Males also need adequate nutrition to achieve optimal performance and conception rates.

Experienced breeders seem to have knowledge about nutritional programs for reproducing dogs based primarily on personal experience, augmented to varying degrees by scientific information. To be effective, veterinarians and their health care teams should have a good understanding of appropriate and practical nutritional programs for reproduction and the neonatal period. These programs should be based on up-to-date, science-based information about the nutritional demands of estrus, gestation and lactation.

PATIENT ASSESSMENT

Estrus and Mating

Optimal nutrition for reproducing animals should precede mating and conception (Sheffy, 1978). As a rule, only healthy dogs in a good nutritional state (body condition score [BCS] 2.5/5 to 3.5/5) should be used for breeding because effects of malnutrition before breeding are often unnoticed until puppies are born (**Table 15-1**). A BCS of 2/5 may be acceptable for a house pet that is only bred for an exceptional occasion (Donoghue, 1992). Obese bitches may have a lower ovulation rate, smaller litter size and insufficient milk production (Meyer, 1990). Obesity may also cause silent heat, prolonged interestrous intervals and anestrus. Therefore, to optimize fertility, overweight bitches should lose weight before breeding (Grandjean and Paragon, 1986). A good history and general physical examination should precede breeding to document and correct problems that may interfere with successful breeding.

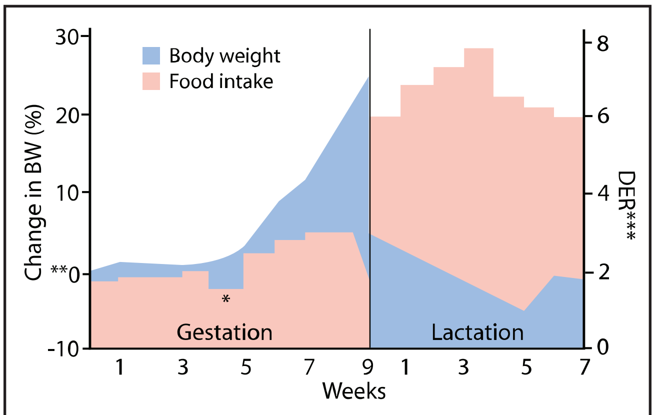
Pregnancy

Gestation in dogs averages 63 days and is typically divided into 21-day trimesters. Assessment includes a detailed dietary history, a physical examination and pertinent laboratory analyses. During the physical examination, particular attention should be given to body weight, body condition and vaginal discharges. Ultrasound of the abdomen can provide additional information. Adequately fed bitches gain about 15 to 25% more than

Table 15-1. Effects of improper nutrition on reproductive performance and health in bitches.*

Factors	Reproductive and health consequences
Underfeeding	Small litter size Low birth weight Increased neonatal morbidity and mortality Decreased milk yield Decreased immunity and decreased response to vaccination Decreased fertility later Hair loss and weight loss in bitches
Obesity	Decreased ovulation Decreased fertility Silent heat Prolonged interestrous interval Anestrus Smaller litters
Malnutrition*	
Protein deficiency	Low birth weight Increased neonatal morbidity and mortality Decreased neonatal immunity
Carbohydrate-free food	Low birth weight Increased neonatal morbidity and mortality Increased numbers of stillbirths
Zinc deficiency	Fetal resorption Smaller litters
Iron deficiency	Decreased immunity and response to vaccination
Pyridoxine and biotin deficiency	Decreased immunity and response to vaccination
Hypervitaminosis A	Congenital abnormalities Smaller litters
Hypervitaminosis D	Soft-tissue calcification

*Malnutrition is uncommon when balanced commercial foods are fed, but may occur if homemade foods are not properly formulated.



* Transient decrease in food intake around the fourth week after conception is indicative of pregnancy.
** Prebreeding body weight
*** Daily energy requirement. Numbers are multiples of resting energy requirement.

Figure 15-1. Typical changes in body weight and food intake of a bitch during gestation and lactation. A bitch only weighs 5 to 10% above pre-breeding weight after parturition, and should not lose more than 5% of its body weight during the first month of lactation. Food intake may drop precipitously during the last days of gestation.

their pre-breeding weight before whelping (**Table 15-2** and **Figure 15-1**) (Meyer, 1990; Gesellshaft, 1989; Leibetseder, 1989). After parturition, bitches should weigh about 5 to 10% more than their pre-breeding weight. This weight gain corresponds with development of mammary tissue, extracellular water and some gain in extragenital tissue (Meyer, 1990; Gesellshaft, 1989; Leibetseder, 1989; Mosier, 1978). Retention of more than 10% above pre-breeding weight may adversely affect whelping. Furthermore, unlike cats, dogs do not need to maintain a body fat reserve to provide energy for the subsequent lactation because they can increase their food intake during lactation (Meyer, 1990; Grandjean and Paragon, 1986).

Laboratory analyses can include a complete blood count, serum protein, glucose, calcium, phosphorus and potassium concentrations and culture of vaginal discharges, if present. During pregnancy, red blood cell counts, hematocrit values and red cell volume may decrease because of plasma volume expansion, and may reach their lowest level during the second week of lactation (Concannon et al, 1989; Wallace and Davidson, 1995; Meyer et al, 1985). In most bitches, serum albumin and calcium concentrations also decrease during gestation (Meyer et al, 1985; Kaneko, 1989). Urea nitrogen concentrations may be below the normal range just before parturition; however, this finding should not be alarming, because levels return to normal during the first weeks of lactation (Meyer et al, 1985).

Malnutrition, due to inadequate and/or excessive intake of nutrients, may affect pregnancy and lactation (**Table 15-1**). Fertilized eggs may die at an early stage resulting in embryo loss. Alternatively, fetuses may develop incorrectly, die and be resorbed, expelled before term (abortion) or carried to full term (stillbirth) (McDonald et al, 1995). Embryo loss and in utero resorption are manifested by smaller litter size. Malnutrition during pregnancy is also a cause of low birth weight puppies that are particularly prone to hypoglycemia, sepsis, pneumonia and hemorrhage and have reduced survival (Mosier, 1978, 1978a; Schroeder and Smith, 1994).

Obesity at the end of pregnancy may increase dystocia, prolong labor and therefore predispose puppies to hypoxia and hypoglycemia. Studies indicate that obesity in pregnant women is the most important factor predisposing to preterm parturition and increases perinatal mortality sixfold (Prentice and Goldberg, 1996). Obesity in pregnant women increases the risk of congenital central nervous system defects (e.g., neural tube defects) and low birth weight infants (Prentice and Goldberg, 1996). Rats that were obese during gestation and lactation had inadequate milk production and were unable to maintain their litters. Surviving pups were significantly smaller than normal. These findings occurred irrespective of whether rats were underfed or overfed during lactation (Rasmussen, 1992).

Lactation

Successful lactation depends on body condition before breeding, and adequate nutrition throughout gestation and lactation. During lactation, nutrient requirements are directly related to milk production, which in turn depends primarily on the num-

ber of suckling puppies. A bitch's nutrient requirement during lactation is greater than at any other adult lifestage and equal to or higher, in some cases, than for growth. Only extreme exercise (Chapter 18) is more energy demanding. The superior ability of bitches to produce milk is illustrated by the following examples. A German shepherd bitch, with six puppies, may produce about 1.7 liters of milk/day during the third and fourth week of lactation (Rüsse, 1961). Beagles with five to seven puppies are able to produce an average of 964 ml of milk/day (7.6% of body weight) at three weeks postpartum, and 1,054 ml/day (8.3% of body weight) at four weeks (Oftedal, 1984). In contrast, a woman produces about 750 ml/day during a three-month lactation (Pellet, 1990). Peak milk production of bitches equates to that of dairy cows, which produce about 7.3% of body weight during peak lactation (exceptional cows can peak at 11% or higher) (Rothbauer, 1994). Additionally, bitch's milk contains more than twice the protein and fat of cow's milk (**Table 15-3**) and more protein than goat's milk. More nutrient-dense milk is necessary to support the more rapid growth rate (as a percent of birth weight) of puppies vs. that of calves, kids and children (**Table 15-4**). A physical examination and anamnesis should be performed as described for gestation, above.

During the first week of lactation, milk production is approximately 2.7% of body weight. Thereafter, milk production steadily increases and peaks during the third and fourth week of lactation and has been estimated to be as much as 8% of a bitch's body weight (Ontko and Phillips, 1958; Rüsse, 1961; Oftedal, 1984; Meyer et al, 1985; Zentek and Meyer, 1992; Scantlebury et al, 2000; NRC, 2006).

After the first two to five days of lactation, the composition of the milk is stable and the bitch's nutrient requirements are primarily determined by the quantity of milk produced (Meyer et al, 1985; Rüsse, 1961; Oftedal, 1984; Mundt et al, 1981). During peak lactation, the quantity of milk produced depends primarily on the number of nursing puppies (Meyer et al, 1985; Ontko and Phillips, 1958). The puppies' intake of solid food begins to increase around the fifth week, after which milk production progressively declines (Gesellshaft, 1989). Therefore, the stage of lactation and the number of nursing puppies primarily determine the bitch's protein and energy requirements for lactation.

Urea nitrogen levels may be decreased just before parturition; however, values normalize during the first few weeks of lactation. Serum total protein concentrations should be within the normal physiologic range (6.0 to 6.5 g/dl) and remain stable during lactation (Meyer et al, 1985). A decrease in total protein may indicate undernutrition. Serum calcium concentrations may temporarily decrease during Weeks 3 and 4 of lactation, whereas inorganic phosphorus concentrations should be normal or slightly increased (Meyer et al, 1985).

Key Nutritional Factors

Compared with maintenance for young adult dogs, there are no special nutritional requirements for bitches during estrus (Grandjean and Paragon, 1986). As for maintenance, breeding bitches should be fed to be in ideal body condition (2.5/5 to

Key: DM = dry matter, ME = metabolizable energy, kcal = kilocalories, kJ = kilojoules, DHA = docosahexaenoic acid.
*Foods for most breeding males and females are usually similar to those for young and middle-aged adults (Table 13-4).
**If the caloric density of the food is different, the nutrient content in the DM must be adapted accordingly.

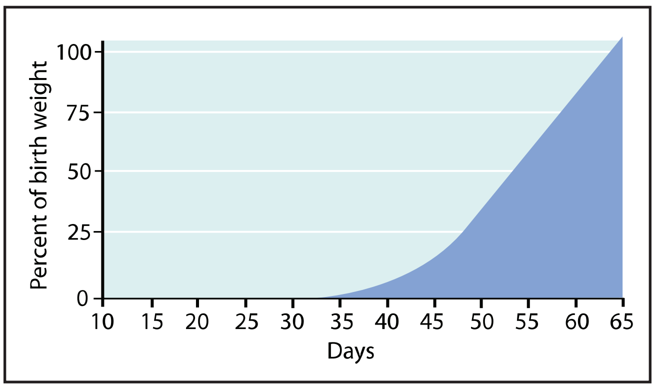

Figure 15-2. The development of fetal mass during pregnancy in beagle dogs. Only 2% of total fetal mass is developed at 35 days of pregnancy and 5.5% at 40 days. After Day 40, fetal tissue growth becomes exponential. (Adapted from Gesellschaft für Ernährungsphysiologie. Empfehlungen für die Versorgung mit Energie. Ausschuß für Bedarfsnormen der Gesellschaft für Ernährungsphysiologie Energieund Nährstoffbedarf/Energy and Nutrient Requirements, No. 5 Hunde/Dogs. Frankfurt/Main, Germany: DLG Verlag, 1989; 32-44. Leibetseder J. Ernährung der Zuchthündin und der Junghunde. Der Praktischer Tierarzt 1989; 70: 12-20.)

3.5/5). Like breeding females, most sires do not have special nutritional needs beyond maintenance requirements for young adults and do well when fed foods for young adult dogs (Chapter 13). However, intact males and females may require more energy than their neutered counterparts to maintain ideal body condition (BCS 2.5/5 to 3.5/5).

Table 15-5 summarizes key nutritional factors for breeding males and females and for pregnant and lactating bitches. The following section describes these key nutritional factors in more detail.

Water

Although often overlooked, water is the first nutrient needed for lactation. Water is needed in large quantities to produce milk and aids in thermoregulation. Water requirements in ml are roughly equal to energy requirements in kcal. A 35-kg bitch nursing a large litter may require five to six liters of water per day at peak lactation. Therefore, it is critical that clean, fresh water be available at all times during gestation and lactation.

Energy

Only 2% of total fetal mass is developed at 35 days of pregnancy and 5.5% at 40 days (**Figure 15-2**). Therefore, during the first two-thirds of gestation, energy requirements are not different from those of young adult dogs (Gesellshaft, 1989a; Ontko and Phillips, 1958). However, during this period bitches should be adequately fed and not allowed to lose weight or body condition. After Day 40, fetal tissue grows exponentially (Gesellshaft, 1989a; Leibetseder, 1989); energy needs correspondingly increase markedly during Week 5 and peak between Weeks 6 and 8 of gestation (Meyer, 1990; Ontko and Phillips, 1958; Romsos et al, 1981). Energy requirements for gestation peak at about 30% above adult maintenance for bitches with smaller litters, whereas energy needs for bitches with larger litters can increase by 50 to 60% (**Table 15-6**) (Meyer, 1990; Romsos et al, 1981; Meyer et al, 1985a).

Although energy needs are highest during Weeks 6 to 8 of gestation, food intake is limited by abdominal fullness as a result of the gravid uterus. Giant breeds may have difficulty ingesting enough food and maintaining body weight even before the last week of gestation (Zentek and Meyer, 1992). Food intake may decrease precipitously just before whelping with some bitches becoming completely anorectic (Romsos et al, 1981; Meyer et al, 1985). Enough energy should be provided to bitches during the earlier weeks of gestation, otherwise bitches may be underweight during mid and late gestation and have difficulty maintaining body condition and milk production after whelping (Bebiak et al, 1987). As mentioned above, bitches should not be allowed to lose body condition during the earlier weeks of gestation. Thus, during gestation, particularly during the last few weeks, the food should be high in energy density (≥4.0 kcal/g [≥16.7 kJ/g]) to provide adequate energy, especially for large-breed bitches.

After whelping, the bitch's energy requirement steadily increases and peaks between three and five weeks (Leibetseder, 1989; Ontko and Phillips, 1958) at a level two to four times higher than the daily energy requirement (DER) for non-lactating adults (Grandjean and Paragon, 1986; Bebiak et al, 1987; Meyer et al, 1985). The energy requirement returns to maintenance levels about eight weeks after whelping (Ontko and Phillips, 1958). Bitches are capable of increasing food intake

during lactation (Meyer et al, 1980, 1985); however, the energy density of the food is usually the limiting factor for meeting DER of lactating dogs (Lewis et al, 1987). If foods with low energy density are fed (<3.5 kcal [<14.6 kJ]/g), the bitch may not be physically able to consume enough food and may lose weight, have decreased milk production and display signs of severe exhaustion (Meyer et al, 1985). These signs are most pronounced in giant-breed dogs with large litters (Zentek and Meyer, 1992). Therefore, for these bitches, foods should provide at least 4 kcal metabolizable energy [ME] (16.7 kJ)/g dry matter (DM).

Energy requirements for lactating bitches can be subdivided into energy for maintenance and energy used for milk production. The DER for lactating bitches, without allotment for milk production, is slightly higher than that for average adults because of stress and increased activity associated with caring for puppies. Energy requirements have been estimated to be approximately 145 kcal (600 kJ) digestible energy/$BW_{kg}^{0.75}$ or about 2.1 x resting energy requirement (RER) (Meyer et al, 1985). This is compared to 132 kcal (550 kJ) ME/$BW_{kg}^{0.75}$ for maintenance of active dogs (NRC, 2006) or about 1.9 x RER. The energy used for milk production, by week of lactation, can be estimated using the method described in **Table 15-7**. **Table 15-8** provides a method for calculating milk production.

Other methods for determining energy requirements of lactating bitches have also been reported but each has limitations (Debraekeleer et al, 2000). Regardless, the body condition of bitches should be evaluated and food adjustments made as necessary to maintain a BCS on the high end of the ideal range

Table 15-6. Practical recommendations for energy intake during gestation.*

Week of gestation	Total DER	
-	**kcal ME/day****	**kJ ME/day****
1-4	DER***	DER***
5	DER + 18 kcal ME/kg BW	DER + 75 kJ ME/kg BW
6-8	DER + 36 kcal ME/kg BW	DER + 150 kJ ME/kg BW
9	DER + 18 kcal ME/kg BW	DER + 75 kJ ME/kg BW

Key: DER = daily energy requirement, kcal = kilocalories, kJ = kilojoules, ME = metabolizable energy, BW = body weight, RER = resting energy requirement.

*Adapted from Gesellschaft für Ernährungsphysiologie. Empfehlungen für die Versorgung mit Energie. Ausschuß für Bedarfsnormen der Gesellschaft für Ernährungsphysiologie Energie- und Nährstoffbedarf/Energy and Nutrient Requirements, No. 5 Hunde/Dogs. Frankfurt/Main, Germany: DLG Verlag, 1989; 32-44.

**Energy requirements during gestation are the sum of the energy needed for normal adult maintenance of a non-pregnant dog plus what is needed for accretion of fetal and maternal tissue. Because accretion of fetal and maternal tissue is minimal during the first 35 days of gestation, the increase in energy requirement only becomes significant after Week 6. However, it is better to increase the food intake progressively during Week 5. This allows the bitch to build reserves for the last week of gestation, when food intake is compromised by abdominal fill.

***During gestation DER is estimated as 1.9 x RER (DER = 132 kcal ME/$BW_{kg}^{0.75}$ or 550 kJ ME/$BW_{kg}^{0.75}$).

Table 15-7. Two methods for calculating the total daily energy requirements for lactating bitches.

Method 1*

The total energy for lactation consists of the bitch's daily energy required for maintenance and the energy required for lactation and uses the formula: ME (kcal) = DER + (BW_{kg} x [24n + 12m] x L), where DER equals the DER for maintenance.

The calculation requires the DER for lactating bitches, without allotment for milk production, which is 145 kcal x $BW_{kg}^{0.75}$ (DER for maintenance of lactating bitches is thought to be higher than for bitches not lactating [see text]).

The calculation also requires the energy needed for lactation, which is based on the bitch's body weight in kg, the week of lactation and the number of puppies in the litter. The week of lactation (L) uses correction factors: Week 1 = 0.75; Week 2 = 0.95; Week 3 = 1.1; Week 4 = 1.2. The number of puppies in the litter is represented by "n" if one to four puppies are in the litter and "m" if the number of puppies in the litter is between five and eight; for fewer than five puppies, m = 0.

These values are inserted into the formula to determine the energy requirement for a lactating bitch:

ME (kcal) = DER + (BW_{kg} x [24n + 12m] x L) where DER is the daily maintenance energy requirement without lactation and BW_{kg} x [24n + 12m] x L represents the energy requirement for lactation.

For example, what would be the total energy requirement for a 20-kg bitch, in the second week of lactation, with a litter of six puppies?

DER (without lactation) = 145 kcal x $20^{0.75}$ = 145 kcal x 9.5 = 1,378 kcal
Number of puppies = 6: n = 4, m = 2
Week of lactation = L = 0.95 (correction factor for Week 2)
Requirement for lactation = 20 x (24 x 4 + 12 x 2) x 0.95 kcal = 2,280 kcal
Total requirement for maintenance and lactation = 1,378 + 2,280 = 3,658 kcal

Method 2

A simplified approach exists to determine DER for peak lactation; however, this method does not allow variation due to week of lactation as does Method 1. It uses the $ME_{peak\ lactation}$ (kcal) = 2.1 x RER_{bitch} plus 25% per puppy.

Using the same example, what would be the total energy requirement for a 20-kg bitch, in the second week of lactation, with a litter of six puppies?

DER = 2.1 x 70($20^{0.75}$) = 1,390 kcal
Requirement for lactation = 25%/puppy or 348 kcal x 6 = 2,088 kcal.

*Adapted from NRC, 2006.

Table 15-8. Calculation of milk production in bitches.*

TP (liters) = (BW_{kg} x k) + [(n–4) x (0.1 x BW_{kg})]
Peak milk production (Weeks 3 to 4) = TP x 0.04.
Example = 30-kg bitch with 8 puppies
TP = (30 x 2) + [(8–4) x (0.1 x 30)] = 60 + (4 x 3) = 72 liters milk
Peak milk production (Weeks 3 to 4) = 72 x 0.04 = 2.9 liters/day
Key: TP = total milk production through Day 45 of lactation, n = number of puppies, k = 1.6 for bitches ≤8 kg BW, 1.8 for bitches >8 to <25 kg BW and 2.0 for bitches ≥25 kg BW, BW = bitch's body weight.
*Adapted from Grandjean D, Paragon B-M, Grandjean R. Rationnement alimentaire et prévention chez le chien 1. Le Point Vétérinaire 1986; 18: 519-524.

(BCS 3.5/5). Foods for lactation should provide at least 4.0 kcal ME (16.7 kJ)/g DM (Leibetseder, 1989; Meyer et al, 1985; Grandjean et al, 1987).

Protein

Protein needs during mating are the same as for maintenance for young adult dogs (i.e., 15 to 30% DM) and do not increase substantially during the first two trimesters of gestation. During late gestation, the protein requirement increases from 40 to 70% above maintenance (Gesellshaft, 1989b; Leibetseder, 1989; Meyer et al, 1985a), and follows the increase in energy requirement. Thus, foods for dogs in late gestation should also have increased levels of protein to meet nutrient requirements at the same time that DM intake is limited. The increased protein requirement can be met by providing about 7 g of digestible protein/$BW_{kg}^{0.75}$ (an increase of 30 to 50% vs. recommendations for young adults) (Gesellshaft, 1989b; Meyer et al, 1985a). The food should contain about 4 g digestible protein/100 kcal ME (about 10 g of digestible protein/MJ) (Gesellshaft, 1989b; Meyer and Heckötter, 1986). A food containing 20 to 25% DM crude protein and 4.0 kcal/g DM (16.7 kJ/g) provides this level of protein. The quality of the protein should also be higher to improve vigor of newborn puppies and minimize neonatal mortality (Ontko and Phillips, 1958). Protein deficiency during pregnancy may decrease birth weight, increase mortality during the first 48 hours of life and decrease immunocompetence of offspring (**Table 15-1**) (Ontko and Phillips, 1958).

The requirement for protein appears to increase more than the requirement for energy during lactation (Meyer et al, 1985). Therefore, the protein-energy ratio must be higher in foods for lactation than in foods for adult maintenance. Ratios of 4.8 to 6.8 g digestible protein/100 kcal ME (10.5 to 15 g/MJ digestible energy) have been recommended (Leibetseder, 1989; Meyer et al, 1985; Meyer and Heckötter, 1986). This recommendation corresponds to about 19 to 27% DM digestible protein of an energy-dense food (4.0 kcal [16.7 kJ] ME/g).

The minimum recommended crude protein allowance for foods for gestation and lactation in bitches ranges from 20% (NRC, 2006) to 22% (AAFCO, 2007). For optimal reproductive performance, foods for gestation and lactation should contain between 25 to 35% DM crude protein.

Fat and Fatty Acids

Fat provides essential fatty acids and enhances absorption of fat-soluble vitamins. Increasing fat levels in foods improves digestibility and provides energy, which in turn improves nitrogen retention (Schaeffer et al, 1989). Although young adult maintenance-type foods are appropriate for the first two-thirds of pregnancy in most breeds, a food with an energy density of approximately 4.0 kcal (16.7 kJ) ME/g is recommended for the last third of gestation. Feeding a food containing slightly more than 19% DM fat usually achieves this recommendation; however, this level may need to be altered depending on litter size, body condition of the bitch, food intake of the bitch and other extraneous factors as discussed previously. The minimum recommended allowance for fat in foods intended for late gestation and peak lactation is 8.5% DM (NRC, 2006). The Association of American Feed Control Officials (AAFCO) recommends at least 8% DM fat (2007). However, to ensure optimal reproductive performance, particularly for late gestation and for lactating bitches with fewer than four puppies, at least 20% DM crude fat is recommended. At least 20% DM fat is also recommended for giant-breed bitches throughout gestation and lactation.

Increased fat intake results in better food efficiency during lactation (Siedler and Schweigert, 1954). One study showed that increasing the fat content in the food from 12 to 20% DM might increase the fat content in the milk by 30% (Gross, 1993). Because puppies are born with a very low energy reserve (Stadtfeld, 1978; Meyer et al, 1985a), sufficient energy should always be available via the milk. Increasing concentrations of fat also increase the caloric density of foods and help meet the high energy requirements of bitches during lactation. An increase in fat should be balanced by increasing other nutrients proportionally to match the increased energy density.

Milk fat and fatty acid composition are highly variable components of milk. Perhaps because of the type of food typically consumed by dogs and cattle, fat in bitch's milk contains a high percentage of unsaturated fatty acids and is rich in linoleic acid compared to cow's milk (**Table 15-3**). The type of fat fed and the fatty acid profiles of endogenous fat deposits may affect the fatty acid composition of milk. In one study, the fatty acid composition of bitch's milk reflected that of foods fed during gestation and lactation. Furthermore, the milk of bitches fed foods enriched with α-linolenic acid (ALA) but not docosahexaenoic acid (DHA) was high in ALA. Puppies fed this milk accumulated more plasma phospholipid DHA than the control group (but not as much as puppies fed preformed DHA) (Heinemann et al, 2005). In children, during early growth, DHA supports retinal and auditory development (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003). Furthermore, brain development and learning ability were enhanced in infants supplemented with DHA (Birch et al, 2002; Hoffman et al, 2003). Similar to findings in other species, including fish oil as a source of DHA in puppy foods improved trainability (Kelley et al, 2004). Foods containing long-chain omega-3 (n-3) polyunsaturated fatty acids fed during gestation and lactation improve retinal func-

Key: ME = metabolizable energy, Ca = calcium, P = phosphorus, Ca:P = calcium-phosphorus ratio, na = information not available from manufacturer, g = grams, DHA = docosahexaenoic acid.

*From manufacturers' published information or calculated from manufacturers' published as-fed values; all values are on a dry matter basis unless otherwise stated. Digestibility: Foods with higher energy density are more likely to have higher digestibility. Foods for most breeding males and females are usually similar to those for young and middle-aged adults (Table 13-4).

**Energy density values are listed on an as fed basis and are useful for determining the amount to feed; cup = 8-oz. measuring cup. To convert to kJ, multiply kcal by 4.184.

tion of young dogs (Bauer et al, 2006, 2006a). Because milk concentrations of DHA parallel dietary intake, it seems prudent to include DHA in foods fed to lactating bitches. Common ingredients such as fish and poultry meal are sources of DHA in foods for reproducing bitches. Foods for late gestation and peak lactation should contain the minimum recommended allowance of DHA plus eicosapentaenoic acid (EPA) of at least 0.05% (DM) (NRC, 2006). Therefore, DHA needs to be at least 40% of the total DHA plus EPA, or 0.02% DM.

Carbohydrate

Technically the term "carbohydrate" includes digestible (soluble) carbohydrates (mono-, di- and polysaccharides such as starch and glycogen) and dietary fiber. This chapter refers to digestible carbohydrates. Feeding a carbohydrate-free food to pregnant bitches may result in weight loss, decreased food intake, reduced birth weight and neonatal survival of the puppies and may increase the risk of stillbirth (**Table 15-1**) (Romsos et al, 1981; Kienzle et al, 1985; Kienzle and Meyer, 1989). Because more than 50% of the energy for fetal development is supplied by glucose (Romsos et al, 1981), bitches have a high metabolic requirement for glucose during the last weeks of gestation. Feeding a carbohydrate-free food to pregnant bitches increases the risk of hypoglycemia and ketosis during late pregnancy. Furthermore, the lactose concentration in the milk may decrease by 40% during peak lactation (Romsos et al, 1981; Kienzle et al, 1985; Kienzle and Meyer, 1989) (**Box 15-1**).

Providing approximately 20% of the energy from carbohydrate is sufficient to prevent the negative side effects of a carbohydrate-free diet (Kienzle et al, 1985; Kienzle and Meyer,

Box 15-1. Periparturient Hypoglycemia.

Clinical hypoglycemia (i.e., glucose values <45 mg/dl or 2.5 mmol/l) occurs infrequently in bitches, but when it develops it is usually observed during the last two to three weeks of gestation. Neurologic signs of hypoglycemia predominate, and differentiation from eclampsia is not always easy. Elevated levels of serum ketones (mainly β-hydroxybutyrate) are characteristic in bitches with clinical disease; however, ketonemia may be missed when strips or tablets containing nitroprusside are used to detect ketones. Nitroprusside primarily detects acetone and acetoacetate.

Risk factors that may predispose bitches to this syndrome include: 1) poor body condition during pregnancy, 2) malnutrition and 3) feeding a high-fat, carbohydrate-free food. If a carbohydrate-free food is fed, gluconeogenic precursors such as protein should be increased by at least 50% when energy requirements are moderate and may have to be doubled if the energy requirement of the dam is high.

Treatment of clinical hypoglycemia during pregnancy should consist of intravenous administration of a bolus of 20 to 50% glucose solution, which can be followed by intravenous infusion of a 5% glucose solution at a rate of 2 ml/kg body weight/hour. During or soon after the infusion, a palatable food should be provided that has adequate carbohydrate, protein and calories (**Table 15-5**) and has above average digestibility (**Table 15-9**).

The Bibliography for **Box 15-1** can be found at www.markmorris.org.

1989). If no carbohydrate is given, protein intake must almost be doubled; the food must provide at least 12 to 13 g digestible protein/$BW_{kg}^{0.75}$ (Gesellshaft, 1989b; Kienzle et al, 1985; Kienzle and Meyer, 1989). In a study in which a food that had about 50% DM protein was fed, no problems with hypoglycemia or ketosis resulted and puppies were born healthy (Blaza et al, 1989). These protein levels are very high and may cause soft, foul-smelling stools (Paquin, 1979). Providing approximately 20% of the energy from carbohydrate translates to about 23% DM carbohydrate. Foods for gestation should contain at least 23% DM digestible carbohydrate.

When lactating bitches are fed foods without digestible carbohydrates, the lactose level in the milk may decrease to about 2% vs. the normal range of 3 to 3.5% (Romsos et al, 1981; Kienzle et al, 1985). In one study, increasing the digestible carbohydrate level in the food corrected low lactose levels; however, the same effect was not achieved by increasing protein levels (Kienzle et al, 1985). Therefore, these and other investigators recommend that foods for lactation provide at least 10 to 20% of the energy intake in the form of digestible carbohydrate to support normal lactose production (Leibetseder, 1989; Kienzle et al, 1985). Foods for bitches during lactation should also contain at least 23% DM digestible carbohydrate.

Calcium and Phosphorus

For most breeds, during the first two trimesters of gestation, calcium and phosphorus needs are similar to those for maintenance of young adults (0.5 to 1.0% DM calcium and 0.4 to 0.7% DM phosphorus: Ca-P ratio 1:1 to 1.5:1). During the last part of gestation, requirements for calcium and phosphorus roughly increase by 60% because of rapid skeletal growth of the fetuses (Gesellshaft, 1989c; Meyer et al, 1985a). The minimum recommended allowance for calcium in foods intended for late gestation and peak lactation is 0.8% (DM) (NRC, 2006). The AAFCO minimum allowance is 1% (2007). As occurs with some dairy cows, excessive calcium intake during pregnancy may decrease activity of the parathyroid glands and predispose the bitch to eclampsia during lactation (Smith, 1986; Drazner, 1987). Therefore, it has been recommended for most breeds to feed a food during pregnancy that avoids large excesses of calcium (1.0 to 1.7% DM) and has a calcium-phosphorus ratio of 1.1:1 to 2:1 (**Box 15-2**). The range for phosphorus should be from 0.7 to 1.3% (DM). These amounts are also recommended for giant-breed bitches.

Mineral requirements during lactation are determined by mineral excretion in milk (Meyer, 1982) and thus by the number of nursing puppies. A definite increase in calcium content is seen over the course of lactation; however, the calcium-phosphorus ratio is consistently maintained around 1.3:1 (Meyer et al, 1985). This is reflected by the fact that even without clinical eclampsia, plasma calcium levels tend to decrease during the third and fourth week of lactation (Meyer et al, 1985a). Bitches need two to five times more calcium during peak lactation than for adult maintenance (Meyer, 1982, 1990a) (**Box 15-2**). Depending on the number of puppies, bitches need 250 to 500 mg calcium and 175 to 335 mg of phosphorus/kg body weight per day (Gesellschaft, 1989c). One investigator recommended that a food for lactation contain at least 0.8 to 1.1% calcium and 0.6 to 0.8% phosphorus (Leibetseder, 1989); however, reducing these needs by 10 to 20% will not necessarily lead to disturbances in milk mineral content. The recommended range for calcium during gestation and lactation is 1.0 to 1.7% and the corresponding recommended range for phosphorus is 0.7 to 1.3% (DM), respectively. The calcium-phosphorus ratio should be 1.1:1 to 2:1. Calcium supplementation is not recommended during gestation or lactation when appropriately balanced commercial foods are fed.

Digestibility

Nutrients in foods should be highly available due to the considerable nutritional demands associated with late gestation and lactation. Apparent digestibility is the difference between the amount of food ingested and that excreted in feces. During late gestation, the ability to ingest adequate amounts of food may exceed food intake capacity, especially if the food is poorly digestible. Therefore, it is important to assess digestibility and recommend foods with above average digestibility for the reproductive process.

Digestibility information for commercial foods marketed for reproduction is not readily available. However, energy density is an indirect indicator of digestibility. Foods that have an energy

Box 15-2. Eclampsia in the Bitch.

Eclampsia is an acute, life-threatening condition due to a sudden decrease in extracellular calcium concentration. Bitches are at highest risk for developing eclampsia (puerperal tetany) during Weeks 2 and 3 of lactation when calcium losses via secretion in milk are highest. Eclampsia is less common during Weeks 1 and 4 of lactation, and is seen rarely in the last two weeks of gestation. Occasionally, bitches may be affected at or just before whelping.

The number of nursing puppies is the most important stimulus for milk production; therefore, it is not surprising that eclampsia is seen commonly in bitches nursing large litters. Typically, affected bitches are primipara, are less than four years of age, are toy-breed dogs and have low body weight-to-litter size ratio. Investigators have suggested that toy breeds may be more predisposed to developing eclampsia than large breeds because toy breeds tend to receive more meat-based homemade foods, which are low in calcium. Serum total calcium and ionized calcium concentrations usually are decreased. Serum total calcium concentration is an insensitive measure of ionized calcium concentration. Ionized calcium is the biologically active form. In-hospital serum chemistry analyzers and point-of-care analyzers allow veterinarians to obtain serum total calcium and ionized calcium concentrations rapidly. Diagnosis of hypocalcemia is based on low serum ionized calcium concentrations. Serum ionized calcium concentrations were <0.8 mmol/l (reference range, 1.13 to 1.33 mmol/l) in a retrospective study of eclampsia in the bitch. Other causes of clinical signs typical of hypocalcemia should be considered if the serum ionized calcium concentration is >0.8 mmol/l.

Although most bitches with eclampsia are hypocalcemic, some may be normocalcemic. Some bitches with hypocalcemia, on the other hand, may not exhibit clinical signs. Typical clinical signs are anxiety, panting, whining, hypersalivation, vomiting, ataxia, stiff gait, muscle tremors, tetany and seizures. Other signs include hyperthermia, tachycardia and death, if the condition is untreated. However, clinical signs vary, based on the degree of hypocalcemia and the time over which it develops.

Lack of clinical signs may indicate that factors other than hypocalcemia determine whether tetany manifests clinically or not. The bitch may have additional serum biochemical abnormalities. Blood glucose should be measured, because hypoglycemia may be present concurrently. Magnesium levels in bitches with eclampsia may be low or normal. The ratio of serum total magnesium to total calcium may be significantly lower in affected bitches than in normal bitches. Hyperkalemia has been reported and some bitches may have abnormal serum phosphorus concentrations (either hypophosphatemia or hyperphosphatemia). Further study is needed about the role of other serum biochemical abnormalities in the clinical signs of eclampsia. The incorporation of magnesium into the treatment and prevention of the disorder should be evaluated.

Hypocalcemia leads to increased neuromuscular irritability resulting in restlessness and whining, stiffness of gait, ataxia and tonic-clonic seizures. Decrease in extracellular calcium ion levels leads to increased permeability of nerve cells (primarily of peripheral nerves) to sodium ions. Neuromuscular irritability is directly proportional to:

$[Na^+] \times [K^+] \div [Ca^{++}] \times [Mg^{++}] \times [H^+]$

Suggested causes of hypocalcemia during the periparturient period include calcium supplementation during pregnancy, poor dietary calcium and loss of calcium through fetal skeletal ossification and lactation. High calcium intake may down-regulate parathyroid gland secretion and impair normal mobilization of calcium from skeletal stores. As demand for calcium increases during late gestation and lactation, calcium homeostasis is unable to maintain critical serum levels.

Slow intravenous infusion (over five to 10 minutes) of 10% calcium gluconate, administered to effect (1 to 2 mg calcium/kg body weight), results in rapid clinical improvement. Heart monitoring (e.g., auscultation, electrocardiography) should be performed during intravenous calcium gluconate infusion. If bradycardia or dysrhythmias develop, the infusion must be slowed or discontinued. In addition, body temperature should be monitored because hypothermia may occur following calcium gluconate administration. To lessen the risk of relapse, calcium may be injected subcutaneously or intramuscularly, in addition to the immediate intravenous infusion. However, subcutaneous injections may cause skin necrosis and should be administered only when other routes are inaccessible. Following correction of acute signs, the bitch should be provided with oral vitamin D and calcium supplementation (e.g., calcium carbonate, 100 mg/kg/day, divided with meals) throughout lactation.

If possible, puppies should be separated from the bitch for the first 24 hours of treatment and fed canine milk replacer by bottle or orogastric tube feeding. If tetany recurs during the same lactation, the puppies should be weaned. Administration of corticosteroids is contraindicated because they may further decrease plasma calcium levels.

Prevention of eclampsia starts during pregnancy by feeding a balanced food, without excess calcium and with a balanced calcium-phosphorus ratio. Foods with a calcium-phosphorus ratio close to 1:1 have been recommended during pregnancy. Vitamin D therapy (10,000 to 25,000 IU daily) during the last week of gestation has been proposed, just as cows are treated to prevent postparturient paresis. This approach may not be valid for bitches because eclampsia and the highest calcium losses generally do not occur immediately after whelping.

The Bibliography for **Box 15-2** can be found at www.markmorris.org.

density of 4 kcal ME/g (16.7 kJ/g) or higher have more fat and less fiber. Fat is typically highly digestible; fiber is poorly digestible. Thus, high-fat, low-fiber foods are usually more digestible.

Other Nutritional Factors

In addition to the key nutritional factors for commercial foods discussed above, the following nutritional factors are highlighted because they are of particular concern for homemade foods

intended for reproducing dogs (Chapter 10).

Essential Fatty Acids
Homemade foods with rice and meat as the main ingredients may not provide enough essential fatty acids for lactation, and may need to be supplemented with vegetable oil (Meyer, 1990b).

Iron, Zinc and Copper
Requirements for most trace elements depend on litter size. Hematocrit, hemoglobin and plasma iron values often decrease in bitches near the end of gestation (Meyer et al, 1985a). Iron requirements are particularly high during the last week of gestation, when large quantities are stored in the liver of the fetuses, and mobilized from the bitch's body for colostrum (Meyer et al, 1985a). Colostrum is very rich in iron; however, levels decrease within 48 hours (Meyer et al, 1985a). Iron concentrations are low in mature milk. Because of this, iron requirements increase only slightly during lactation when compared with adult maintenance requirements (Gesellshaft, 1989d). Therefore, neonates must have an iron reserve to overcome the initial three-week nursing period, when milk is the only source of food (Meyer et al, 1985a). Latent iron deficiency may impair neutrophil phagocytic function and cell-mediated immunity, increasing susceptibility to infections (Bhaskaram, 1988). The minimum recommended allowance for iron is 70 mg/kg (DM) (NRC, 2006). Oxides of iron should not be used as an iron source because they are poorly available (NRC, 2006).

During periods when requirements for tissue synthesis are greater than normal (e.g., pregnancy, lactation and growth), animals are particularly susceptible to zinc deficiency. Most commercial foods provide adequate zinc. However, if zinc deficiency does occur during pregnancy, it may lead to fetal resorption or fewer, less viable offspring (Fletcher et al, 1988). The minimum recommended allowance for zinc during gestation/lactation is 96 mg/kg (DM) (NRC, 2006).

Copper is an integral constituent of enzymes that catalyze oxidation reactions and plays an important role in connective tissue formation via lysyl oxidase. It is involved in hematopoiesis because it is a constituent of ferroxidases. It is also a cofactor of superoxide dismutase and thus helps protect against oxidative stress. There are numerous sources of copper but oxides of copper should not be used because they are poorly available (NRC, 2006). The minimum recommended allowance for copper is 12.4 mg/kg DM (NRC, 2006). Copper needs during gestation/lactation increase disproportionately to increased energy needs (Gesellshaft, 1989d).

Phenylalanine and Tyrosine
Tyrosine is not an essential amino acid but is made from phenylalanine. However, tyrosine in adequate amounts spares about half of the need for phenylalanine. Therefore, it is appropriate to consider the amount of phenylalanine required as the sum of phenylalanine plus tyrosine. Although phenylalanine and tyrosine are not thought to be the most limiting amino acids for growth in commercial foods, at least twice as much phenylalanine, or phenylalanine plus tyrosine, is required for maximal black hair color as for growth (NRC, 2006; Biourge and Serheraert, 2002). Other metabolic needs for phenylalanine and tyrosine include protein, thyroid hormone and catecholamine synthesis (NRC, 2006). The minimal recommended DM phenylalanine allowance for foods for bitches during late gestation/peak lactation is 0.83% and 1.23% DM for phenylalanine plus tyrosine (NRC, 2006). About one and one-half to two times this much tyrosine is required to maximize black hair color (NRC, 2006).

FEEDING PLAN

Generally, recommendations are based on information from populations of dogs at similar stages of reproduction. However, the feeding plan should be tailored to meet the needs of individual dogs based on unique variations in genetics, environment, litter size and health status. Information gleaned from the assessment step (i.e., patient, food and feeding method) sets the stage for developing the feeding plan; specifically which foods to feed and which feeding methods to use in providing the food.

Assess and Select the Food
Food assessment includes a comparison of the current food's levels of key nutritional factors with those recommended in **Table 15-5.** For convenience, **Table 15-9** compares the key nutritional factor content of selected commercial foods marketed for dogs during reproduction to the key nutritional factor targets determined above. Pet food labels usually lack information about carbohydrate content (other than crude fiber), digestibility, energy density and specific vitamins and minerals. If the food in question is not listed in **Table 15-9**, it may be necessary to contact the manufacturer for information.

The food should also be approved by a credible regulatory agency to ensure it will support gestation and lactation (i.e., AAFCO or equivalent). This information should be listed on the product label. The food assessment step determines the appropriateness of the current food. Food selection involves choosing the food that most closely fits the key nutritional factor recommendations. If a food change is warranted, gradually transition the bitch to the new food over several days as described in Chapter 1.

Oftentimes foods marketed for gestation/lactation are also growth-type foods. Thus, they can be referred to as growth/reproduction-type foods. Generally, foods for non-reproducing sexually intact adult dogs (Table 13-4) will suffice for the first four weeks of gestation (Gesellshaft, 1989a). However, it is probably best to feed a growth/reproduction food throughout gestation, particularly for giant breeds. This recommendation also negates the need for a food change during mid- to late-gestation. Lactation represents an extreme test of a food's nutritional adequacy, because no other physiologic endeavor, other than extreme exercise, requires such a marked increase in energy density and nutrient content (Lewis et al,

Chapter 16

Feeding Nursing and Orphaned Puppies from Birth to Weaning

Jacques Debraekeleer
Kathy L. Gross
Steven C. Zicker

"Happiness is a warm puppy."
Charles M. Schulz

INTRODUCTION

Compared with the young of other species, newborn puppies are relatively immature at birth. For example, their skeletons have a low degree of mineralization (Meyer and Stadtfeld, 1980; Meyer et al, 1985). Large-breed puppies are less mature than small-breed puppies, which may be one of the reasons why they are more susceptible to malnutrition and developmental orthopedic diseases during the rapid growth phase.

Growing puppies progress through three critical phases in the first 12 months of life, during which nutrition is essential for survival and healthy development.

- A nursing period during which the transition is made from in utero nutrition to postpartum nutrition. This period is largely influenced by the nutrition of the bitch during gestation and early lactation. This chapter focuses on feeding nursing and orphaned puppies.
- A weaning period, which is very stressful due to changes in food and environment. The transition from bitch's milk to solid food for further growth must therefore be handled properly. Because weaning overlaps with the nursing period, it is also covered in this chapter.
- A postweaning period that occurs from two to 12 months of age and is a critical time for development. Proper feeding during this period is especially critical for large- and giant-breed puppies because nutrition has proved to be the most important non-genetic factor for healthy bone development. Chapter 17 covers postweaning feeding of growing puppies.

Before weaning, mortality may be as high as 10 to 30%, with two-thirds of the deaths occurring during the first week of life (Pibot and Jean-Blain, 1989; Lawler and Evans, 1989). Three factors are critical to successful transition from fetal life to the nursing period: 1) the bitch's nutrition during gestation and early lactation, 2) the bitch's behavior and physical health and 3) provision of good neonatal care (husbandry practices) by the owner.

Puppies are considered orphaned if they lack sufficient maternal care for survival from birth to weaning. Several physiologic needs normally provided by the bitch must be met to ensure survival of neonates: heat, humidity, nutrition, immunity, elimination, sanitation, security and social stimulation. A foster bitch or the caregiver must meet these needs for orphaned puppies. Most orphans can be raised successfully with proper care and nutrition.

Box 16-1. Puppy Behavior from Birth to 12 Weeks of Age.

Three phases of puppy behavior are described during the first 12 weeks of life:

- Neonatal period: From whelping to when the eyes open at about 13 days of age.
- Transition period: From when the eyes open to three weeks of age.
- Socialization period: From three weeks of age to weaning.

NEONATAL PERIOD

A newborn puppy has two basic activities: sleeping and nursing. Puppies quickly learn to find the bitch's teats when the bitch lies down for nursing. Nursing should be vigorous and active, and after nursing, the puppy's abdomen should be enlarged. Following nursing, puppies usually return to sleep. Neonates spend more than 80% of their time sleeping. However, a healthy puppy never sleeps deeply and quietly. Involuntary muscle contractions such as jerks and twitches (especially of the facial muscles) and irregular respiration are common. This pattern of activity is called "activated sleep" and should not be mistaken for shivering, a reflex that is not operant until about seven days of age. A puppy sleeping without these movements may be ill and should be observed closely. Puppies start crying when hungry or away from the litter; however, healthy puppies will stop crying soon and sleep again, even without nursing. Weak puppies may also have an enlarged abdomen but are restless and continue to vocalize. Such vocalizing is a constant high-pitched crying and is different from the crying of healthy puppies when they are hungry.

TRANSITION PERIOD

Puppies become more responsive to their environment as they become older. They no longer cry consistently when hungry or separated from littermates, but will cry when placed in an unfamiliar environment, even if warm and fed. Puppies begin to respond to visual stimuli when their eyes open. Puppies first start to play fight, clumsily pawing and mouthing at one another during this period. Tail wagging also occurs.

The first teeth may begin to erupt during the third week of life. Puppies lose the need for perineal stimulation to eliminate. Sucking on objects other than the bitch's nipples progressively decreases. By the end of the transition period puppies begin to lap liquids. A gruel or milk replacer should be presented in a bowl or saucer at this time; ground meat or thick gruels can be handfed.

SOCIALIZATION PERIOD

After a puppy can see and hear, it begins more active social interactions with its dam, littermates and people. Social bonds are formed and social hierarchies are begun. The critical period for socialization lasts until about 12 weeks, and exposure to people and other dogs is essential. Puppies achieve the full-grown dog form of locomotion, although they are still clumsy and have little endurance. Play fighting among puppies becomes a predominant behavior during this period. Eruption of deciduous teeth is complete by the first half of this period. Puppies no longer eliminate reflexively when the perineum is stimulated and they leave the nest box to do so. During the socialization period, puppies develop the ability to lap liquids well and are able to eat solid foods. The dam becomes less tolerant to nursing.

The Bibliography for **Box 16-1** can be found at www.markmorris.org.

PATIENT ASSESSMENT

History

When raising puppies, owners should be encouraged to maintain a logbook that may provide important information about the health and nutritional status of the puppies and dam. Owners should record birth weights of the puppies followed by their body weights every one to two days for the first four weeks of life, which also helps with socialization. Changes in behavior and other indicators of health such as opening of eyes, eruption of teeth, consistency of feces and food intake should also be recorded. **Box 16-1** provides a brief review of normal behavior for nursing puppies. **Table 16-1** lists normal physiologic values for neonatal puppies. Puppies should be identified in some manner (e.g., with a colored collar, nail polish, etc.) to facilitate easy recognition (**Box 16-2**).

Physical Examination

The goal of a physical examination is to assess indicators of impaired health that may reveal serious metabolic perturbations such as hypoglycemia, hypothermia and dehydration. Special attention should be paid to assessing puppy behavior, environmental conditions and hygiene. These parameters are important markers/risk factors for potential health problems. However, because puppies depend on bitch's milk during the neonatal period, assessment must always include a thorough evaluation of the health and maternal behavior of the bitch.

The most important areas of evaluation of nursing puppies are assessment of body weight and condition (especially with respect to temporal changes), body temperature and other physical parameters.

Orphaned puppies should be thoroughly evaluated when first seen. A careful physical examination of neonates and the bitch, if available, should be performed to detect the potential cause for abandonment. Particular attention should be given to detect common problems such as hypothermia, hypoglycemia, dehydration and congenital defects. The nutritional and hydration status should also be noted.

Body Weight

Low birth weight is highly correlated to neonatal mortality. Low birth weight puppies are particularly prone to hypoglycemia and sepsis, and are less likely to survive without special care. **Table 16-2** provides birth weights for selected dog breeds. Nursing puppies should be weighed daily or every other day on a gram scale. Monitoring the puppies' weight is a good way to evaluate the quality and quantity of milk the bitch is producing and the milk intake and health status of the puppies

Table 16-1. Normal physiologic values for neonatal puppies and data for neonatal care.

Birth weight	Individual	1-6.5% of mother's weight
	Total litter	12-14% of mother's weight
	BW at 8-10 days	2 x birth weight
Daily weight gain	Week 1	8% (5-10%)
	Weeks 2-4	5% (3.5-6%)
	Weeks 5-10	2 g/kg adult BW
	>10 weeks	2-4 g/kg adult BW
Body temperature	24 hr after birth	35.5 ± 0.8°C (96 ± 1.4°F)
	Weeks 1-2	34.5-37.2°C (94-99°F)
	Weeks 2-4	36.0-37.8°C (97-100°F)
	>4 weeks	37.8-38.3°C (97-101°F)
Heart rate	Weeks 1-2	230-240 beats/min.
	Weeks 3-4	210-220 beats/min.
	Weeks 5-6	195 beats/min.
	Week 7	185 beats/min.
	Weeks 8-12	165-175 beats/min.
Respiratory rate	At birth	15-35 breaths/min.
Shivering reflex develops	-	6-8 days
Eyes	Eyes open	10-14 days
	Visual following of moving objects	3-4 weeks
	Recognition of owner and mother	4-5 weeks
Ears	Open	12-17 days
	Reaction to auditory stimuli	3-4 weeks
Locomotion	Stepping movements with forelimbs	5-6 days
	Stepping movements with pelvic limbs	7-10 days
	Ability to stand	10 days
	Steady gait	3 weeks
	Walking and running	4 weeks
Micturition and defecation	Voluntary control	16-21 days
Activated sleep	Muscle tic disappears	4 weeks
Descent of testes	-	18-45 days
Urine specific gravity	-	1.006-1.007
Water requirement	-	180 (130-220) ml/BW_{kg}/day
Eating solid food	-	4-5 weeks
Deciduous teeth eruption	Incisors	3-4 weeks
	Canines	3 weeks
	Premolars	4-12 weeks
Permanent teeth eruption	Incisors	3-5 months
	Canines	4-6 months
	Premolars	4-6 months
	Molars	5-7 months
Body water	At birth	80%
Fat reserves	At birth	1-2%
	At 2 weeks	10%
	At 1 month	17%
	Non-obese adult dogs	22-23%

Key: BW = body weight, C = centigrade, F = Fahrenheit.

(**Box 16-3**). Puppies should neither lose weight nor fail to gain weight for more than one day. Loss or failure to gain weight in an individual puppy or the entire litter may indicate disease in the puppies or bitch, inadequate milk production or inability to suckle. It is essential to evaluate puppies' growth rate in relation to changes in behavior such as restlessness and continuous vocalization.

Body Temperature

When examining a puppy, the clinician should determine whether the puppy is warm. Neonates show a certain degree of poikilothermy during the first two weeks of life (Mosier, 1978), and have an extremely low amount of body fat (Rauchfuss, 1978). Therefore, it is vital for newborn puppies to eat and be kept in a warm environment. During the first week, the immediate environment of the puppies should be kept between 29 and 32°C (84 to 90°F). This means that the temperature in the room with the bitch and its litter should be maintained between 24 and 27°C (75 to 81°F). **Table 16-3** lists optimal environmental temperatures for orphaned puppies. Marginal hypothermia can often be detected by palpation of the lower limbs (**Box 16-4**). The behavior of the bitch may indicate whether a puppy is hypothermic or ill. A bitch may push a puppy away and neglect its cries when the puppy's skin temperature drops below a certain level (Mosier, 1978).

Box 16-2. General Husbandry Practices for Neonates.

Puppies should be housed in warm draft-free enclosures. Incubators are ideal, particularly for newborns. Pet carriers, shoeboxes or cardboard boxes are suitable substitutes. The bedding should be soft, absorbent and warm. Thread-free cloth, fleece and wood shavings are appropriate materials and help puppies feel secure as they snuggle into them.

Neonates demonstrate a certain degree of poikilothermy and are unable to regulate body temperature well during the first four weeks of life. Puppies huddle together close to the bitch, which generates an optimal microclimate, protects them against changes in environmental temperature and decreases the rate of heat loss. Orphans cannot seek protection near the bitch and are more sensitive to suboptimal environmental conditions.

Without the bitch, puppies can quickly become hypothermic, which leads to circulatory failure and death. Artificial heat should provide age-optimal environmental temperatures (**Table 16-3**). It is best to set the heating source to establish a gradation of heat in the nest box. A gradation of environmental temperatures allows neonates to move toward or away from the heat source as needed to avoid hyperthermia, which can be as detrimental as hypothermia. Puppies can rapidly become dehydrated secondary to overheating. Maintaining humidity near 50% helps reduce water loss and maintains the moisture and health of mucous membranes.

To fulfill non-nutritive nursing needs, hand-reared puppies often nurse other littermates in the nest box. To avoid skin trauma related to excessive nursing, puppies can be housed individually or separated by dividers. Although beneficial for alleviating problems due to non-nutritive nursing, separation of the litter reduces temperature and humidity in the immediate environment and social stimulation by littermates. Brief, but regular handling, provides social stimulation. The stress associated with regular handling may increase neural development and improve weight gain in puppies. Neonates raised without social stimulation develop abnormal behavior patterns (i.e., reduced normal exploratory behavior and neonates become more suspicious and aggressive as adults). Peer contact can compensate for maternal deprivation. Therefore, benefits of separating neonates must be weighed against the potential for development of abnormal behavior and increased risk for hypothermia. Puppies should interact with littermates as much as possible until weaning.

Puppies obtain passive systemic immunity from colostrum and passive local immunity from continued ingestion of bitch's milk. If possible, neonates should receive colostrum or bitch's milk within the first 12 to 16 hours of birth. This is particularly critical for puppies fed only milk replacers because they lack systemic and local immune protection.

Normally the bitch will sever the umbilical cord. If not, it should be cut to 1.5 in. (3.5 to 4 cm) and an appropriate topical antiseptic applied. Orphaned puppies are at greater risk for infectious diseases; thus, sanitary husbandry practices are important. To reduce risk for diseases, puppies should not be exposed to older animals or grouped within multiple litters. Feeding equipment and bedding should be kept clean and sanitized frequently. Caretakers should wash their hands before handling neonates and after stimulating elimination.

Puppies cannot voluntarily urinate or defecate until about three weeks of age. Until that time, they rely on the bitch to stimulate the urogenital reflex to initiate elimination. Caretakers should stimulate puppies after feeding by gently swabbing the perineal region with a warm moistened cotton ball or cloth.

Often, puppies within a litter look similar; therefore, it may be difficult to tell them apart when hand rearing, especially in large litters. Different colored nail polish can be applied to the claws to help differentiate individuals; owners can paint a different paw for each puppy (e.g., blue front left paw, blue right rear paw, pink right front paw, etc.).

Other Physical Parameters

When evaluating neonates, the clinician should hold each puppy to assess alertness, muscle tone and response to handling. Attentive, experienced breeders often are good observers and make these evaluations routinely. Gastric fullness should be evaluated and the owner asked if the puppies are nursing. Healthy puppies, if hungry, might start crying but in a short time they generally stop crying and sleep, even without nursing (**Box 16-1**). Small and weak puppies may appear to nurse and develop abdominal fullness, yet fail to thrive. Weak puppies may also have an enlarged abdomen but are often restless and vocalize, which should alert the owner. This distention may result from aerophagia (Bebiak et al, 1987); however, more often it is caused by malnutrition or illness of the bitch or puppy. Weak puppies cannot reach the bitch's nipples and stimulate milk release, which is usually achieved by kneading the mammary glands with their forelimbs.

Key Nutritional Factors

Colostrum and Milk

The liquid secretions from the mammary glands during the first few days postwhelping are known as colostrum. The composition of the milk changes rapidly to become normal or "mature" milk between 24 hours postpartum and the end of the first week of lactation. Colostrum transfers immunoglobulins, provides a concentrated source of energy and selected nutrients and produces a laxative effect.

The immune system of neonatal puppies is immature, which is offset by passive transfer of immunoglobulins from the bitch across the placenta and in the colostrum (Banks, 1981; Tizard, 1992). Investigators estimate that puppies receive only 5 to 10% of IgG from transplacental transfer; therefore, they depend primarily on immunity derived from the intake of colostrum (Tizard, 1992). Colostrum contains about twice as much protein as mature milk; globulin proteins make up the entire difference (Meyer et al, 1985a; Rüsse, 1971). Colostrum is particularly rich in IgG, as opposed to mature milk, which is richer in IgA (Banks, 1981).

Colostrum has a very different composition than mature milk. Due to its high dry matter (DM) content, colostrum is sticky and viscous (Meyer et al, 1985a), which makes nursing more difficult, especially for weaker puppies. The DM content

of colostrum decreases within 12 to 24 hours after whelping, primarily reflecting a decrease in protein.

The lactose concentration of colostrum is very low compared with that of mature milk (i.e., 1.0 vs. 3.4%) (Meyer et al, 1985a). Levels of calcium, phosphorus and magnesium are very high in colostrum and decrease after two to three days to levels that are lower than in mature milk (Meyer et al, 1985a).

Just after whelping, colostrum contains high levels of iron, copper and zinc, which decrease within 48 hours postpartum (Meyer et al, 1985a). Colostrum is high in vitamin A (Meyer et al, 1985; Ferrando et al, 1975); colostrum levels increase the liver reserve of vitamin A in puppies by 25% within a week (Meyer et al, 1985).

Milk is assumed to be a complete food for neonates. The composition of milk (i.e., water, protein, fat, lactose, minerals and vitamins) is designed to support the normal growth rate of neonates. Thus, the nutrient content of bitch's milk in **Table 16-4** summarizes the key nutritional factors for nursing puppies. For nutrients in which the concentration in mature milk is unknown, values recommended by the Association of American Feed Control Officials for growth should suffice (2007). In lieu of other information, the key nutritional factor discussion for weaning and postweaning puppy growth provides information that could be extrapolated to neonates (Chapter 17).

Milk from different mammalian species contains the same components but in different proportions. One reason for the difference in milk composition may be the relative growth rates of each species (Johnson, 1974). The faster the rate of growth, the more concentrated the milk nutrients to support growth (Table 15-4). Bitch's milk is higher in energy, protein and minerals than cow's milk (Table 15-3). As with other species, the nutrient concentration in bitch's milk changes with duration of lactation (Adkins et al, 2001).

Water

Water is one of the most important nutrients in orphan feeding. The normal water intake of puppies is relatively high. A normal puppy needs about 60 to 100 ml of fluid/lb body weight per day (130 to 220 ml/kg body weight per day) (Lawler, 1991; Mosier, 1977). On average, orphaned puppies should receive about 180 ml of water/kg body weight to make orphan feeding successful. Water should be given until 180 ml/kg body weight is reached if the milk replacer doesn't provide this much water at the recommended dilution.

Energy

Data from two studies show that bitch's milk is extremely digestible (Mundt et al, 1981; Kienzle et al, 1985). The energy intake of suckling puppies can be expressed in terms of gross energy (GE) because the energy digestibility is greater than 95%. The high digestibility of milk maximizes its usage and helps puppies survive the critical first weeks. Bitch's milk is high in energy and provides about 146 kcal GE (610 kJ)/100 g of milk.

Total milk intake per puppy is lowest during the first week of

*Because of the very large variation in adult body weight (BW) and number of puppies per litter, there is no direct relationship between the birth weight of a puppy and the BW of the mother. Puppies from largest breeds are approximately 1% of the bitch's BW, whereas a Chihuahua puppy averages 6.4% of its mother's BW. However, there is a strong relationship between the weight of the total litter and the bitch's BW. On average, the total litter weight is about 12 to 14% of the bitch's BW. This relationship and the values in this table may be helpful to determine if individual puppies are far below the average expected birth weight, and to assess the bitch's nutritional status during pregnancy.

Box 16-3. Body Weight Gain in Puppies.

Birth weight of puppies is the single most important measure of their chances of survival, and reflects, among other factors, the adequacy of the bitch's nutrition during pregnancy. The evolution of a puppy's body weight gives useful information about food intake and general health. Body weight should be recorded within 24 hours after parturition, and then daily or every other day for the first four weeks of life, using an accurate gram scale.

BIRTH WEIGHT

Due to variation in breed size, an exact optimal birth weight is difficult to estimate for individual puppies. Body weight at birth correlates primarily with the weight of the mother; birth weights range from 1% for some large and giant breeds to about 6.5% in Chihuahuas. Interestingly, investigators found a consistent ratio between the weight of the total litter and the body weight of the dam. Birth weight of the entire litter averages about 12 to 14% of adult body weight. The ratio can be slightly smaller in large breeds. Given the number of puppies and the ratio of litter to adult body weight, the birth weight of individual puppies can be evaluated in relation to the expected total number of puppies per litter.

BODY WEIGHT GAIN

Daily weight gain averages about 5% of the puppy's current body weight during the first four weeks after parturition. The absolute daily weight gain is lowest during the first week of life; however, the relative increase is largest (average 7.7% of body weight), and can reach 10% of body weight (**Table 1**). In the first 48 hours, the increase in body weight is not related to the puppy's body weight, because healthy smaller puppies eat relatively more in an effort to replete body reserves.

The puppy's body weight often doubles by eight to 10 days after parturition and it may triple by the third week. Although the relative weight gain gradually decreases, weight gain in g/day varies little from the second to the fourth week of life.

Daily gain can vary markedly. Although puppies should be weighed every day or every other day, a more precise evaluation should be based on the average weekly weight gain.

Between one and two months of age, daily weight gain may average 3 g/kg adult body weight, and between 2 and 4 g/kg adult body weight through weaning. These numbers may be used to help assess growth rates. However, dogs do not grow linearly; the growth curve has a sigmoid shape, with a fast exponential growth component first followed by slower growth. The exact timing of these phases differs from breed to breed. As a rule, small- and medium-sized dogs (up to 25 kg) reach about 50% of their adult weight around four months of age, whereas dogs with adult weights above 25 kg reach the 50% point at about five months of age.

Fortschritte in der Tierphysiologie und Tierernährung (Advances in Animal Physiology and Animal Nutrition) 1985; Suppl. No. 16: 27-50. Mundt H-C, Thomée A, Meyer H. Zur Energieund Eiweißversorgung von Saugwelpen über die Muttermilch. Kleintierpraxis 1981; 26: 353-360.

The Bibliography for **Box 16-3** can be found at www.markmorris.org.

life. However, expressed per kg body weight, puppies' milk intake is highest during the first week and decreases progressively (Kienzle et al, 1985). Puppies born with a lower body weight ingest an amount of milk similar to that of their larger littermates during the first 48 hours of life (Oftedal, 1984; Kienzle et al, 1985).

The energy requirement of a puppy is the sum of energy needed for maintenance and the requirement for growth. Because puppies sleep more than 80% of the time, and huddle together in a warm whelping box, they are able to decrease their energy requirements for maintenance to a level that approaches resting energy requirement (70 kcal/$BW_{kg}^{0.75}$) (Mundt et al, 1981) during the first week of life. Therefore, all additional ingested energy can be used for growth. Their energy intake averages about 240 kcal (1 MJ)/kg body weight/day during the first four weeks of life. Averages, however, may vary from as high as 287 kcal GE (1.2 MJ)/kg body weight during the first week of life to as low as 190 kcal GE (0.8 MJ)/kg body weight by Week 4 (Oftedal, 1984; Mundt et al, 1981; Kienzle et al, 1985).

This information can also be generally applied to orphaned puppies. A very common mistake is to underestimate the energy requirements of neonates. In the beginning, however, it is better not to over feed orphaned puppies to avoid diarrhea. **Table 16-5** summarizes the estimated energy requirements of orphans to transition them to milk replacers. The initial amounts in **Table 16-5** are lower than the amounts discussed above. These lower levels are intended to help orphaned puppies adapt to orphan formulas. When using commercial milk replacers, it is usually best to follow the label recommendations.

Protein

Protein digestibility of bitch's milk is very high (up to 99%), and nitrogen retention is about 90% during the first week (Mundt et al, 1981). Compared with cow's milk, bitch's milk contains more than twice as much protein per 100 ml (7.5 vs. 3.3%) (Table 15-3). Bitch's milk also provides high levels of arginine, lysine and branched-chain amino acids (Meyer et al, 1985a; Swaisgood, 1995). This nutrient profile is important when assessing and formulating milk replacers, and reflects the enormous anabolic activity of puppies at this young age. Protein requirements should be met if puppies ingest adequate amounts of energy as that contained in bitch's milk.

Commercial milk and homemade replacer formulas should have adequate protein and essential amino acid content and

appropriate ratios of these constituents. The arginine and histidine levels in a formula are particularly important. Deficiency of these amino acids can cause cataract development in neonates and contribute to anorexia and poor growth. The minimum recommended levels of these two amino acids for growth in puppies after weaning are 0.79 and 0.39% (DM), respectively (NRC, 2006). These recommendations are based on a food with 22.5% DM crude protein. For four- to 14-week-old puppies, 0.01 g of arginine should be added for every 1% of crude protein in excess of 22.5% (NRC, 2006). The amount of arginine in milk is 420 mg/kg (as fed) or 1.85% (DM) (**Table 16-4**).

Fat

Approximately 1.5% of a puppy's total body mass at birth is fat, which is very low compared to the 22% body fat of non-obese adult dogs (Stadtfeld, 1978; Rauchfuss, 1978). Puppies increase body fat during the first month of lactation; accretion of body fat is about 50% of total weight gain (Kienzle et al, 1985). Fat increases to about 10% of body weight by two weeks of age (Meyer and Stadtfeld, 1980) and to 17% after one month (Kienzle et al, 1985). The dam's milk, therefore, must contain enough energy (fat) to support development of these reserves. Milk fat and fatty acid composition are two of the most variable components of milk. The fat content and fat quality of milk depend on the food the bitch receives during lactation (Gross, 1993). Bitch's milk should contain 9 g or more fat/100 g of milk. Fat in bitch's milk contains a high percentage of unsaturated fatty acids and is rich in linoleic acid compared with cow's milk (Table 15-3).

Milk fat and fatty acid composition are highly variable components of milk and often reflect dietary intake of the bitch. The type of dietary fat fed in conjunction with the fatty acid profile of endogenous fat deposits may affect the fatty acid composition of milk. In one study, the fatty acid composition of bitch's milk reflected the foods fed during gestation and lactation. Furthermore, the milk of bitches fed foods enriched with α-linolenic acid (ALA) but not docosahexaenoic acid (DHA) was high in ALA. Puppies fed this milk accumulated more plasma phospholipid DHA than the control group (but not as much as puppies fed preformed DHA) during suckling (Heinemann et al, 2005). In children, during periods of early growth, DHA may be needed to support retinal and auditory

Box 16-4. Hypoglycemia, Hypothermia and Dehydration in Neonates.

Before weaning, mortality of puppies can be as high as 10 to 30%, with 65% of the deaths occurring during the first week of life. Healthy puppies sleep and nurse; when a puppy continues to vocalize it is probably ill, malnourished, cold or dehydrated.

The syndrome of hypoglycemia, hypothermia and dehydration is by far the most common nutrition-related condition seen in neonates. Orphaned puppies are at a much higher risk than nursing puppies, especially when deprived of colostrum. Low fat stores and the degree of poikilothermy make puppies dependent on effective nursing and optimal environmental temperature during the first two weeks of life. The first three days of life, however, are the most critical. Rectal temperatures of newborn puppies may decrease up to 4 to 5°C (7 to 8°F) immediately after parturition. Furthermore, healthy puppies may lose about 0.5 g of body weight every 30 minutes that they sleep without being fed.

When food intake is inadequate or when the environmental temperature is too low, newborn puppies rapidly deplete glycogen and fat stores and soon chill and become hypoglycemic, weak and dehydrated. Etiology includes inadequate milk production by the bitch (qualitative or quantitative), and all the causes of anorexia and reasons why a puppy refuses or is unable to nurse, including early maternal rejection, prematurity and low birth weight.

Infections, parasites and other illnesses lead to anorexia and may cause hypoglycemia, dehydration and hypothermia. Diarrhea rapidly causes dehydration in young puppies.

Hypoxia is an important cause of anorexia and hypoglycemia. Hypoxia may result from dystocia, prolonged birth or trauma caused by the bitch. Neonates have significantly lower blood glucose levels during the first day of life when their dam refused food during the last days of pregnancy.

Hypoglycemia, hypothermia and dehydration are interrelated; one can cause or worsen the others, starting a vicious cycle (**Figure 1**).

HYPOTHERMIA

After a puppy's rectal temperature drops below 34.5°C (94°F) the puppy becomes less active and nurses ineffectually, bowel movements stop and digestion no longer occurs. When a puppy's skin feels cold, the dam will push the puppy away and ignore its cries. The puppy then becomes hypoglycemic and is too weak to nurse, initiating a vicious cycle from which the puppy will not survive without help. Tissue hypoxia and metabolic acidosis may reach profound proportions. After the body temperature reaches the critical level of 32°C (90°F), hypothermia becomes severe and the puppy lies motionless, with a very slow respiratory rate and an occasional air hunger response. It has been reported that healthy newborn puppies can survive up to 12 hours of deep hypothermia and recover if warmed slowly. In practice, however, hypothermic puppies can be rescued only when the problem is detected early and treated correctly.

Hypothermia that develops in puppies kept at the correct environmental temperature may indicate insufficient milk intake by the puppy due to disease or weakness, inability to reach the bitch's nipples, insufficient milk production and/or inadequate maternal behavior and poor milk quality or quantity due to insufficient nutrition of the dam, disease of the dam and/or inherited factors.

Orphaned puppies are at greater risk because they are more sensitive to suboptimal temperatures without the dam. Additionally, the milk replacer formula or feeding schedule may be inadequate.

HYPOGLYCEMIA

Fetuses receive continuous infusion of glucose from the placenta, so they do not depend on their own gluconeogenesis. Because they have very low fat and glycogen reserves at birth, canine neonates may develop hypoglycemia after only 12 hours of fasting. In contrast, adult dogs can undergo weeks of starvation without developing hypoglycemia. During starvation, gluconeogenesis becomes the

Box 16-4 continued

sole means of glucose homeostasis. The neonate's small muscle mass, decreased use of free fatty acids as an alternate energy source and a possible lack or decreased levels of gluconeogenic enzymes limit the neonate's capacity to maintain normal glucose levels. Dietary carbohydrate and protein levels can also affect activities of gluconeogenic enzymes in puppies. Transient hypoglycemia is sometimes seen in toy-breed puppies between two and three months of age; however, transient hypoglycemia is different from this syndrome.

DEHYDRATION

Dehydration is characterized by wrinkled skin and dry, sticky mucous membranes, which may appear deep pink or red.

TREATMENT

The three treatment goals for hypoglycemia, hypothermia and dehydration are to: 1) achieve optimal core body temperature, 2) maintain glucose within physiologically normal levels and 3) achieve adequate hydration status.

Chilled puppies should receive a mixture of equal amounts of physiologic saline solution (or lactated Ringer's solution) and a 5% glucose solution by subcutaneous injection before rewarming. Glucose is necessary to meet the sudden increase in energy requirements during warming.

Hypothermic puppies should first be warmed to 34.5°C (94°F), a temperature that allows digestive enzymes to become active again. If they are not warmed before being fed, hypothermic puppies will develop diarrhea, resulting in further dehydration and hypothermia, because of nonfunctioning digestive enzymes.

Hypothermic puppies should be warmed slowly and progressively over one to three hours to prevent oxygen and energy requirements of tissues from increasing faster than the puppy can supply. Aggressive, rapid warming can compromise vascular integrity and aggravate fluid loss and dehydration, resulting in hyperthermia, hypovolemia, shock and death. Slow warming is best accomplished by using body heat. A simple method such as placing a chilled puppy in an inside pocket of a loose-fitting garment will result in slow warming and gentle massage. Warm water (36.5°C [98°F]) or a warm-water heating blanket is a good alternative. If a closed incubator is used, humidity should be around 60%. Because their normal body temperature is lower than that of adult dogs, newborn puppies should not be warmed to adult body temperature, but to about 36 to 36.7°C (97 to 98°F). Hypothermic animals are susceptible to infections, so administration of antibiotics may be lifesaving.

Dehydration should not be treated orally in markedly hypothermic puppies because of their depressed gastrointestinal motility. Parenteral fluid solutions, warmed to body temperature, can be given subcutaneously, at the dose of 1 ml/30 g body weight, and repeated as needed. After body temperature is restored, oral solutions can be administered by stomach tube. Nursing should recommence as soon as possible, although hand rearing will be necessary if the bitch is incapable of feeding the puppies.

Tube feeding with an appropriate milk replacer, parenteral fluid administration and other supportive therapy should be implemented at once each time a young puppy becomes weak and before hypothermia and dehydration are a problem.

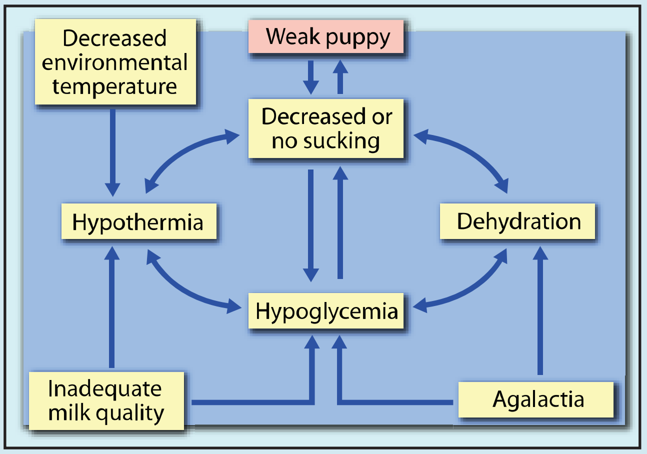

Figure 1. This figure shows how hypothermia, hypoglycemia and dehydration interrelate, creating a cycle that often results in neonatal death.

The Bibliography for **Box 16-4** can be found at www.markmorris.org.

development (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003). In addition, infants supplemented with DHA had enhanced brain development and learning ability (Birch et al, 2002; Huffman et al, 2003). As in other species, including fish oil as a source of DHA in puppy foods improved trainability (Kelley et al, 2004). Retinal function of young dogs improved when foods containing long-chain omega-3 (n-3) polyunsaturated fatty acids were fed during gestation and lactation (Bauer et al, 2006). The recommended level of DHA plus eicosapentaenoic acid (EPA) for puppies after weaning is 0.05% (DM). At this level, EPA should not exceed 60% of the total amount of DHA plus EPA (NRC, 2006). These levels probably also apply to orphan formulas. Thus, DHA needs to be at least 40% of the total DHA plus EPA, or 0.02%.

Linoleic acid is an essential fatty acid and is required for normal growth. The DM linoleic acid content of bitch's milk is 4.9% (**Table 16-4**). Bitch's milk has an energy density of 6.43 kcal/g (DM). Converting this amount of linoleic acid to a 4 kcal/g basis results in a linoleic acid equivalent of 3.0% (DM). This is greater than the minimum recommended allowance of 1.3% for foods for puppies after weaning (NRC, 2006) and probably reflects the more rapid growth rate and subsequently higher requirement of neonates.

Carbohydrate

Lactose is the primary carbohydrate in milk. Lactose levels in bitch's milk vary between 3.0 and 3.5%, which are about 30% lower than those in cow's milk (Table 15-3). Although the lactose content of milk varies widely among animal species, it is very consistent and maintained within narrow limits within a species. Lactose and minerals in milk primarily contribute to osmolarity. Any increase or decrease in lactose content is offset by changes in the content of other soluble components (Johnson, 1974).

Lactose, a disaccharide, is absorbed after digestion into its constituent monosaccharides. Lactose is unique in that its glucose

and galactose molecules are linked with a β-1,4 bond instead of the α-1,4 linkage commonly found in other soluble glucose polymers (Stryer, 1988; Newberg and Neubauer, 1995). This linkage makes lactose a less suitable substrate for microbes that may infect the mammary gland or the neonate's gastrointestinal tract. Furthermore, large amounts of lactose may favor colonization of the intestine by more beneficial microflora, which compete with and exclude many potential pathogens (Newberg and Neubauer, 1995). To avoid diarrhea, lactose should be the main carbohydrate source during the first weeks of life. Pancreatic amylase activity is insignificant at four weeks of age and low at eight weeks, whereas intestinal lactase activity is enhanced until about four months of age (Kienzle, 1988; Meyer, 1992).

Calcium and Phosphorus

Calcium levels are very high in colostrum; however, after two to three days, levels decrease to less than those found in mature milk (Meyer et al, 1985a). Calcium content increases over the course of lactation; however, the calcium-phosphorus ratio remains consistent around 1.3:1 (Meyer et al, 1985a). Calcium and phosphorus levels in milk are similar among canine breeds. Canine milk is rich in calcium and phosphorus; the amounts of these minerals in bitch's milk could be regarded as recommendations for daily intake by growing puppies, despite the fact that skeletal calcification does not keep pace with the increase in body size until after weaning (Gesellshaft, 1989; Baines, 1981).

Potassium, Sodium, Magnesium and Copper

Potassium helps maintain acid-base and osmotic balance, transmit nerve impulses, facilitate muscle contractility and serves as a cofactor in several key enzyme systems. Sodium is also important for maintaining acid-base and osmotic balance, and transmitting nerve impulses and muscle contractions. Sodium controls passage of nutrients into cells, including absorption of sugars and amino acids from the intestinal lumen. Sodium is involved in calcium absorption and the absorption of several water-soluble vitamins. Magnesium is involved in carbohydrate and lipid metabolism and is a catalyst for a wide variety of enzymes. It is required for ATP production, catalyzes most phosphate transfers and has a potent influence on neuromuscular activity. Numerous copper-containing enzyme systems exist including those involved in hematopoiesis, control of neurotransmitters, connective tissue integrity, oxidative metabolism and protection against superoxide radicals. Thus, it is important that these minerals be present in adequate amounts and correct proportions. **Table 16-4** lists the levels of these minerals in milk.

Iron

Deficiency may occur if iron stores are not accumulated during the last week of pregnancy, or if excessive blood loss occurs due to severe hookworm infection or severe flea infestation. During the first three to four weeks of life, body iron stores and hematocrit and hemoglobin values decrease below levels at birth. Decreasing hematocrit and hemoglobin values might also be due to a relative increase in total body water over this time period. The decrease is more pronounced in fast-growing, large-breed puppies (Gesellshaft, 1989a).

Milk is a poor source of iron and puppy requirements are usually higher than intake (Kienzle et al, 1985). Iron reserves increase when puppies receive food at weaning; body iron stores normalize around four months of age (Kienzle et al, 1985).

Table 16-4. Key nutritional factors for foods for nursing puppies (the nutritional content of bitch's milk).*

Nutrient	Per 100 g milk, as fed	DM basis**

**Units are expressed in percentages unless otherwise indicated.

Table 16-5. Recommendations for energy intake of orphaned puppies as a basis for determining orphan formula dose.*

Feeding period	kcal ME/100 g BW	kJ ME/100 g BW
Days 1-3	15	60
Days 4-6	20	85
>6 days	20-25	85-105

Key: ME = metabolizable energy, BW = body weight.

*Do not over feed orphan formulas initially. The feeding amount for the first six days intentionally provides less energy than would normally be provided, which is gradually increased so that the orphaned puppies' energy requirements are being met after about one week.

Table 16-6. Feeding plan summary for nursing puppies.

1. Ensure good husbandry practices are understood and in place (Box 17-2).
2. Ensure colostrum intake by the puppies within the first 24 hours.
3. Provide bitch's milk until three to four weeks of age; then gradually initiate the weaning process by introducing small amounts of semisolid to solid food, which augments nursing of bitch's milk (**Box 16-5**).
4. The weaning food should be a good quality growth/reproduction type commercial food (Tables 15-9 and 17-4).
5. Assess nursing puppies daily, including recording of body weight and tracking weight gain for the first month of age (**Box 16-3**); then weekly. Recommend weekly veterinary checks for the first month.
6. Puppies failing to thrive on bitch's milk should be fed via partial or total orphan feeding techniques; check bitch, including bitch's food, to ensure no health or nutrition issues are affecting lactation.
7. Wean at six to seven weeks (**Box 16-5**) and feed according to recommendations in Chapter 17 (growing puppies).

Table 16-7. Feeding plan summary for orphaned puppies.

1. Ensure good husbandry practices are understood and in place (**Box 16-2**); have owner(s) attempt to provide as much total care as the bitch would have.
2. Puppies should have colostrum within the first 24 hours of birth; if not, administer frozen colostrum or consider colostrum from other species, commercial colostrum sources or serum from vaccinated dogs given subcutaneously.
3. Use foster bitch if possible; partial orphan feeding is next best and bottle feeding is the best of hand-feeding techniques (**Figures 16-1** through **16-3**).
4. **Table 16-9** provides three homemade formulas and **Table 16-10** compares them to bitch's milk. Commercial milk replacers are best.
5. To determine the initial amount to feed, use **Table 16-5** to estimate the puppies' daily energy requirement (DER); divide the DER by the energy density of the milk replacer to determine the daily amount to feed. Besides energy and other nutrients, orphaned puppies should receive about 180 ml of water/kg body weight/day; if necessary, add additional water to the milk replacer if the recommended dilution doesn't provide this amount of total fluid intake.
6. Milk replacers should be heated to 38°C (100°F) and the daily amount divided and fed ≥4 times/day at equal intervals.
7. Good hygiene is critical and includes washing/boiling feeding utensils before each feeding, preparing no more than the amount of milk replacer that can be fed in 24 hours (keep refrigerated) and carefully washing puppies with a moist, soft cloth twice weekly.
8. Have owners gradually initiate the weaning process by introducing small amounts of semisolid to solid food, which augments the milk replacer (**Box 16-5**).
9. The weaning food should be a good quality growth/reproduction type commercial food (Table 17-4).
10. Assess nursing puppies daily, including recording of body weight and tracking weight gain for the first month of age (**Box 16-3**); then weekly. Recommend weekly veterinary checks for the first month.
11. For puppies not thriving on milk replacer, review milk replacer quality (**Table 16-8**), dilution calculations and feeding amounts; switch to a different milk replacer if necessary.
12. Wean at six to seven weeks (**Box 16-5**) and feed according to recommendations in Chapter 17 (growing puppies).

Therefore, puppies should receive solid food as soon as possible (around three weeks of age).

Milk replacers are often fortified with iron at concentrations higher than those found in bitch's milk. Orphaned puppies, especially low birth weight neonates born with low iron reserves, may benefit from iron intakes higher than those normally found in milk. The additional iron supports hematopoiesis and helps avoid anemia sometimes observed in three- to four-week-old neonates.

Digestibility

DM digestibility of bitch's milk is very high (>95%) (Mundt et al, 1981; Kienzle et al, 1985). Digestibility of milk replacer formulas should also be high (>90%) to allow for smaller quantities to be fed and avoid diarrhea.

Osmolality

The osmolality of bitch's milk is approximately 569 mOsm/kg. Milk replacers with osmolality values considerably higher than these concentrations should be avoided because they may cause hyperosmolar diarrhea and potentiate dehydration. High osmolality may delay gastric emptying and predispose to regurgitation, vomiting and aspiration during the next meal, if the stomach is not completely empty.

FEEDING PLAN

The feeding plan includes determining the best food and feeding method. **Tables 16-6** and **16-7** provide feeding plan summaries for nursing and orphaned puppies, respectively.

Assess and Select the Food

Puppies should receive colostrum within the first 12 to 24 hours after birth to ensure adequate intake of immunoglobulins. If bitch colostrum is unavailable, colostrum from a different species may be used. Although antibody protection may be limited, providing nonspecific defense substances such as lactoferrin, oligosaccharides, lactoperoxidases and lysozymes may be beneficial. Alternatively, sterile serum from vaccinated dogs administered subcutaneously has been recommended (England, 2005).

Direct assessment of milk quality is difficult; therefore, indirect parameters should be evaluated, including failure to grow, weakness, an enlarged abdomen and abnormal behavior such as restlessness and continuous vocalization. After illness is ruled out, these signs may indicate insufficient milk production by the bitch and/or deficient milk quality.

Milk intake can be estimated by weighing puppies before and after they nurse. The ratio of weight gain to milk intake may indicate milk quality. However, weight gains range from about one g/two g of milk intake to one g/to almost five g of milk intake during the first weeks of life (Oftedal, 1984; Mundt et al, 1981; Jean-Blain, 1973). This wide range results primarily from differences in ability to estimate milk intake. Also, an underweight bitch (body condition score 1/5 or 2/5) may be at risk for producing inadequate or poor quality milk. Therefore,

Box 16-5. Weaning.

Weaning is a gradual process with two phases. The first phase begins when puppies start eating solid food between three and four weeks of age. This phase should be encouraged, especially if the bitch has a large litter. Additionally, nursing is an important stimulus for milk production. Therefore, milk production will progressively decline as the puppies' intake of solid food increases, making complete weaning (second phase) less stressful. However, some bitches may continue to produce large quantities of milk and are at risk for development of mammary congestion when the puppies are completely separated. The feeding schedule in **Table 1** may be helpful, particularly in cases of early weaning (around the fifth week of age).

Limiting food intake for a day or two while weaning reduces nutrients available for milk production, thereby reducing mammary gland engorgement. Leaving one or two puppies to nurse will not alleviate mammary gland engorgement in bitches that are still producing a large amount of milk at weaning. This practice continues to stimulate milk production, and therefore prolongs the problem. When it is decided to completely separate the puppies from the mother, all puppies should be taken away at once.

Puppies should be encouraged to start eating solid food as soon as possible. This practice will reduce reliance on the bitch, reduce the nutritional burden on the bitch and make complete weaning less stressful. Most puppies will start eating solid food between three and four weeks of age, the time when deciduous teeth begin to erupt. Oftentimes, during play, puppies will come in contact with the bitch's food and progressively start eating small amounts.

Puppies can be offered gruel to stimulate food intake at three weeks of age. Gruels are made by blending a moist growth/reproduction-type food with an equal volume of warm water. Alternatively, one part of dry food can be ground and mixed with three parts of warm water (volume basis). Puppies should be encouraged to lap the gruel; owners can dip their fingertips in the gruel and then into the puppies' mouth. Ideally, the food used to make the gruel should be highly digestible, contain at least 25 to 30% protein and have an energy content of at least 4.0 kcal (16.7 kJ) metabolizable energy/g (dry matter). A good quality growth/reproduction-type food such as the bitch is eating should be appropriate (Chapters 15 and 17). Puppies are very prone to vomiting and diarrhea during this period. If gastrointestinal disturbances occur, gruel can be made from a highly digestible moist food intended for dietary management of diarrhea with a minimum of about 25% dry matter protein.

As the puppies' interest in solid food increases, the water content of the gruel can be reduced progressively. Puppies should be eating sufficient quantities of solid food at five weeks of age because the bitch's milk production will probably start declining.

From three weeks of age on, puppies can be separated from their mother for short periods of time. The time away from the dam can be progressively increased to about four hours a day by around six weeks of age. Weaning should be effectively completed between six and seven weeks of age and puppies can be removed from the dam. After weaning, the puppies should be fed the same food to minimize stress and the risk of diarrhea.

Table 1. Recommended feeding schedule for reducing mammary congestion in bitches during weaning of puppies.*

Day of weaning	No food
First day after weaning	One-fourth of DER for adult maintenance (0.5 x RER)
Second day after weaning	One-half of DER for adult maintenance (RER)
Third day after weaning	Three-fourths of DER for adult maintenance (1.4 x RER)

Key: DER = daily energy requirement, RER = resting energy requirement.

the bitch's food and feeding method should also be assessed. Most lactating bitches should be fed free choice (Chapter 15).

Foods used to feed orphans may consist of bitch's milk, commercial milk replacer or homemade replacer formulas. Milk from a healthy bitch is the food of choice and is assumed to provide nutrients in the proper levels for nursing puppies. Bitch's milk is rarely available in sufficient quantities to hand raise orphans. Of the alternatives, commercial milk replacers are preferred although several homemade formulas have proved sufficient. **Table 16-8** lists commercial milk replacers and compares their nutrient profiles (key nutritional factors) with bitch's milk. **Table 16-9** provides three homemade milk replacer recipes and **Table 16-10** compares these recipes' nutrient profiles with that of bitch's milk. Commercial and homemade milk replacers should closely mimic the profile of bitch's milk. Unsupplemented ruminant milk may be used as a base for homemade formulas but doesn't meet the nutritional needs of puppies. For puppies, goat's milk provides no nutritional benefit over cow's milk.

Foods should be liquid until nursing puppies and orphans are three to four weeks old, then semisolid to solid foods should be introduced. This transition marks the beginning of weaning (**Box 16-5**).

Assess and Determine the Feeding Method

Puppies should be encouraged to nurse often during the first week of life (eight to 12 times per day); after Week 1, they should be encouraged to nurse at least three to four times daily. Inexperienced bitches should be carefully observed to ensure that all puppies receive sufficient amounts of colostrum within 24 hours of birth, when puppies are able to absorb intact proteins such as immunoglobulins. This involvement may include positioning the puppies on the bitch's nipples at feeding time or encouraging a nervous bitch to lie quietly as the puppies nurse. Handling the dam and puppies facilitates monitoring the progress of the litter.

*Manufacturers' data; nutrient content for reconstituted powdered products are manufacturers' calculations based on the recommended dilution. Nutrient data per 100 ml would be reduced slightly (between 1 to 2%) because the specific gravity of milk is greater than that of water.
**g/100 g = %.
***The first number is the milk powder, the second the water (e.g., 1+2 = one part of powder plus two parts of water).
†Nutrients in liquid and powder forms are averages from the yearly laboratory analyses of composite samples from 2004 to date.
††The nutrient levels per 100 kcal ME were calculated from the nutrient and energy levels in the top portion of the table.

Competition in large litters may prevent smaller, weaker puppies from nursing and predispose them to dehydration and hypoglycemia. Partial orphan rearing of the entire litter should be done in these cases (see below). Partial orphan rearing allows the puppies to stay with the dam in their normal environment and permits proper socialization.

Puppies that fail to thrive when receiving bitch's milk should be fed immediately via partial or total orphan feeding techniques (see below) to avoid the risk of hypoglycemia, hypothermia and dehydration.

It may be necessary to alter the feeding method when managing orphaned puppies, especially if they are hand reared. Evaluation of the current feeding method with knowledge of growth demands will facilitate this part of feeding plan development. Orphaned puppies and those too weak to nurse are candidates for fostering, partial orphan rearing or hand feeding. The caregiver for orphans should provide the level of care provided by the bitch; good husbandry is essential.

Fostering

The optimal means of feeding orphaned or rejected puppies is to foster them to another lactating bitch. In general, fostering is the least labor intensive, provides optimal nutrition, reduces mortality, improves immune status, usually provides an optimal physical environment and promotes normal social development of puppies. Unlike large animals, bitches readily accept additional puppies during lactation. If several foster mothers are available, it is best to place orphans in litters with fewer than 14 days age difference. Larger puppies often crowd out smaller individuals if the age discrepancy is too large. This situation can be managed by supervised feeding until the orphans can fend for themselves. Unfortunately, foster mothers are not normally available and alternative techniques must be used. Foster mothers should be well fed.

Puppies fostered onto another bitch should be supervised initially to detect any behavioral problems between the foster parent, its young and the orphans. Puppies should be accepted immediately and allowed to nurse. Encourage owners to watch for signs of rejection or impending cannibalism by the mother.

Partial Orphan Rearing

Puppies that cannot be successfully raised by the bitch for reasons such as poor health, poor lactation performance or too large of a litter may be left with the mother but given supplemental feeding to support nutritional needs. Supplemental food may be given by hand feedings or timed feedings using a surrogate bitch. Puppies may also be reared in a communal situation. Partial orphan rearing can be accomplished by dividing the litter into two groups of equal number and size. One group remains with the mother while the other is removed and fed milk replacer. The groups are exchanged three to four times daily. It is important to feed the separated group before it is returned to the mother. As a result, the group just placed with the dam will be less inclined to nurse immediately (Björck, 1984). It is better to supplement all the puppies in the litter rather than just a few. The advantages of partial orphan rearing are similar to those of fostering. In addition, continued access to the mother can help stimulate milk production and mothering behaviors. When using foster or surrogate mothers, clients should monitor for signs of rejection and cannibalism. Partial orphan rearing may be necessary to assist the efforts of foster mothers. Unfortunately, foster and surrogate mothers are rarely available.

Hand Feeding

The most common method of raising orphaned puppies is hand feeding. Eyedroppers, syringes, bottles and stomach tubes are typically used to feed orphans.

BOTTLE FEEDING

Bottle feeding is the preferred method for vigorous puppies with good nursing reflexes (**Figures 16-1** and **16-2**). Bottle feeding has the advantage that neonates will nurse until they are satiated and reject the milk or formula when full. However, bottle feeding can be time consuming, especially with large litters.

Most puppies will readily suckle small pet nursers, which are available in pet stores (**Figure 16-3**). Feeding bottles for dolls or bottles with nipples for premature human infants are alternatives. The nipple opening should only allow one drop at a time to fall from the nipple when the bottle is inverted. A horizontal slit made with a razor blade instead of a round hole may make it easier for neonates to obtain milk or formula. Milk should be sucked-never squeezed-from the bottle. A rapid flow rate may lead to aspiration of milk and pneumonia and/or death.

Puppies should normally be held horizontally with the head in a natural position (**Figure 16-1**). This position reduces the risk of aspiration. Although some puppies may prefer a different position during feeding (**Figure 16-2**), careful observation is necessary because the risk of aspiration is increased.

Figure 16-1. This is the preferred position for bottle feeding puppies. This position mimics the normal nursing position and decreases the likelihood of aspiration.

Figure 16-2. Some neonates prefer different positions for bottle feeding. This puppy prefers nursing in dorsal recumbency. Close observation is required because this position may predispose to aspiration.

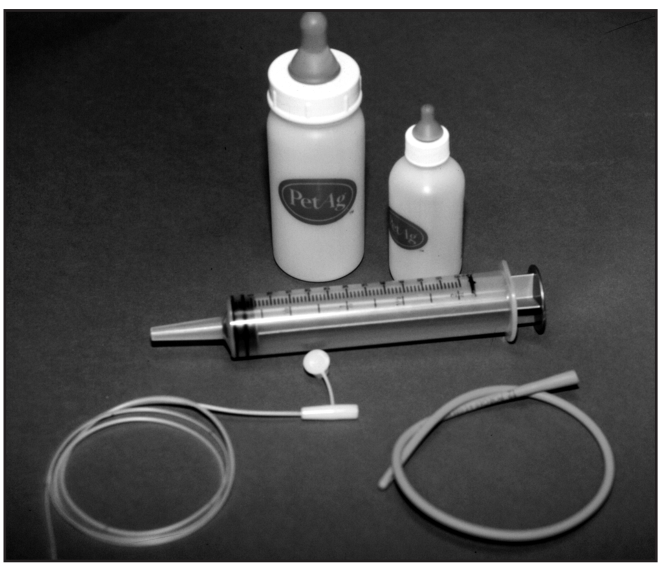

Figure 16-3. Various bottles and feeding tubes can be used for hand feeding orphaned puppies.

TUBE FEEDING

Puppies that are weak or suckle poorly may need to be tube fed. Tube feeding is quicker than bottle feeding and is often used when the same person must care for several orphans. Bottle feeding allows puppies to control the amount of food intake, whereas tube feeding bypasses this control mechanism. Infant feeding tubes (5 to 8 Fr.) or soft urethral or intravenous catheters may be used (**Figure 16-3**).

The tube should be lubricated and placed in the lower esophagus, which is approximately 75% of the distance from the nose to the last rib. Measure and mark the tube with an indelible marker or a piece of tape before insertion. Recheck measurements every few days to account for growth. The orphan should normally be placed horizontally in the palm of the hand with its head in a natural position.

The mouth can be opened using the same hand that steadies the head. Gently advance the tube to the premeasured mark. If resistance is encountered or the puppy suddenly struggles, the tube may be in the trachea. It should be removed and repositioned into the esophagus. Do not feed until proper placement is ensured. After the tube is placed, attach the feeding syringe and slowly administer the warmed formula (over about one to two minutes). The stomach may be palpated to determine the degree of distention. Administration should be stopped if the stomach becomes taut or resists formula flow. Continuation of feeding may result in overdistention and regurgitation. If regurgitation occurs, withdraw the tube and discontinue feeding until the next meal.

Feeding Schedule: Amount, Rate and Formula Temperature

An important part of successful hand feeding is adhering to a strict feeding schedule. Orphans should be fed at least four times daily. Very young neonates and weak puppies should preferably be fed every two to four hours. Older puppies should be fed every four to six hours. Normally, one- to two-week-old puppies will obtain more than 90% of their normal daily intake in four to five meals.

To determine the initial daily amount to feed, first use **Table 16-5** to estimate a puppy's daily energy requirement (DER). Then divide the DER by the energy density of the milk replacer to determine the daily amount to feed. When properly diluted, most milk replacers will provide approximately one kcal/ml. Besides energy and other nutrients, on average, orphaned puppies should receive about 180 ml of diluted milk replacer/kg body weight/day; if necessary, add additional water to the milk replacer if the recommended dilution doesn't provide for this amount of total fluid intake. This amount might underfeed energy but is less likely to cause diarrhea. During the first week of life, the capacity of milk intake by smaller breeds may be limited to about 10 to 15 ml per feeding.

Milk replacers should be warmed to 38°C (100°F) and delivered slowly. Cold foods, rapid feeding rates and over feeding may result in regurgitation, aspiration, bloating and diarrhea. Review and correct the feeding methods if untoward signs develop. If diarrhea is observed, food volume should be reduced or the food

should be diluted with water, then gradually returned to levels to meet caloric requirements over successive feedings. It is better to underfeed than over feed neonatal puppies.

Hygiene

Success of hand feeding orphans also depends on how well the caregiver fulfills the daily routine of hygienic measures. Hygienic measures must be more stringent for orphaned puppies because they may have received less colostrum and be more susceptible to infections than other neonates.

- Feeding materials (e.g., bottles and nipples) should be cleaned thoroughly and boiled in water between uses.
- Ingredients for homemade milk replacers should be fresh and refrigerated until used.
- Never prepare more milk replacer than can be used in 24 hours and refrigerate.
- Formulas should be discarded after one hour at room temperature.
- At least twice a week, orphans should be washed gently with a soft moistened cloth to simulate cleaning by the dam's tongue.

REASSESSMENT

Nursing puppies should be reassessed daily. Puppy body weights should be obtained at birth, daily or every other day for the first four weeks and then weekly. Adequacy of the bitch's milk production can be assessed by the growth rate of the puppies, puppy contentment and mammary gland distention. To determine whether an individual mammary gland is producing milk, gently express milk from the nipple while the bitch is relaxed. Most breeders are experienced enough to do this without help. Less experienced owners may need to be taught how to do this; weekly veterinary checkups during the first month may be helpful.

Orphaned puppies should be evaluated daily for the first two weeks of life. They should remain normally hydrated, sleep quietly between feedings and gain weight at a rate similar to bitch raised neonates. Alertness, eagerness to suckle, general behavior, body temperature (i.e., temperature of skin and lower limbs), body weight and stool character should be recorded daily or more often if neonates appear weak or listless.

Orphan rearing requires precise measurement of food intake. Nursing puppies should gain from one g body weight/two to five g of milk intake during the first weeks of life. It is realistic to expect orphaned puppies to gain somewhat less because they are fed at a lower energy intake and milk replacers are not the same as bitch's milk. However, if orphaned puppies do not thrive when fed a commercial milk replacer or homemade replacer, the nutrient content should be compared with mother's milk (**Tables 16-8** through **16-10**). The dilution recommended by the manufacturer should also be checked. In some cases, it may be necessary to switch to another formula.

Puppies with rectal temperatures less than 35°C (95°F) should not be fed milk formula. At this temperature, the sucking reflex is usually absent and normal gut motility has ceased. Neonates should first be warmed slowly after receiving a warm solution of 2.5% glucose by subcutaneous injection (1 ml/30 g body weight).

Weaning is an important event and is integral to successful feeding of nursing and orphaned puppies (**Box 16-5**).

Chapter 17

Feeding Growing Puppies: Postweaning to Adulthood

Jacques Debraekeleer

Kathy L. Gross

Steven C. Zicker

"Whoever said you can't buy happiness forgot little puppies."
Gene Hill

INTRODUCTION

This chapter covers puppy growth from immediately postweaning to adulthood, which generally occurs between 10 to 12 months of age, depending on breed. The goal of a feeding plan for puppies is to create a healthy adult. The specific objectives of a good puppy feeding plan are to achieve healthy growth, optimize trainability and immune function and minimize obesity and developmental orthopedic disease. Growth is a complex process involving interactions between genetics, nutrition and other environmental influences. Nutrition plays a role in the health and development of growing dogs and directly affects the immune system (Sheffy, 1985), body composition (Meyer and Zentek, 1992; Toll et al, 1993), growth rate (Meyer and Zentek, 1992) and skeletal development (Hazewinkel, 1985; Hedhammar et al, 1974; Kealy et al, 1992). Chapter 33 provides in-depth recommendations for feeding large- and giant-breed puppies (>25 kg adult weight) to avoid developmental orthopedic disease.

PATIENT ASSESSMENT

Puppies should be assessed for risk factors before weaning to allow implementation of recommendations for appropriate nutrition. A thorough history and physical evaluation are necessary. Special attention should be paid to large- and giant-breed puppies (Chapter 33) and breeds and sexes (intact and neutered) at risk for obesity (Chapter 27). In addition, growth rates and body condition scores (BCS) provide valuable information about nutritional risks.

Besides being breed dependent, growth rates of young dogs are affected by the nutrient density of the food and the amount of food fed (Meyer and Zentek, 1992). Puppies should be fed to grow at an optimal rate for bone development and body condition rather than at a maximal rate. Growing animals reach a similar adult weight and size whether growth rate is rapid or slow. Feeding for maximum growth increases the risk for skeletal deformities (Hedhammar et al, 1974; Kealy et al, 1992) and decreases longevity in other species (Chipalkatti et al, 1983). In Labrador retrievers, even moderate overfeeding resulted in overweight adults and decreased longevity (Kealy et al, 2002).

The most practical indicator of whether or not a puppy's growth rate is healthy is its BCS. All puppies should have their body condition evaluated and reassessed at least every two weeks to allow for adjustments in amounts fed and, thus, growth rates (Chapter 1). Owners can be trained to assess body condition and are likely to become more aware of the appearance of a healthy growing puppy. A markedly less effective option is to compare the puppy's weight to breed standards for

Table 17-1. Key nutritional factors for foods for growing puppies.*

	Recommended levels in food (DM)	
Factors	Puppies with an adult BW <25 kg	Puppies with an adult BW >25 kg

Energy density (kJ ME/g)	14.6-18.8	14.6-18.8
Crude protein (%)	22-32	22-32
Crude fat (%)	10-25	10-25
DHA (%)	≥0.02	≥0.02
Calcium (%)	0.7-1.7	0.7-1.2
Phosphorus (%)	0.6-1.3	0.6-1.1
Ca:P ratio	1:1-1.8:1	1:1-1.5:1
Digestibility	See energy density recommendations, above; foods with higher energy density values tend to be more digestible	See energy density recommendations, above; foods with higher energy density values tend to be more digestible

Key: DM = dry matter, BW = body weight, kcal = kilocalories, kJ = kilojoules, ME = metabolizable energy, DHA = docosahexaenoic acid.
*For large- and giant-breed dogs (adult BW >25 kg), also see Table 33-5.

Table 17-2. Recommendations for initial estimate of energy intake of growing dogs.

Time frame	x RER	kcal/$BW_{kg}^{0.75}$	kJ/$BW_{kg}^{0.75}$
Weaning to 50% of adult BW*	3	210	880
50 to 80% of adult BW	2.5	175	735
≥80% of adult BW	1.8-2.0	125-140	525-585

Key: RER = resting energy requirement, kcal = kilocalories, kJ = kilojoules, BW = body weight. RER can be obtained from Table 5-2 or calculated. If calculating RER, use one of these two formulas: for puppies of all body weights, $RER_{kcal} = 70(BW_{kg}^{0.75})$; or for puppies weighing more than 2 kg, $RER_{kcal} = 30(BW_{kg}) + 70$. To convert kcal to kJ, multiply by 4.184.
*Great Dane puppies may need 25% more energy during the first two months after weaning = 250 kcal or 1,050 kJ/$BW_{kg}^{0.75}$. See text.

various months of age based on its estimated mature weight. Furthermore, regularly assessing body condition provides more immediate feedback about optimal nutritional status than using body weights based on estimated adult size.

Key Nutritional Factors

The requirements for all nutrients are increased during growth compared with requirements for adult dogs. Most nutrients supplied in excess of that needed for growth cause little to no harm. However, excess energy and calcium are of special concern; these concerns include energy for puppies of small and medium breeds (for obesity prevention) and energy and calcium for puppies of large and giant breeds (for skeletal health). Also, essential fatty acids can affect neural development and trainability of puppies.

Table 17-1 summarizes the key nutritional factors for growing puppies. The following sections describe these key nutritional factors in more detail. The concept of key nutritional factors is based on the assumption that commercial foods are fed.

Energy

Energy requirements for growing puppies consist of energy needed for maintenance and growth. During the first weeks after weaning when body weight is relatively small and the growth rate is high, puppies use about 50% of their total energy intake for maintenance and 50% for growth (Gesellshaft, 1989; Sheffy, 1978). Gradually, the growth curves reach a plateau, as puppies become young adults (**Figure 17-1**). The proportion of energy needed for maintenance increases progressively, whereas the part for growth decreases. Energy needed for growth decreases to about 8 to 10% of the total energy requirement when puppies reach 80% or more of adult body weight. Because of the shift in energy usage, total food intake of a typical German shepherd puppy (adult body weight ~35 kg), based on energy needs, may no longer increase after about four months of age.

A puppy's daily energy requirement (DER) should be about 3 x its resting energy requirement (RER) until it reaches about 50% of its adult body weight (**Table 17-2**). Thereafter, energy intake should be about 2.5 x RER and can be reduced progressively to 2 x RER. When approximately 80% of adult size is reached, 1.8 to 2 x RER is usually sufficient. Great Dane puppies may have energy requirements 25% higher than those of other breeds. Young Great Dane puppies may not grow when daily energy intake is less than 175 kcal (735 kJ) metabolizable energy (ME)/$BW_{kg}^{0.75}$ (2.5 x RER) (Meyer and Zentek, 1992; Meyer and Zentek, 1991). However, this finding should not be extrapolated to other giant-breed puppies (Rainbird and Kienzle, 1990). These factors are general recommendations or starting points to estimate energy needs. Body condition scoring should be used to adjust these energy estimates to individual puppies.

Prevention of obesity is essential and should start at weaning. As in people, after puppies become overweight, it is very difficult to return to, and maintain, normal weight. Excessive food intake during growth may contribute to skeletal disorders in large- and giant-breed puppies (Chapter 33) (Kealy et al, 1992). If overweight and obesity are carried into adulthood, the risk for several important diseases is increased (Chapter 27). These include hypertension, heart disease, diabetes mellitus, dyslipidemias, osteoarthritis, heat and exercise intolerance and decreased immune function. Obesity also increases cellular oxidative stress. Long-term oxidative stress has its own serious health implications (Chapter 7). Studies show that moderate energy and food restriction during the postweaning growth period reduces the prevalence of hip dysplasia in large-breed (Labrador retriever) puppies and increases longevity in rats without retarding adult size (Kealy et al, 1992; Chipalkatti et al, 1983; Nolen, 1972; Ross and Bras, 1973; Ross, 1972). However, feeding a food with a very low energy density and low digestibility may not supply enough energy and nutrients to support optimal growth. This

approach can lead to intake of large quantities of the food, which can overload the gastrointestinal (GI) tract resulting in vomiting and diarrhea. Together, these factors make for a prudent argument to initiate monitoring of energy and food intake and body condition at an early age. Recommended energy density requirements for growing dogs are listed under the key nutritional factor "Fat" below.

Protein

Protein requirements of growing dogs differ quantitatively and qualitatively from those of adults. Quantitatively, at this stage of growth, protein requirements are highest at weaning and decrease progressively (Meyer, 1990; Burns et al, 1982; Case and Czarnecki-Maulden, 1990). For example, the level of crude protein in bitch's milk is 33% dry matter (DM). Bitch's milk is a highly digestible food with an energy density of 6.4 kcal/g DM. This level is equivalent to 21% highly digestible protein in a commercial food with 4 kcal/g DM. In one study, beagle puppies needed a food with a minimum of 15% DM protein of high biologic value and 90% digestibility to achieve optimal growth immediately after weaning. Only 11.7% (DM) of the same high-quality protein was needed at three months of age (Burns et al, 1982).

For puppies 14 weeks and older, the minimum recommended allowance for crude protein is 17.5% DM (NRC, 2006). The recommended protein range in foods intended for growth in all puppies (small, medium and large breed) is 22 to 32% DM (**Table 17-1**). Most dry commercial foods marketed for puppy growth provide protein levels within this range.

Protein levels above the upper end of this range have not been shown to be detrimental but are well above the level in bitch's milk. Earlier work suggested that excessive protein intake might play a role in the development of skeletal deformities in giant-breed dogs (Hedhammar et al, 1974). Since then, it has been shown that foods containing 23 to 31% crude protein (6.4 to 8.8 g/100 kcal ME) do not have a deleterious effect on skeletal development. Furthermore, these levels support optimal growth, provided calcium and energy levels are appropriate (Nap et al, 1991; Nap, 1993). Most commercial foods for puppy growth contain more protein than is needed.

Protein requirements of growing dogs differ quantitatively and qualitatively from those of adults. An important difference is that arginine is an essential amino acid for puppies, whereas it is only conditionally essential for adult dogs (Young et al, 1978) (Arginine is present in ample amounts in essentially all pet foods and thus is not considered a key nutritional factor for commercial foods).

Foods formulated for adult dogs should not be fed to puppies. Although protein levels may be adequate, energy levels and other nutrients may not be balanced for growth.

Fat

Dietary fat serves three primary functions: 1) a source of essential fatty acids, 2) a carrier for fat-soluble vitamins and 3) a concentrated source of energy. Growing dogs have an estimated daily requirement for essential fatty acids (linoleic acid) of about 250 mg/kg body weight (Meyer, 1990b), which can be provided by a food containing between 5 to 10% DM fat (Meyer, 1990). The fat source must be carefully chosen when low-fat foods (<10% DM fat) are fed to ensure that sufficient amounts of linoleic acid are provided.

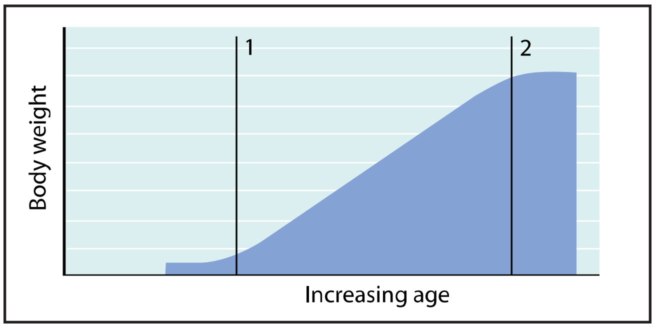

Figure 17-1. Typical sigmoidal growth curve of puppies. Growing puppies' energy needs may be subdivided into two components: the energy needed for maintenance and the energy required for accretion of body tissue. During the first weeks after weaning, when body weight is relatively small and growth rate exponential, puppies use about 50% of the energy for maintenance and 50% for growth. Gradually, the growth curve reaches a plateau. As body weight increases, the share of energy needed for maintenance increases progressively, whereas the part for growth becomes proportionately less important. The starting (line 1) and endpoint (line 2) of exponential growth can shift depending on the breed and individual variation. (See text and references.)

Studies indicate that docosahexaenoic acid (DHA) is essential for normal neural, retinal and auditory development in puppies (Pawlosky et al, 1997). Similar results have been found in other species (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003; Hoffman et al, 2003). Inclusion of fish oil as a source of DHA in puppy foods improves trainability (Kelley et al, 2004). Conversion of short-chain polyunsaturated fatty acids to DHA is an inefficient process in puppies (Bauer et al, 2006). Thus, adding a source of DHA should be considered essential for growth. The minimum recommended allowance for DHA plus eicosapentaenoic acid (EPA) is 0.05% DM; EPA should not exceed 60% of the total (NRC, 2006). Thus, DHA needs to be at least 40% of the total DHA plus EPA, or 0.02% DM.

Fat contributes greatly to the energy density of a food; however, excessive energy intake can cause overweight/obesity and developmental orthopedic disease, as discussed above. The minimum recommended allowance of dietary fat for growth (8.5% DM) is much less than that needed for nursing, but more than is needed for adult maintenance (5.5% DM) (NRC, 2006). To provide a DM energy density between 3.5 to 4.5 kcal/g, between 10 and 25% DM fat is required; this range of dietary fat is recommended from postweaning to adulthood.

Calcium and Phosphorus

Although growing dogs need more calcium and phosphorus than adult dogs, the minimum requirements are relatively low. Puppies have been successfully raised when fed foods contain-

Table 17-3. Feeding plan summary for growing puppies.

1. Estimate adult body weight for determination of the recommended calcium range (>25 kg adult weight, use large-/giant-breed recommendation).
2. Using **Table 17-4** (or manufacturer's information), select a food with the recommended levels of key nutritional factors; ensure the selected food has been approved for puppy growth by a credible regulatory agency (e.g., AAFCO).
3. Avoid free-choice feeding; use food-restricted meal feeding, dividing the amount fed into two to four daily feedings.
4. Estimate the initial amount to feed from recommendations on product package or by calculation (**Table 17-5**). Remember, such recommendations and calculations should be used as guidelines or starting points and not as absolute requirements.
5. Teach owners to perform body condition scoring and have them monitor body condition at least every two weeks and adjust the amount fed by 10% increments to maintain a BCS of 2.5/5 to 3/5.
6. Veterinarians should assess body condition and weight of puppies in conjunction with routine vaccinations and more frequently if any indication of under- or overnutrition is detected. The feeding plan, including food dosage, should be modified as necessary.
7. Underfeeding through the growth phase is healthier than overfeeding and results in the same mature size.

Key: AAFCO = Association of American Feed Control Officials, BCS = body condition score.

Box 17-1. Digestible Carbohydrates in Foods for Growing Puppies.

No specific recommendations for digestible (soluble) carbohydrate levels are available for growing dogs. It has been suggested that foods contain about 20% digestible carbohydrate until puppies are four months of age to ensure optimal health. In one study, feeding young puppies a food high in protein and fat without carbohydrate resulted in lethargy, poor appetite, diarrhea and mortality, which were attributed to fatty liver syndrome. However, another study failed to confirm these results. Body fat is higher when puppies are fed a very high-fat, low-carbohydrate food during growth.

The Bibliography for **Box 17-1** can be found at www.markmorris.org.

ing 0.37 to 0.6% DM calcium and 0.33% DM phosphorus (Jenkins and Phillips, 1960; Jenkins and Phillips, 1960a). Intestinal absorption of calcium can vary from almost 0 to 90% (Hazewinkel, 1985; Nap, 1993), and phosphorus absorption can increase to almost 80% to adapt to intake (Gesellshaft, 1989a; Jenkins and Phillips, 1960). Generally, calcium absorption depends on requirements and calcium intake (Meyer, 1990a). Calcium homeostatic mechanisms may be less precise in young puppies. In puppies between two and six months of age, intestinal absorption of calcium never decreases below approximately 40%, even if they receive high levels of calcium in foods (Hazewinkel, 1985; Hedhammar et al, 1974; Nap, 1993; Jenkins and Phillips, 1960). Retention of calcium, therefore, increases when young dogs receive high levels of calcium, either in the food or as a supplement (Hazewinkel, 1985; Nap, 1993). Absorption of calcium gradually is more regulated after puppies are about 10 months old (Hedhammar et al, 1974).

Foods for large- and giant-breed puppies should contain 0.7 to 1.2% DM calcium (0.6 to 1.1% phosphorus) (Chapter 33). Foods with a calcium content of 1.1% DM provide more calcium to puppies just after weaning than if bitch's milk is fed exclusively (Resnick, 1978). Because small- to medium-sized breeds are less sensitive to slightly overfeeding or underfeeding calcium (Nap, 1993), the level of calcium in foods for these puppies can range from 0.7 to 1.7% DM, (0.6 to 1.3% phosphorus) without risk. The phosphorus intake is less critical than the calcium intake, provided the minimum requirements of 0.35% DM are met and the calcium-phosphorus ratio is between 1:1 and 1.8:1 (Jenkins and Phillips, 1960; Jenkins and Phillips, 1960a). For large- and giant-breed dogs, the calcium-phosphorus ratio should be between 1:1 and 1.5:1.

Digestibility

The ability of 11-week-old puppies to digest foods was less than at 60 weeks of age (Weber et al, 2003). Also, puppies fed foods low in energy density and digestibility need to eat larger quantities of food to achieve growth, increasing the risk of flatulence, vomiting, diarrhea and the development of a "pot-bellied" appearance. Therefore, foods recommended for puppies should be more digestible than typical adult foods. Most pet food companies, however, do not provide digestibility data. An indirect indicator of digestibility is energy density. Foods with a higher energy density are likely to be more digestible.

Other Nutritional Factors

Copper

Most commercial pet foods should contain adequate levels of copper unless the availability is low (e.g., when sources such as copper oxide are used) (Aoyagi and Baker, 1993). Puppies with copper deficiency may have loss of hair pigmentation, with graying of black and dark brown hair (Zentek, 1991; Zentek et al, 1991). Hyperextension of the distal phalanges and splayed toes on the front feet and normochromic, normocytic anemia may develop in more extreme cases (Zentek, 1991; Zentek et al, 1991). The recommended minimum allowance for copper in growing puppies is 1.1% DM (NRC, 2006).

Phenylalanine and Tyrosine

Tyrosine is not an essential amino acid but is made from phenylalanine. Also, tyrosine spares about half of the need for phenylalanine. Therefore, it is appropriate to consider the amount of phenylalanine required as the sum of phenylalanine plus tyrosine. Although phenylalanine and tyrosine have not been shown to be the most limiting amino acids for growth in commercial food, at least twice as much phenylalanine, or phenylalanine plus tyrosine, is required for maximal black hair color as for growth (Biourge and Sergheraert, 2002). Other metabolic needs for phenylalanine and tyrosine include protein, thyroid hormone and catecholamine synthe-

sis (NRC, 2006). The recommended minimum allowance for phenylalanine plus tyrosine in foods for puppy growth is 1.0% DM.

Carbohydrates

Although no specific level of digestible (soluble) carbohydrates exists for growing puppies, inclusion of about 20% (DM) may optimize health (**Box 17-1**).

FEEDING PLAN

The feeding plan consists of choosing the best food and the best feeding method. Reassessment at appropriate intervals is another key to a successful feeding plan. **Table 17-3** summarizes the feeding plan.

Assess and Select the Food

The food assessment phase will help determine the best food to feed or whether it is necessary to change foods if a food has already been selected. If a change is indicated, select a food that has been approved by a credible regulatory agency such as the Association of American Feed Control Officials (AAFCO). However, AAFCO feeding trials only last 10 weeks. During this time, potential problems related to excess calcium and energy consumption, especially in large- and giant-breed puppies may not have had time to manifest. Therefore, foods selected for growth should have key nutrients in the ranges provided in **Table 17-1.**

If the appropriate food was selected for reproduction, puppies of small- to medium-sized breeds (<25 kg anticipated adult weight) may continue to receive the same food as the bitch received during lactation. These puppies were probably transitioned to this food during weaning. Large- and giant-breed puppies should be fed a food that contains less calcium and energy to decrease the risk of developmental orthopedic disease. If possible, such foods should be fed during early weaning. Chapter 33 contains more detailed information about feeding large- and giant-breed puppies. The greatest nutritional influence on the incidence of phenotypic hip dysplasia occurs when energy is restricted very early in life (Lust et al, 1973).

Besides selecting an AAFCO (or a food approved by another credible organization) approved food, the food assessment/selection process includes comparing the nutrient profile of the current food, or the food under consideration, with the key nutritional factors in the amounts discussed above. **Table 17-4** lists levels of key nutritional factors in selected commercial foods marketed for healthy puppy growth and compares them to the recommended levels. If the food in question is not listed in **Table 17-4**, contact pet food manufacturers for this or other missing information. The guaranteed or typical analysis on pet food labels is of limited use and will not contain information about digestibility. Information about digestibility and energy density should be obtained from the manufacturer; digestibility must be sufficiently high to avoid GI problems. Also, foods with similar label declarations can have markedly different nutrient availabilities and growth performance (Huber et al, 1986; Huber et al, 1991).

Growing dogs should not receive vitamin-mineral supplements when fed complete, balanced commercial foods. Supplements may be justified to balance homemade foods. Because it is very difficult for breeders to exactly balance a homemade food, large- and giant-breed puppies should only receive a commercially prepared food specifically designed for such breeds. If an owner insists on using homemade foods, it is best to consult with a qualified veterinary nutritionist to ensure a homemade recipe is balanced (Chapter 10).

The calcium and energy content of treats should be similar to that recommended for the food (**Table 17-4**). If not, the number of treats fed should be limited to no more than 10% of the total amount of food fed. Treats given in large amounts may almost double a puppy's calcium intake (Box 33-5). Most treats are not complete and balanced for puppy growth. Check the product label for this information.

Assess and Determine the Feeding Method

Feeding method assessment is critical to successful management of growing puppies, especially those of large and giant breeds. The feeding method includes how much food is fed and how it is offered. Food can be offered three ways: free choice, time-restricted meal feeding and food-restricted meal feeding. Free-choice and time-restricted feeding should be avoided during rapid growth.

Free-choice feeding may increase body fat, predispose the dog to obesity and, in large breeds, induce skeletal deformities at a young age. Breeders who want to maximize growth of large- and giant-breed puppies should be informed that overfeeding predisposes to developmental orthopedic disease. Even under these circumstances, rate of weight gain and body condition should be monitored closely (at least every two weeks).

Previously, time-restricted meal feeding was recommended (feeding a puppy all it can eat in 20 minutes, twice daily) (Lewis et al, 1987). However, more recent research showed that puppies fed using this method had increased body weight, more body fat and increased bone mineral accretion than puppies receiving the same food free choice (Toll et al, 1993).

During periods of rapid growth, puppies should be fed a measured amount of food (food-restricted meal feeding) every day based on body condition and age. The allotted amount of food can be offered in one or two meals per day. This recommendation includes thin puppies owned by clients who are tempted to feed more food so their puppies can "catch up."

Feeding puppies an allotted amount of food is best for most puppies because it allows for better control of body condition and rate of growth. Using this feeding method for growing puppies is complicated because the amount fed per unit body weight needs to be adjusted regularly. Initially the amount fed needs to be greater per unit body weight and then is reduced as the growth rate and energy requirements per unit body weight decline (**Figure 17-1** and **Table 17-2**). Also, the initial amount fed needs to be determined.

The initial daily food dose can be estimated by dividing the puppy's DER by the energy density of the food. From a practi-

Table 17-4. Comparison of recommended levels of key nutritional factors for small- to medium-breed puppies (adult BW <25 kg) to the key nutritional factor content of selected commercial foods marketed for healthy puppy growth.* For large- to giant-breed puppies (>25 kg), see foods and recommended levels in Table 33-6.

Key: BW = body weight, ME = metabolizable energy, DHA = docosahexaenoic acid, Ca = calcium, P = phosphorus, na = not available from manufacturer.
*From manufacturers' published information or calculated from manufacturers' published as-fed values; all values are on a dry matter basis unless otherwise stated.
**Energy density values are listed on an as fed basis and are useful for determining the amount to feed; cup = 8-oz. measuring cup.
***Energy density also reflects digestibility; foods with higher energy density are likely to have better digestibility than foods with lower energy density; for kJ/g, multiply kcal/g by 4.184.

cal standpoint, the energy requirement can be estimated but not determined precisely. Estimates of a puppy's DER can be obtained from **Table 17-2** (i.e., this phase of growth can be divided into three periods). The DER can also be calculated. DER calculations are simple and are based on the puppy's RER; **Table 17-2** lists RER factors. RER can be calculated (**Table 17-5**) or obtained directly from Table 5-2 or the food manufacturer.

The initial daily food dose estimate is merely a starting point. Body condition scoring (Figure 1-2) should be used to adjust the food dose estimate to individual puppies and will need to be readjusted regularly (10% increments) to allow for changes in growth rate. This amount can be fed in two to four meals per day. Note that Great Dane puppies may have energy requirements 25% higher than those of other breeds. As mentioned above, young Great Dane puppies may not grow when daily energy intake is less than 175 kcal (735 kJ) ME/$BW_{kg}^{0.75}$ (2.5 x RER) (Meyer and Zentek, 1992; Meyer and Zentek, 1991).

However, this finding should not be extrapolated to other giant-breed puppies (Rainbird and Kienzle, 1990).

REASSESSMENT

Owners should weigh growing puppies weekly and record body weights and food intake (including snacks and treats). Veterinarians, or members of their health care team, can instruct owners about how to BCS their own puppies. A BCS should be obtained at least every two weeks. During office calls for routine vaccinations, veterinarians can compare the owners' scores with their own. This level of attention to BCS can be important to the development of a healthy puppy. The owner is then prepared to continue to make these observations throughout the life of the dog. Such dogs, as adults, should be less likely to experience skeletal diseases (large and giant breeds) and overweight or obesity and the myriad of related problems (most breeds).

Veterinarians should reassess puppies at the time of routine vaccinations and more frequently if any indication of under- or overnutrition is detected. Reassessment should include body weight and body condition assessment, food assessment and determination of correct food dosage (**Table 17-5**).

Table 17-5. Example of a food dosage calculation for a growing puppy.

Problem: what is the estimated amount of a growth food (375 kcal/cup) that should be fed to a five-month-old male Labrador retriever puppy weighing 18 kg?

1) Determine RER by using the linear formula: RER_{kcal} = 30(BWkg) + 70; RER_{kcal} = 30(18) + 70 = 610 kcal/day or from Table 5-2.
2) Determine DER by using the RER factors in **Table 17-2**, based on age: 2.5 x RER = 2.5 x 610 kcal = 1,525 kcal/day.
3) Divide the DER by the energy density of the food (**Table 17-4**), to obtain the estimated daily amount to feed: 1,525 kcal ÷ 375 kcal/cup = 4 cups/day.
4) Divide the daily amount to feed into two to four individual meals.
5) This amount is only an estimate and is intended to be used as a starting point. The puppy's body condition should be monitored regularly (at least every two weeks) and the amount fed should be increased or decreased by 10%, depending on body condition score.

Key: cup = 8 volume oz. measuring cup (240 cc), RER = resting energy requirement, DER = daily energy requirement.

CASE 17-1

Initial Health Care for a Welsh Corgi Puppy

Jacques Debraekeleer, DVM
Hill's Science and Technology Center
Etten Leur, The Netherlands

Kathy L. Gross, PhD
Hill's Science and Technology Center
Topeka, Kansas, USA

Patient Assessment

A 10-week-old, female Welsh corgi puppy was examined as part of a routine health maintenance program. The owners had recently purchased the puppy from a local breeder and had never owned a dog before. They were interested in vaccinations and any other information about caring for puppies. They had had the puppy for two days and indicated that everything appeared normal.

Physical examination revealed an alert and active puppy with no obvious problems. The puppy weighed 6.5 kg and had a normal body condition (body condition score [BCS] 3/5). The estimated adult weight was about 17 kg. Results of a fecal flotation test were negative for intestinal parasites. Routine vaccinations were given.

Assess the Food and Feeding Method

The breeder provided a small amount of an unknown dry food in a plastic bag. The owners had offered small amounts of this food three times per day, and the puppy ate the food very well. They were also given a bottle of chewable vitamin-mineral tablets by the breeder and instructed to give the puppy one tablet per day.

Questions

1. What are the key nutritional factors to consider in developing a feeding plan for this puppy?
2. Outline a specific feeding plan for this patient including an appropriate food and feeding method.
3. Should the owners continue to provide the chewable vitamin-mineral supplement?

4. Besides nutrition, what other health care topics for puppies should be discussed with these owners?

Answers and Discussion

1. Key nutritional factors for growing dogs include energy, protein, fat, calcium, phosphorus and digestibility. Energy is required to support rapid accretion of new tissue; however, excessive energy intake increases the risk of obesity and, in some breeds, developmental orthopedic disease. Foods for puppies should contain 3.5 to 4.5 kcal (14.6 to 18.8 kJ) metabolizable energy (ME)/g dry matter (DM). Fat makes the greatest contribution to the energy density of food and should be 10 to 25% DM in growth-type foods. Puppies also have higher protein requirements than adult dogs to support tissue growth. Protein levels of 22 to 32% DM are recommended for puppies. Adequate calcium is important in foods for growing dogs to support skeletal development. Known calcium deficiency is rarely a concern in growing dogs fed commercial foods, but it may be a problem for dogs fed homemade foods. Excess calcium intake is a risk factor for developmental orthopedic disease and may occur in growing dogs eating some commercial foods and/or receiving mineral supplements. Calcium levels of 0.7 to 1.7% DM are generally recommended for growing dogs. Phosphorus is less critical than calcium provided minimum requirements of 0.35% DM are met and the calcium-phosphorus ratio is between 1:1 and 1.8:1. No specific recommendations for dietary carbohydrate are available for growing dogs; however, puppies appear to do better if growth-type foods contain more than 20% complex carbohydrate DM. Gastrointestinal (GI) distention ("pot-bellied" appearance) and GI disturbances (i.e., flatulence, vomiting, diarrhea) are less common in puppies fed highly digestible foods.
2. A food specifically formulated for growing dogs that addresses the key nutritional factors described above should be recommended. A number of commercial products meet these objectives. Homemade foods can also be fed to growing dogs; however, recipes should be used that contain adequate protein, fat, calcium, vitamins and trace minerals to support growth.Feeding methods for growing dogs include free-choice (ad libitum) feeding, time-limited feeding and food-limited feeding. Free-choice feeding is relatively effortless and may reduce abnormal behavior such as barking at feeding time. In addition, frequent trips to the food bowl may help reduce boredom and coprophagy, and timid or unthrifty dogs experience less competition when eating. Disadvantages of free-choice feeding include food wastage, only dry or semi-moist forms of pet food can be fed and competition or boredom may stimulate overeating. The most serious disadvantage in young growing dogs is increased risk for obesity and developmental orthopedic disease due to over consumption of even a properly balanced food.

   Time-limited feeding is a method in which dogs are allowed free access to food for a defined period, usually 10 to 15 minutes, once or twice daily. This feeding method may result in less overall food consumption when compared with puppies fed free choice. Time-limited feeding may also help in disciplining and housetraining young puppies. The owner interacts with the puppy during this time and is able to observe its general condition and behavior, which may lead to earlier detection of problems. A routine of feeding a puppy and then taking it outdoors can reinforce housetraining by taking advantage of the gastrocolic reflex. Advocates of this feeding method suggest that when some dogs fed in this manner reach adulthood they may voluntarily limit their feeding to once or twice a day and thus avoid overeating. However, research has shown that some dogs may eat as much in 15 minutes as when fed free choice. In this study, dogs fed by a time-limited method had higher weight gain, more body fat and increased bone mineral accretion than dogs receiving the same food free choice. This method is also less convenient for the owner than free-choice feeding.

   Food-limited feeding (feeding a measured amount of food every day) requires knowing how much to feed. This is best obtained by estimating the amount to feed based on the puppy's calculated daily energy requirement or as recommended by the manufacturer, and then adjusting the amount as necessary to maintain a BCS between 2.5/5 to 3.5/5. This amount is divided into two to four meals per day. This is the method of choice for feeding all puppies to reduce the risk of obesity and developmental orthopedic disease because it limits food intake to maintain optimal growth rate and body condition. This method is also less convenient and more time consuming than free-choice feeding because food amounts must be increased as growth occurs.
3. Routine vitamin-mineral supplementation is not necessary for healthy puppies eating balanced commercial growth foods. Supplementation is important if homemade foods are used.
4. In addition to vaccination, intestinal parasite control and nutritional counseling, the following health maintenance procedures should be discussed with puppy owners: 1) external parasites and appropriate control programs, 2) heartworm preventive programs, in endemic areas, 3) the pet's behavior and socialization, 4) specific breed characteristics, 5) routine grooming procedures, 6) basic obedience training and reputable obedience schools, 7) recommendations for neutering, 8) housetraining and 9) manipulation of the mouth to accustom the puppy to toothbrushing later on. All of these topics should be discussed with these clients, especially because they are novice dog owners.

Progress Notes

All of the health maintenance procedures mentioned above were discussed with the owners by the veterinarian or veterinary technician. A commercial specialty brand dry food formulated for canine growth (Science Diet Puppy Healthy Development Original[a]) was recommended. The quantity of food to be fed was based on the feeding instructions on the pet food bag. This amount was divided into three equal daily meals. The owners were instructed to discontinue the vitamin-mineral supplement and were given an

instruction sheet that outlined how to assess the body condition of puppies. The food amount was to be adjusted as the puppy grew according to the feeding guidelines on the bag. The owners were asked to weigh and assign a BCS for the puppy every other week and adjust the food amount as needed to maintain optimal body condition. The veterinary technician would also assess the body weight and condition during subsequent office visits when the puppy was 14 to 16 and 20 to 22 weeks of age.

**To convert to kJ, multiply kcal x 4.184.

bic metabolism and accumulation of lactate in the blood.

The important points from the above discussion are: 1) exercise increases metabolism and therefore increases the need for energy, 2) cardiovascular function increases and fluid shifts/losses occur during exercise-adequate water intake is important to support these needs and 3) transient changes also occur in the composition of blood that can influence the interpretation of results from blood samples drawn soon after exercise.

Energy Cost of Running

The energy cost of running depends on body size and distance traveled. **Table 18-6** shows the caloric cost of running 1 km for dogs of various sizes. This table also illustrates an important principle about the mass-specific caloric cost of running as size changes. As body size increases, the efficiency of running increases (i.e., larger animals use fewer kcal/kg to run the same distance). By using the data in **Table 18-6**, it is possible to estimate the energy requirement for a dog of a known size to run a given distance (**Box 18-5**).

PATIENT ASSESSMENT

History

In addition to the normal historical information that is usually obtained about a patient, the following information should be gathered from owners: environmental/housing data, medications, dietary history and exercise type, amount, frequency and performance. Detailed information should be gathered about how the dog is housed, including: indoors or outdoors, size and type of housing, opportunity for spontaneous exercise, type of surfaces, number of dogs housed together and access to food and water. All medications used should be recorded, including drugs used to suppress estrus and drugs used to enhance performance.

The dietary history should include all foods and supplements used. The amount fed, nutrient profile and timing of feeding in relation to exercise should be noted. The amount eaten should also be assessed (i.e., Does the dog have a normal appetite and is it actually consuming a reasonable amount?). In some cases, the composition of the overall diet (food plus supplements) may be complex and individual meals may vary in composition. It is also important to ascertain the duration of a particular feeding plan. Abrupt or frequent changes in food or feeding method may affect performance.

Exercise Type

Functionally, exercise can be divided into three types (**Table 18-1**) based on intensity and duration: 1) sprint-high-intensity physical activity that can be sustained less than two minutes, 2) intermediate-physical activity lasting a few minutes to a few hours and 3) endurance-physical activity that lasts many hours. These definitions are arbitrary and vague, but are useful for assessing and developing feeding plans.

Most canine sprinters are sight hounds, racing greyhounds being the most notable example. Metabolically, weight-pull dogs might also fit into this category. Some racing sled dogs that participate in shorter, high-speed events are referred to as "sprinters." However, they fit better in the intermediate or endurance categories from a metabolic and nutritional standpoint because their events may last several hours. Other breeds that engage in activities such as agility, fly ball and lure coursing also do considerable sprinting. However, because they compete multiple times per day, they too fit better in the intermediate category.

Based on energy needs, most canine athletes participate in intermediate exercise activities. Most of these activities are of low to moderate intensity and last only a few hours. Intensity and duration of exercise vary widely within this category. For example, most guide dogs work at a low level of physical exertion for variable lengths of time throughout the day, whereas a search and rescue dog may work at a much higher level for many consecutive hours. Other dogs at the upper end of the intermediate exercise range can include foxhounds, coonhounds and other hunting dogs in the field. At times, they work at levels that are near the lower end of the energy requirement range for endurance dogs. Dogs that work at a relatively high intensity level for many hours, such as racing sled dogs, have much greater energy requirements and are true endurance athletes.

Exercise amount can be quantified as hours per day or week. Frequency is how often the animal exercises: daily, weekly, weekends only or seasonally. Many hunting dogs only work hard on weekends during hunting season, whereas some livestock dogs may work several hours daily. Canine athletes should be categorized as either "full-time" or "part-time" athletes.

Environmental Influences on Exercise

Ambient temperature and humidity, psychological stress and geography are environmental factors that may influence performance and nutritional needs of working and sporting dogs. Of these, ambient temperature and humidity exert the greatest effect. Hot temperatures result in increased work and water loss (i.e., to excrete metabolic heat and maintain body temperature

Box 18-5. The Energy Cost of Running.

Daily energy requirement (DER) for canine athletes is highly variable and is directly related to the amount of work done in a day. Work for canine athletes is usually running. A racing greyhound that usually only runs a fraction of a mile in a race has a DER very similar to that of a house pet (1.6 to 1.8 x resting energy requirement [RER]). At the other extreme is the sled dog that runs many miles a day pulling a load and has a very high DER (up to 11 x RER). Understanding the energy cost of running and being able to quantify it in kcal is central to the correct feeding of canine athletes.

The following discussion and calculations are based on experimental data and on running on a flat surface. However, these data show good agreement with data from food consumption records. These calculations are essential for assessing feeding methods (food dose) and making feeding recommendations for canine athletes.

RUNNING

Running is the predominant type of work done by canine athletes. Force generation in the muscle is transmitted through the skeleton to move the dog's mass through a distance. The physics and biomechanics of running are complicated and are described elsewhere. The rate of energy use (power) is proportional to running speed. However, the amount of energy used to cover a given distance is independent of velocity. For running on a flat surface, energy use is a function of body size and distance. One study described the effect of size on the energy cost of running for a variety of mammals; the study used an equation to relate VO_2 to velocity and body weight. The following equation, which was derived from the research equation, relates the energy cost of running to body weight and distance, assuming an energy yield of 4.8 kcal (20.1 kJ)/l of oxygen consumed.

$ERR = 1.77d \times BW^{-0.40} + 1.25BW^{-0.25}$

Where ERR is the energy requirement for running in kcal/kg, d is distance in km, and BW is body weight in kg. Larger animals have a biomechanical advantage resulting in greater efficiency of running and lower mass specific cost of running (kcal/kg) for a given distance. The negative exponents in the equation make calculations difficult. Therefore, **Table 18-6** summarizes the caloric cost of running for dogs of various sizes.

RUNNING WITH WEIGHTS

The caloric cost of running with weights is the sum of the cost of running without added weight and the incremental cost of carrying that weight. When carrying added weight, VO_2 increases the same percentage as gross weight. In other words, the percentage increase in the cost of running is equal to the percentage increase in gross weight. This is not the same as simply increasing the dog's size. Efficiency of running changes with body size whereas simply adding weight increases workload without affecting efficiency (increased gross weight with no change in body size). The total cost of running (ERR_{tot}) is calculated by adding the cost of running (ERR) and the incremental cost of running with added weight (ERR_{incr}). The incremental cost of running is the product of ERR and the percent increase in gross weight.

ERR_{incr} = ERR x % increase in gross weight
ERR_{tot} = ERR + ERR_{incr} or
ERR_{tot} = ERR x gross weight ÷ body weight

Clinical Example

What is the caloric requirement of 30-kg dog carrying a 3-kg pack on a 15-mile (25-km) hike with its owner? The energy requirement of running for a 30-kg dog is 30 kcal/km (**Table 18-6**) or 750 kcal for 25 km. The incremental energy required for carrying the 3-kg pack is 750 kcal x 3 kg ÷ 30 kg or 75 kcal. The total energy required for exercise is 750 kcal + 75 kcal or 825 kcal. The DER for an average dog this size is 1.6 x RER or 1,435 kcal/day. With the added activity of carrying extra weight, the DER becomes 2,260 kcal/day (2.5 x RER). To convert to kJ, multiply kcal x 4.184.

PULLING WEIGHT

The kinematics of running and center of mass seem to be unaffected with added weight, at least up to 30% of body weight (i.e., the biomechanics do not change with added weight). This finding is unlikely to be true for dogs pulling weight such as sleds. However, it seems reasonable to assume that the cost of pulling a weight on a flat surface is similar to that of carrying the same weight. When applied to sled dogs, the calculations used above agree well with food record data. The incremental cost of running for a sled dog is based on the fraction of sled weight pulled by that dog.

Clinical Example

What is the caloric requirement for a 25-kg racing-sled dog that runs 167 km (100 miles) per day pulling a sled and driver with a combined weight of 180 kg in a team of 12 dogs? The cost of running (ERR) for this 25-kg dog is 4,342 kcal, based on an efficiency of a 25-kg dog of 26 kcal/km (**Table 18-6**) and a distance of 167 km. Assuming all dogs pull equally, the weight pulled by this dog is 15 kg (total sled weight ÷ number of dogs) or 60% of the dog's body weight. The incremental cost of running (ERR_{incr}) is 60% of ERR or 2,605 kcal. The total cost of running (ERR_{tot}) for this dog is 6,947 kcal. Note that RER for a 25-kg dog is 783 kcal (3.28 MJ). The energy needed for exercise is almost 9 x RER. The DER for this dog is 10 x RER, assuming no additional energy is needed for thermogenesis. To convert to kJ, multiply kcal x 4.184.

Table 18-7. Disorders affecting olfaction in people.*

Disorder	Effect on olfaction
Adrenal cortical insufficiency	Increased detection
Allergic rhinitis	Absent or diminished
Bronchial asthma	Absent or diminished
Chronic kidney failure	Absent or diminished
Cobalamin deficiency	Absent or diminished
Cushing's syndrome	Absent or diminished
Diabetes mellitus	Absent or diminished
Head trauma	Absent or diminished
Hepatic cirrhosis	Absent or diminished
Hypothyroidism	Absent, diminished or distorted
Nasal polyposis	Absent or diminished
Upper respiratory infections	Absent, diminished or distorted
Viral hepatitis (acute)	Absent, diminished or distorted

*Many of these diseases would also be expected to cause similar problems in dogs. Adapted from: Schiffman SS. Taste and smell in disease. New England Journal of Medicine 1983; 308: 1275-1279.

Table 18-8. Drugs that can cause changes in the sense of smell in dogs and people.*

Drug	Effect on olfaction
Amiodarone	Abnormal sense of smell reported in 1 to 3% of human patients
Amlodipine	Disturbance of smell reported rarely in human patients; resolves after drug withdrawal
Bromocriptine	Olfactory hallucination in 9% of human patients receiving 0.5 to 5 mg/day
Cimetidine	Decrease in olfactory acuity in human patients; reported rarely
Dexamethasone	Reduced olfactory acuity in dogs after only one week
Doxycycline	Loss or distortion of sense of smell in a small number of human patients
Nifedipine	Disturbance of sense of smell in human patients; rare and symptoms resolve after drug withdrawal
Phenylephrine	Decreased ability to smell in 1% of human patients

homeostasis). High humidity impairs evaporative cooling thus adding to the work of heat excretion. Cold temperatures without exercise increase the energy requirement for thermogenesis. For working dogs, cold environmental temperatures aid in heat dissipation during exercise. Excitement or stress associated with some activities increases body temperature and respiration, leading to greater requirements for energy, water and perhaps electrolytes. Stress may also negatively affect food intake. Geographic factors such as high elevation, changing elevation (running up and down hills), bodies of water (swimming) and the presence of sand or tall grass underfoot can increase workload. These factors are important to consider for their potential effects on exercise and olfactory performance. Dogs that are out of breath and are panting excessively have reduced ability to detect scent (Gazit and Terkel, 2002).

Physical Examination

During the physical examination, the veterinarian should evaluate the dog's general health, musculoskeletal soundness, hydration, upper respiratory function, cardiopulmonary function and body condition. A complete physical examination is crucial because disease affecting any body system can impair performance. For example, severe periodontal disease can cause sufficient pain to affect food intake, thus causing a retriever to retrieve poorly or a greyhound to run poorly. Likewise any injury or deterioration of the musculoskeletal system affects performance. All major muscle groups and joints should be palpated and moved through a complete range of motion during the routine physical examination of canine athletes.

Certain infectious, traumatic, endocrine and metabolic diseases can affect olfaction. **Table 18-7** summarizes diseases that modify olfaction in people. Many of these diseases would be expected to cause similar problems in dogs. For example, viral upper respiratory infections (e.g., canine distemper), including intranasal inoculation with modified-live virus distemper vaccine will cause dysosmia (Myers, 1990). In a survey of field trial participants requesting information about the prevalence of anosmia in their hunting dogs, 85% of owners reported that they currently owned or had owned a dog with some loss of its sense of smell (Holloway, 1961). In another report, only 40% of canine patients presenting with complaints of dysosmia actually had dysosmia. In the remaining 60%, other disorders were interfering with the dogs' ability to hunt, including one dog with hip dysplasia (Myers, 1990).

Drugs can also negatively affect olfaction (**Table 18-8**). For example, corticosteroids reduce olfaction in dogs. The combination of hydrocortisone plus desoxycorticosterone acetate resulted in a reduction of olfactory acuity after 18 days of administration. Dexamethasone administration reduced olfactory acuity in dogs after only one week (Ezeh et al, 1992). These results are not surprising because Cushing's disease results in reduced olfactory acuity and adrenal cortical insufficiency results in increased olfaction (**Table 18-7**). Many hunting dogs receive corticosteroid therapy for skin or musculoskeletal disorders. On the other hand, zinc supplementation is effective in some olfactory disorders (Henkin et al, 1999). In lieu of zinc deficiency, supplemental zinc is not warranted and could be toxic when given at high levels (NRC, 2006).

Cardiopulmonary function is best assessed during routine physical examination by thorough auscultation of the heart and lung fields in a quiet environment. Energy balance can be evaluated by body condition scoring. The body condition score (BCS) is an indication of fat mass. If dietary energy intake is less than energy needs, fat mass declines and BCS decreases. Conversely, if intake exceeds requirement, fat mass and BCS increase. Chapter 1 describes body condition scoring in detail. A BCS of 2.5/5 to 3.5/5 is normal for most pets and for many canine athletes. However, a much leaner body composition is

desirable for some canine athletes (e.g., racing greyhounds and sled dogs). Even small excesses of body fat may represent an unnecessary handicap for racing dogs.

The ability of any athlete to excel at a given event depends on that athlete's physical and metabolic characteristics, level of training and drive or desire. Some dogs are not well suited to some activities. Greyhounds make poor sled dogs and sled dogs make poor retrievers. Assessing how well an individual is suited to a particular type of exercise is partly common sense and partly experience; the fine points may take years of careful observation.

It is possible, however, to make some generalizations about characteristics that favor athletic performance. Sprinters tend to be very lean and fine-boned. A study comparing racing greyhounds to other breeds of dogs noted that as a percent of total body mass, greyhounds have more muscle (58% of body mass), the same amount of bone and less fat than other breeds (Gunn, 1978). Maximal muscle mass with no extra weight in the form of fat or excess bone is an obvious advantage for a sprinter. These characteristics benefit greyhounds in oval track racing. Different body types allow other breeds to perform well in various sprint sports. The smaller body of whippets allows for higher performance in the tight turns of lure coursing fields. The body conformation of Border collies allows for high levels of performance in agility competition and herding livestock. Endurance athletes may require more body fat to meet energy needs during long trips.

Laboratory and Other Clinical Information

Laboratory tests are not usually required for the routine assessment of healthy dogs. However, a few factors should be kept in mind when performing laboratory tests. Laboratory tests should address the two major factors of activity or work: anticipation to work and work itself. Anticipation to perform transiently affects the metabolism of dogs bred and trained for specific activities. Exercise can cause transient changes in blood and serum parameters. Concentrations of blood-borne substrates such as glucose and fatty acids may increase or decrease in relation to exercise. Total protein and electrolyte concentrations may increase simply due to fluid shift. As discussed above, contraction of the spleen and fluid shifts may dramatically increase packed cell volume. Lactate may accumulate in the plasma and blood pH may decrease with very intense exercise.

Excitement and conditioning of dogs bred and trained for working and sporting activities produce metabolic states that need to be addressed when performing nutritional studies (Gillette et al, 2006). Anticipation can initiate metabolic changes that result in exercise-related disease processes. An example is exercise-induced collapse in Labrador retrievers, a two-part problem in which event anticipation leads to medical problems.

Changes related to normal exercise physiology may be present to variable degrees up to two hours following exercise. Persistence of these changes may indicate a problem and should be investigated further. Small, persistent increases in concentration of the muscle isoenzyme of creatine phosphokinase (CPK) may occur in response to continuous exercise training. However, grossly elevated values indicate major muscle injury or rhabdomyolysis.

Key Nutritional Factors

The key nutritional factors for foods for working and sporting dogs are summarized in **Table 18-9**. The following section discusses the bases for these key nutritional factors and their recommended levels in foods.

Water

Water is arguably the most essential of all nutrients. It is the solvent for nearly all biologic solutes and a transport medium for nutrients, wastes and heat. Water also absorbs physical shock and lubricates various internal and external body surfaces. Approximately two-thirds of the body's weight is composed of water (Pivarnik, 1994; Houpt, 1984; Swenson, 1984). Total body water is divided into four major compartments. Approximately 62 to 64% of water is located within cells, 22% within interstitial spaces and 7% within the intravascular space in plasma (Wolter, 1985; Ivy et al, 1988). The remaining 7% is present as transcellular fluids such as vitreous and aqueous humor, cerebral spinal fluid, joint fluid and digestive secretions (Pivarnik, 1994; Houpt, 1984). Osmotic, oncotic and hydrostatic pressures as well as the permeability characteristics of individual membranes direct fluid balance between compartments. Dietary water intake and metabolic water production (10 to 16 ml/100 kcal and 3 to 4 ml/g glycogen) on one hand and evaporative, urinary and fecal losses on the other maintain total body water balance (Pivarnik, 1994; Houpt, 1984).

The fluid content of individual tissues and compartments changes with the onset of muscular activity. Cardiac output, partially a function of plasma volume, increases during exercise to meet the muscle's heightened demand for nutrient delivery and waste removal. The increase in blood flow also helps dissipate the heat produced by working muscles. Only about 20 to 30% of the energy consumed within muscle cells during exercise produces work; the remaining 70 to 80% is converted into heat. This is about the same efficiency as a gasoline engine (Serway, 1984). This heat must be dissipated to prevent performance impairments and perhaps life-threatening increases in body temperature (Pivarnik, 1994; Kozlowski et al, 1985; Kruk et al, 1985).

During prolonged periods of exercise in warm and humid environments, heat dissipation leads to a decrease in total body water and plasma volume. Approximately 60% of the heat dissipated during exercise is lost through fluid evaporation from the upper respiratory tract (Young et al, 1959). Water requirements essentially double in dogs when the ambient temperature reaches 45°C (113°F) (NRC, 2006). Exercise in very cold, dry environments also increases evaporative fluid losses. Significant fluid loss during exercise may impair performance. Even mild dehydration can limit exercise performance (Swenson, 1984) and probably negatively affects olfactory performance. Several studies indicate that hydration status is the single most impor-

Table 18-9. Key nutritional factors for foods for working and sporting dogs.

Factors	Sprint activity	Intermediate activity (low/moderate duration and frequency)	Intermediate activity (high duration and frequency)	Endurance activity
Water	Unlimited access except just before a race	Unlimited access	Unlimited access	Unlimited access
Energy density	Use food with 3.5 to 4.0 kcal ME/g DM	Use food with 4.0 to 5.0 kcal ME/g DM	Use food with 4.5 to 5.5 kcal ME/g DM	Use food with >6.0 kcal ME/g DM
Fat	Use food with 8 to 10% DM fat or 20 to 24% of calories from fat	Use food with 15 to 30% DM fat or 30 to 55% of calories from fat	Use food with 25 to 40% DM fat or 45 to 65% of calories from fat	Use food with >50% DM fat or >75% of calories from fat
Unsaturated fatty acids	-	>60% unsaturated fatty acids to optimize olfaction	>60% unsaturated fatty acids to optimize olfaction	-
Digestible carbohydrate	Use food with 55 to 65% DM NFE or 50 to 60% of calories from NFE	Use food with 30 to 55% DM NFE or 20 to 50% of calories from NFE	Use food with 30 to 35% DM NFE or 15 to 30% of calories from NFE	Use food with <15% DM NFE or <10% of calories from NFE
Protein	Use food with 22 to 28% DM protein or 20 to 25% of kcal (ME) from protein	Use food with 22 to 32% DM protein or 20 to 25% of kcal (ME) from protein	Use food with 22 to 32% DM protein or 18 to 25% of kcal (ME) from protein	Use food with 28 to 34% DM protein or 18 to 22% of kcal (ME) from protein
Digestibility	DM digestibility >80%	DM digestibility >80%	DM digestibility >80%	DM digestibility >80%
Antioxidants				
Vitamin E	≥500 IU vitamin E/kg food (DM)	≥500 IU vitamin E/kg food (DM)	≥500 IU vitamin E/kg food (DM)	≥500 IU vitamin E/kg food (DM)
Vitamin C	150 to 250 mg vitamin C/kg food (DM)	150 to 250 mg vitamin C/kg food (DM)	150 to 250 mg vitamin C/kg food (DM)	150 to 250 mg vitamin C/kg food (DM)
Selenium	0.5 to 1.3 mg/kg food (DM)	0.5 to 1.3 mg/kg food (DM)	0.5 to 1.3 mg/kg food (DM)	0.5 to 1.3 mg/kg food (DM)

Key: ME = metabolizable energy, DM = dry matter, NFE = nitrogen-free extract (represents digestible [soluble] carbohydrate fraction).

tant determinant of endurance capacity (Kronfeld and Downey, 1981; Downey et al, 1980; Young et al, 1959a).

There is currently much debate over the best strategy to maintain fluid and electrolyte balance in working dogs. Under most exercise situations, these athletes lose more water than electrolytes, causing a decrease in plasma volume and an increase in plasma osmolality. Efforts to return electrolyte values to normal should thus concentrate on water replacement. Ideally, fresh clean water should be available at all times. There are occasions when such accommodations cannot be made due to the nature of the athletic event or the environmental conditions. Under these conditions, water should be offered at least three times a day and more often if possible. "Baiting" the water with a flavor enhancer such as meat juice can encourage water intake.

Energy

Providing the right amount of energy from the right sources is central to feeding working and sporting dogs. Providing the correct amount of energy is determined by the food's energy density and the amount fed. The energy density can limit the maximum possible caloric intake and a food's overall digestibility. Additionally, the preferred source of energy (fat vs. carbohydrate) depends on exercise type. Energy for exercise comes from three nutrients: fat, carbohydrate and protein. Fats and carbohydrates are the primary energy substrates for exercise. Fat is the preferred substrate for longer duration exercise, whereas sprinters depend more on carbohydrate. Under most conditions, the energy contribution of protein during exercise is small (Hickson and Wolinsky, 1989); however, its contribution will increase in fatigued dogs.

Energy required depends on the intensity, duration and frequency of exercise. The amount of energy required for exercise depends on total work done (intensity x duration x frequency). The preferred source of energy depends mostly on intensity. Greyhounds, even though they work at a very high intensity, have relatively low energy requirements because the duration of their events is so short and frequency is usually only a few times each week. Generally, 1.6 to 2 x resting energy requirement (RER) is adequate for most sprint athletes. Note the daily energy requirement (DER) for most pet dogs is 1.2 to 1.4 x RER. Most pet dogs are minimally active.

For activities of very short duration and high intensity, the energy substrate source is the main determinant of the nutrient profile. Foods for sprint athletes should be high in carbohydrate and lower in fat, with a resulting energy density lower than that of many dog foods. Intensity, duration and frequency of exercise are variable for intermediate athletes; therefore, the energy requirement is highly variable. DER for these athletes ranges from 2 to 5 x RER. Foods with a higher fat content are typically fed to provide adequate dietary energy density. Endurance athletes require more than 5 x RER. For activities of long duration, providing adequate energy is a major determinant in the choice of a nutrient profile for exercising dogs. Foods that are very high in fat are required.

Table 18-9 lists target energy density levels for foods for

working and sporting dogs, depending on the type, level and duration of physical activity.

Fat

Fat provides approximately 8.5 kcal (36 kJ) of metabolizable energy (ME) per gram of dry matter (DM) or more than twice the amount provided by protein and carbohydrate. Because of these differences in caloric density, the only practical means of significantly increasing the energy density of a food is to increase its fat concentration. Reasonable increases in fat usually also increase palatability. Energy density and palatability make dietary fat levels an important consideration in the formulation of foods for working and sporting dogs. Increasing dietary fat generally also increases a food's digestibility because fat tends to be more digestible than protein or carbohydrate. Also, when a greater quantity of a lower energy density food is eaten in an attempt to provide adequate calories, there is a more rapid rate of passage through the gastrointestinal (GI) tract, further reducing digestibility and energy intake (Davenport et al, 2001).

Ingesting adequate calories to meet daily energy expenditure is often a serious challenge for working dogs. In extreme cases, sled dogs in long-distance races expend from 6,000 to 10,000 kcal/day (25 to 42 MJ/day), in which case DM intake becomes a performance-limiting factor. Because the total daily DM intake is limited to about 3.5% of body weight,[c] the energy density of a food should be maximized. Under these circumstances, each nonessential gram of protein and carbohydrate ingested potentially robs the dog of 5 kcal (21 kJ). The calorie deficit is paid through mobilization of body fat stores. Overreliance on these depots may lead to catabolism of more functionally crucial energy sources, such as muscle and plasma proteins. In addition to its role as an energy store, adipose tissue also functions as an insulator. Excessive adipose depletion may increase a dog's cost of maintaining its body temperature, especially at rest in cold environments.

Even under the less severe conditions of intermediate exercise, increased dietary fat levels provide needed energy and other valuable benefits. Fatigue and dehydration may decrease appetite. Increasing dietary fat concentration increases energy intake and encourages stressed dogs to ingest more food because the higher fat content improves palatability.

Feeding high levels of fat can positively affect endurance. Training may elevate the carbohydrate threshold, thus increasing the proportion of energy supplied by free fatty acid (FFA) oxidation at all but the highest intensities of exercise. Increasing dietary fat concentration may augment this process by enhancing FFA availability (Kronfeld and Downey, 1981; Kronfeld et al, 1977; Reynolds et al, 1994). Working dogs fed high-fat foods have higher circulating levels of FFA at rest and respond to exercise stimuli by releasing more FFA than those fed isocaloric amounts of a high-carbohydrate food (Kronfeld and Downey, 1981; Kronfeld et al, 1977; Young et al, 1962). This difference in FFA availability may be related to the decreased resting plasma concentration of insulin in animals fed high-fat foods, and the induction of key lipolytic enzymes.

Table 18-10. Effect of nutrient profile on stamina.*

	Food A	Food B	Food C
Nutrient (DM)			
Energy density (kcal/g)	4.7	5.9	6.0
Fat (%)	12.8	28.3	33.1
Protein (%)	22.9	48.7	30.5
Performance			
Time (minutes)	103.7	136.1	137.6
Distance (miles)	15.5	20.4	20.6

Key: DM = dry matter, Food A = grocery brand dry food, Food B = grocery brand moist food, Food C = specialty brand dry food.
*Adapted from: Downey RL, Kronfeld DS, Banta CA. Diet of beagles affects stamina. Journal of the American Animal Hospital Association 1980; 6: 273-277.

The effect of food on insulin levels has also been demonstrated in well-trained human athletes (Gleeson et al, 1986; Martin et al, 1978; Coyle et al, 1985; Yoshida, 1986; Brouns et al, 1989). People eating high-fat foods had significantly lower resting insulin concentrations than those eating high-carbohydrate foods (Maughan et al, 1987). Insulin decreases the release of FFA from peripheral adipose stores through its inhibitory effects on the activity of hormone-sensitive lipase. Dogs rely more heavily on FFA for energy generation at all exercise intensities than people do; therefore, the effect of food on resting insulin levels is a matter of even greater concern for working and sporting dogs (Reynolds et al, 1997). Increased dietary fat (from 25 to 65% of kcal) increases VO_2 max and the maximal rate of fat oxidation by 20 to 30% in well-trained dogs (Reynolds et al, 1995). These increases were associated with a 25 to 30% increase in mitochondrial volume, possibly accounting for the increased oxidative capacity. Protein and total caloric intake were identical between groups. Also, event anticipation can suppress insulin concentrations before and during an event activity (Gillette et al, 2006).

The relationship between fat intake and canine endurance is well established. The time to exhaustion for well-conditioned beagles running on a treadmill was directly related to energy density, digestibility and digestible fat intake (**Table 18-10**) (Downey et al, 1980). Practical applications of this concept are evident in the performance foods currently fed to many successful working and sporting dogs. As the duration of the event performed by a dog increases, so should the dietary fat intake.

Dogs can tolerate high levels of dietary fat if fat is gradually introduced and an adequate intake of non-fat nutrients is maintained. Steatorrhea and a decrease in food palatability are indicators that the fat content of a food has exceeded a dog's fat tolerance. Under conditions of extreme training, sled dogs may ingest up to 60% of their energy as fat. During ultra-endurance events, such as the Iditarod or the Yukon Quest, fat intake may compose 80% of the calories ingested.[d] This "super fat loading" should be attempted only during the most strenuous periods of such events, when it is difficult or impossible for dogs to ingest as much energy as they are expending.

Anemia has been associated with impaired performance in dog teams fed very high-fat foods (i.e., 80% kcal from fat) for prolonged periods (i.e., weeks to months) (Reynolds, 1997).

Table 18-11. Saturated and unsaturated fatty acid content of selected fat sources used in commercial pet foods.*

Ingredient	Saturated fatty acids (%)	Unsaturated fatty acids (%)**
Beef tallow	47.4	52.6
Choice white grease	38.7	61.3
Lard (swine fat)	28.6	71.4
Poultry fat	28.6	71.4
Fish oil (menhaden)	20.2	79.8
Corn oil	12.7	87.3
Flax oil (linseed)	9.4	90.6
Safflower oil	8.6	91.4
Soybean oil	14.2	85.8
Sunflower oil	8.9	91.1

*National Research Council. Nutrient Requirements of Dogs and Cats. Washington, DC: National Academies Press, 2006; 328-329.
**Includes both polyunsaturated and monounsaturated fatty acids; derived by subtracting % saturated fatty acid values from 100.

However, during several long expeditions (including the trans-Antarctica expedition of 1991), Will Steger observed no decrement of performance when dogs were fed food containing 80% fat kcal and 17% protein kcal.[e] Other factors such as environment, training and dietary intake of non-fat nutrients (e.g., protein) may play a role in the development of anemia.

The type of fat used must also be considered in the formulation of foods for working and sporting dogs. Essential fatty acids should make up at least 2% of the DM of a food (Chapter 5). The remainder of the fat may come from any of a number of plant or animal sources. Many greyhound and sled-dog trainers believe that dogs run "hotter" when fed saturated rather than unsaturated fats. No objective evidence supports this theory. However, there is evidence that foods containing high levels of saturated fat (60% of the fatty acids saturated) will reduce olfactory performance in dogs, particularly if they are not physically conditioned (Altom et al, 2003). This may be due to effects of dietary fatty acids on brain function. Membrane composition of the central nervous system can be affected by the dietary fat source. Rats fed food high in saturated fat (beef tallow) showed a deficiency of 18:3 fatty acids in the brain vs. rats fed a food with unsaturated fat (corn oil) (MacDonald et al, 1996). The fatty acid composition of membrane phospholipids dictates membrane fluidity and permeability (Coutre and Hulbert, 1995). Changes in membrane fluidity can affect the functions of membrane enzymes. Sodium-potassium ATPase is one of several major components of the pathway that mediates molecular events of olfaction. Dietary fat can affect brain synaptic membrane sodium-potassium ATPase activity (Gerbi et al, 1994; Altom et al, 2003). In the study above that noted a decrease in olfaction when 60% of the fatty acids were saturated (37% unsaturated), another group of dogs fed a food with only 24.5% saturated fatty acids (72% unsaturated) maintained olfactory performance over time, even if the dogs were not physically fit. Thus, higher levels of unsaturated fatty acids in a food appear to protect against decline of olfaction over time in untrained dogs. Anecdotal reports support the use of supplemental unsaturated fatty acids (corn oil) to improve olfactory performance.[f] If corn oil is added to dry commercial foods to increase the fat and/or unsaturated fatty acid content, 1 tablespoon of corn oil for approximately each pound of dry food will increase the overall fat content by about three percentage points. For example, if two tablespoons of corn oil are added to one pound of dry food that contains 20% fat, the resultant mixture of food and corn oil will contain about 26% fat and would have increased levels of unsaturated fatty acids. However, if commercial foods are properly formulated for active dogs, supplementation with fat sources such as corn oil should not be necessary.

Alternatively, large intakes of unsaturated fatty acids may increase the risk of oxidative damage to membrane lipids (NRC, 1985; Van Vleet, 1980), which can severely damage cell membrane function with potentially disastrous implications for working dogs. Relative to their sedentary colleagues, dogs participating in endurance events are at particular risk for developing oxidative membrane damage because they consume more fat and metabolize more oxygen per unit body weight per day. Feeding only well-stabilized (preserved) unsaturated fatty acids reduces the risk of oxidative damage to tissues. Increasing intake of vitamins E and C and selenium to bolster cellular antioxidant capacity has also been recommended (Kronfeld, 1989) and is discussed below in the Antioxidants section.

Unsaturated fatty acids are an important component in a well-balanced food. As mentioned above, they are largely responsible for membrane fluidity, a property critical to the function of all cell membranes. Unsaturated fatty acids are also required for biosynthesis of many regulatory molecules and maintenance of epidermal integrity. All essential fatty acids are unsaturated. In weighing the biologic significance of unsaturated fatty acids with the possible health risks associated with their overconsumption, balanced amounts of saturated and unsaturated fatty acids may be the best solution. **Table 18-11** shows the percentage of saturated and unsaturated fatty acids in various ingredients used as fat sources for pet foods. For commercial foods, product labels will include ingredient listings in descending order of predominance by weight. By reviewing a product's ingredient list, one can obtain an approximate idea of the levels of saturated and unsaturated fatty acids in the food. If additional unsaturated fat sources are added to a commercial food, adequate vitamin E should be provided. (See Antioxidants discussion, below.)

Certain fatty acids are purported to have ergogenic effects. The omega-3 (n-3) family of fatty acids contained in fish oils has been reported to enhance oxygen uptake (Brilla and Landerholm, 1990). The results reported in this study lacked statistical significance, prompting the need for further investigations. Medium-chain triglyceride (MCT) supplementation reportedly enhances performance (Grandjean and Paragon, 1987; Wolter, 1985). These intermediate length (eight to 12 carbon) fatty acids do not rely on L-carnitine for transport across the inner mitochondrial membrane. Because they bypass this rate-limiting step in fatty acid oxidation, some investigators have theorized that increasing the dietary MCT level may increase the maximal rate of fatty acid oxidation. A study of the effects of MCT supplementation failed to demonstrate an increase in oxygen consumption or FFA oxidation in human

athletes (Brilla and Landerholm, 1990). Further research is needed to determine the consequences of MCT supplementation in working dogs.

Sprint exercise depends almost entirely on carbohydrate; therefore, the fat requirement for sprinters is not different than that for other dogs. Total fat content should be 8 to 10% of DM or 20 to 24% of kcal. Dietary fat needs for intermediate athletes are directly proportional to the amount of work done. Part-time athletes during off-season should be fed as other dogs (Chapter 13). Dietary fat content should be increased as the amount of work increases: 15 to 30% DM (30 to 55% fat kcal) for moderate amounts of work and 25 to 40% DM (45 to 65% fat kcal) for large amounts of work. Endurance athletes require very high levels of dietary fat to meet their energy needs, in excess of 50% DM and 75% fat kcal. A balance of saturated and unsaturated fat sources is recommended. **Table 18-9** summarizes recommendations for fat and other nutrients by exercise type. Currently, it is recommended that working and sporting dogs not be fed high-fat meals immediately before or during intense exercise (NRC, 2006).

Digestible Carbohydrate

Provided sufficient gluconeogenic precursors are available, dogs have no dietary requirement for carbohydrates except during gestation and neonatal development (Chapters 15 and 16). Dogs are quite capable of maintaining normal blood glucose and tissue glycogen levels when fed carbohydrate-free foods (Kronfeld et al, 1977; Hammel et al, 1977). Compared with people, dogs are less likely to develop ketosis during long periods of exercise or starvation (Kronfeld et al, 1977; Crandall, 1941). Despite these facts, dogs have great ability to use carbohydrate.

Canine athletes requiring less than twice maintenance levels of energy may derive a significant portion of their kcal from carbohydrate sources. This is an advantage for high-power athletes, such as racing greyhounds that are highly dependent on anaerobic metabolism. Because carbohydrates contain only about 3.5 kcal (15 kJ) ME/g, they cannot be used to increase the energy density of a food. This limitation is an important consideration for endurance athletes that have difficulty ingesting a sufficient volume of food to meet caloric requirements.

Racing greyhounds are highly dependent on carbohydrate stored in muscles as glycogen because they must mobilize energy quickly to run a race. Studies have shown that greyhounds use significant amounts of glycogen during a race; up to 70% of available glycogen in some muscles for an 800-meter race (Dobson et al, 1988; Rose and Bloomberg, 1989). Furthermore, evidence suggests that the rate of glycogen use (and, therefore, energy production) depends on the concentration of glycogen in muscle (Richter and Glabo, 1986). It is logical; therefore, to hypothesize that increasing muscle glycogen will enhance sprint performance. Muscle glycogen content can be increased through a combination of dietary and training protocol changes in some animals (rats, people [Conlee, 1987], horses [Oldham et al, 1989]); these techniques have been used as a means of improving endurance performance (Conlee, 1987; Bergstrom et al, 1967). The possible benefits of increased muscle glycogen on sprint exercise performance of dogs have not been established. It is also unclear if continuous feeding of high-carbohydrate foods to dogs will increase muscle glycogen. For sled dogs, it may be more advantageous to promote glycogen sparing by feeding a high-fat food than increasing pre-exercise glycogen concentrations via ingestion of a high-carbohydrate food. Studies have demonstrated an increase in the amount of muscle glycogen stored and a greater rate of glycogen use in sled dogs fed a high-carbohydrate food (65% of kcal) (Reynolds et al, 1997). When isocaloric amounts of a high-fat food were fed, glycogen was used at a much slower rate, promoting better endurance at all submaximal exercise intensities. In sled dogs, carbohydrate sparing appears to be a more successful strategy than carbohydrate loading.

Two studies have reported the effect of different fat and carbohydrate levels on race time in greyhounds (Toll et al, 1992; Hill et al, 1996). Both studies used seven adult racing greyhounds in a crossover design and used race time in a 5/16-mile (502-m) race as the measure of performance. Investigators in the first study used two foods similar in composition except for fat and carbohydrate content (Toll et al, 1992). The high-carbohydrate food contained 16% DM fat (34% of kcal) and 52% DM carbohydrate (44% of kcal), whereas the low-carbohydrate food contained 56% fat (80% of kcal) and 8% carbohydrate (5% of kcal). No significant difference in race times between the two food groups was detected for the first four weekly measurements. At the end of the fifth week, the dogs fed the high-carbohydrate food ran faster (33.08 ± 0.05 sec) than when they were fed the low-carbohydrate food (33.34 ± 0.05 sec). The results were statistically significant ($p < 0.05$). In this study, dogs performed better when fed a high-carbohydrate/low-fat food than they did when fed a high-fat/low-carbohydrate food. The delay before differences occurred may indicate that some time may be required to adapt to a new food before performance is affected.

The second study compared results of feeding a "high-fat" food (38.2% energy from fat, 23% energy from protein, 38.8% energy from carbohydrate) with those of feeding a "moderate-fat" food (27.6% energy from fat, 20.4% energy from protein, 52.1% energy from carbohydrate) (Hill et al, 1996). Dogs were fed each food for eight weeks. Race times were faster when the dogs were fed the high-fat food than when they were fed the medium-fat food (32.9 ± 0.7 vs. 33.1 ± 0.6 sec at $\alpha .= 0.1$, $\beta .= 0.2$).

Neither of these studies evaluated a truly high-carbohydrate level (60 to 70% of dietary kcal) as is now recommended for glycogen loading in people (Goodyear et al, 1990). Furthermore, although the results of these two studies are mixed, physiologic principles suggest that carbohydrate supplementation should benefit racing greyhounds.

Even endurance athletes may benefit from a low level of dietary carbohydrate. Studies involving sled dogs fed 0 or 17% of their kcal as carbohydrate showed that dogs were more susceptible to developing "stress" diarrhea when fed foods devoid of carbohydrate (Kronfeld, 1973). There are other advantages asso-

ciated with feeding carbohydrates to sprint athletes. Because these dogs derive more of their energy for exercise from glucose/glycogen, glycogen depletion may play a role in the onset of fatigue for athletes working at or above their anaerobic threshold (Pate and Brunn, 1989; Miller and Massaro, 1989; Keizer et al, 1986; Issekutz, 1981; Burke and Read, 1987).

Carbohydrate availability to working muscles is a limiting factor for prolonged exercise in people and other species. This finding has led to development of strategies for carbohydrate loading or glycogen super-compensation. The classic method (Åstrand method) uses a combination of exhaustive exercise and low-carbohydrate foods (≤10% kcal from carbohydrate) to deplete muscle glycogen. Glycogen depletion is followed by consumption of high-carbohydrate foods (80 to 90% kcal from carbohydrate) and little activity. This method dramatically increases muscle glycogen in people (Bucci, 1993). An alternative carbohydrate-loading method (Sherman/Costill method) simply requires consumption of 60 to 70% of kcal from carbohydrate consistently over time. In people, this method produces results similar to those achieved by the classic method (Bucci, 1993).

Glycogen loading is probably not as beneficial for canine endurance athletes as continuous feeding of foods with high-fat levels. However, high-power athletes (e.g., racing greyhounds) should benefit from glycogen loading. Because racing greyhounds do not have dramatically increased energy needs and cannot use fatty acids effectively during a race lasting less than 60 seconds, there is no benefit to feeding high levels of fat. Additionally, glycogen stores are rapidly mobilized during racing. In one study, greyhounds running an 800-m race in 48 seconds mobilized 50 to 70% of their glycogen stores in specific running muscles (Dobson et al, 1988).

Studies in people have shown that feeding moderate amounts of carbohydrate (2 g glucose/kg body weight) during a brief postexercise time window permits very rapid rates of glycogen resynthesis (Goodyear et al, 1990; Keizer et al, 1986; Ivy et al, 1988). This period begins about 30 minutes postexercise (Kronfeld, 1973). Glucose administered during this window permits up to four times the rate of glycogen resynthesis supported by the same amount of glucose administered after this two-hour window. The form of the glucose (i.e., polymer or simple sugar) does not seem to affect the rate of glycogen repletion (Keizer et al, 1986). Severely hypertonic solutions should be avoided to prevent excessive osmotic movement of fluid into the gut, which may lead to cramping and GI distress (Williams, 1985; Buskirk and Puhl, 1989). This strategy for glycogen repletion is effective in human athletes and dogs. Glucose solutions (from 1.5 to 3 g glucose/kg body weight) given before, during or after exercise have been shown to minimize the exercise-associated decline in blood glucose, promote more rapid repletion of muscle glycogen postexercise and improve thermoregulation (Kruk et al, 1987; Reynolds et al, 1997; Wakschlage et al, 2002). Although only speculation, resultant improvements in exercise performance and thermoregulation might also protect against a reduction in olfactory performance by precluding excessive panting. The carbohydrates used in foods for canine athletes should be highly digestible to limit fecal bulk. Excessive amounts of undigested carbohydrates reaching the colon may increase water loss via the stool, increase colonic gas production and increase overall fecal bulk. These changes in fecal consistency have been proposed to increase an athlete's risk of developing "stress diarrhea," further increasing fecal water losses (Kronfeld, 1973). Bulky stools have also been associated with rectal bleeding during exercise-induced colonic evacuation (Kronfeld, 1973). Excessive fecal bulk is also extra weight that must be carried by the athlete. One study estimated that 150 g of extra stool generated by a racing-sled dog was equal to a 7-kg handicap for a thoroughbred horse (Kronfeld and Downey, 1981).

Metabolic power or a high rate of ATP generation is required for sprint performance. Consequently, anaerobic metabolism of glucose and glycogen is the dominant energy generation pathway. High-carbohydrate foods should be fed to maximize muscle glycogen. Dietary carbohydrates should compose 50 to 70% of total kcal to maximize muscle glycogen levels (based on research done with people).

The dietary carbohydrate recommendation for intermediate athletes is highly variable, depending on the intensity and duration of work. Dogs that perform relatively long bouts of low to moderate intensity work require more dietary energy (higher fat) and relatively low carbohydrate levels (as low as 15% of kcal). Dogs that perform short bursts of higher intensity work should be fed more carbohydrate, up to 50% of kcal.

Endurance athletes require very little carbohydrate. Endurance rations should contain less than 15% of kcal from carbohydrate to achieve the energy density required for the amount of work done by these dogs. Some carbohydrate and/or soluble fiber should be included in the food to avoid loose stools.

Technically, the total carbohydrate portion of a food includes fiber. The digestible (soluble) carbohydrate portion of total carbohydrate consists of starches and sugars, typically referred to simply as "carbohydrate." The digestible carbohydrate fraction of a food is also called the nitrogen-free extract (NFE). The percent digestible carbohydrate is usually not stated on the guaranteed analysis listing of a commercial product's label. Such information should be available from product literature supplied by the manufacturer (e.g., product "keys," websites, etc.). However, percent digestible carbohydrate can also be estimated from the guaranteed analysis listing by subtracting the percent crude protein, fat, crude fiber and ash (mineral) from 100. If fiber and ash are not listed, assume 3% fiber and 9% ash in dry foods and 1% fiber and 6% ash in moist (canned) foods. Another, perhaps simpler means of estimating digestible carbohydrate content is to check if the protein and fat recommendations in **Table 18-9** are close to what is listed on the guaranteed analysis portion of the label of the food in question, if they are, its digestible carbohydrate content should also be close to what is recommended.

Table 18-9 summarizes carbohydrate recommendations for canine athletes by exercise type.

Soluble fiber and resistant starches may provide some bene-

fit to racing dogs, particularly if they are fed raw meat. Rapid fermentation of oligosaccharides may decrease colonic pH and inhibit clostridial growth (Amtsbert et al, 1989). Fructo-oligosaccharides inhibit cecal colonization by *Salmonella* species in chickens and could conceivably do so in dogs (Baily et al, 1991).

Protein

Dietary protein is used to fulfill structural, biochemical and, to a lesser extent, energy requirements. Work increases the requirement for protein. The magnitude of this increase and the best strategy for meeting it are subjects of much debate in canine performance nutrition.

The work-induced elevation in protein requirement is most pronounced when the intensity and/or duration of exercise performed is rapidly increased above an animal's present level of conditioning. These circumstances are encountered at the onset of a training program, when the duration or intensity of training bouts is increased and especially during performances (Zackin, 1990; Hickson and Wolinsky, 1989). A common example would be when a bird dog that is also a minimally active pet is hunted the first time during hunting season with little or no exercise training. The increase in protein demand is due to combined increases in the rates of tissue protein synthesis and catabolism.

Several anabolic processes contribute to the exercise-induced increment in protein requirement. Protein demand is elevated due to an increase in the synthesis of structural and functional proteins. Training induces synthesis of many enzymes and transport proteins in each of the energy-generating pathways (Nadel, 1985; Williams, 1985; Costill et al, 1979, 1979a). Blood volume also expands during aerobic training (Nadel, 1985; Williams, 1985; Zackin, 1990; Hickson and Wolinsky, 1989). Such expansion necessitates an increase in plasma protein synthesis to maintain oncotic and osmotic balance between plasma and interstitial fluids (Pivarnik, 1994). The increase in hematocrit sometimes observed during endurance conditioning programs may reflect an increase in tissue protein synthesis (Nadel, 1985; Williams, 1985; Kronfeld and Downey, 1981). Anaerobic training regimens may also induce muscle hypertrophy (Hickson and Wolinsky, 1989). Amino acids are used in the formation of new muscle tissue and in the repair of damage that may occur to muscle and connective tissue during intensive conditioning programs. In addition to enhancing the rate of tissue protein synthesis, exercise increases the rate of amino acid catabolism. Amino acids may provide between 5 and 15% of the energy used during exercise, depending on the intensity and duration of the task (Young et al, 1962; Zackin, 1990; Hickson and Wolinsky, 1989). Most of this energy comes from the oxidation of branched-chain amino acids (Miller and Massaro, 1989; Blomstrand et al, 1988). All three amino acids belonging to this group (leucine, isoleucine, valine) are "essential" and thus cannot be synthesized from other amino acids in sufficient quantities to meet requirements. The branched-chain amino acids lost through exercise must be replaced through dietary intake.

The proportion of energy supplied by amino acids may be even greater in underfed athletes and those participating in ultra-endurance events in which there is a high risk for depletion of endogenous carbohydrate stores (Zackin, 1990; Miller and Massaro, 1989). In these instances, gluconeogenesis becomes the major pathway for maintaining blood glucose levels (Zackin, 1990; Miller and Massaro, 1989). Because amino acids are the predominant substrate used by the gluconeogenic pathway, their rate of catabolism is increased whenever this pathway is accelerated (Hickson and Wolinsky, 1989; Cahill et al, 1970).

This concept raises an important point: it is disadvantageous for an athlete to rely heavily on endogenous sources of protein for energy. There are no known labile stores of protein in the canine body. All protein sources serve a structural or functional purpose (Cahill et al, 1970). Interestingly, skeletal muscle is readily mobilized. Overuse of this source would have an obvious negative impact on performance. Because the small pool of circulating amino acids is insufficient to meet the amino acid requirements of the anabolic and catabolic processes described above, dietary protein intake must supply the deficit if nitrogen balance is to be maintained (Zackin, 1990).

For endurance athletes, there may be some disadvantages inherent to exploiting dietary protein sources for energy. Protein has only about 3.5 kcal (15 kJ) ME/g DM. Thus, increasing the proportion of protein in the formulation cannot increase the energy density of a ration. The energy density of the food is one of the major determinants of endurance capacity when working dogs have difficulty ingesting as many kcal as they expend (Downey et al, 1980).

Excessive protein intake may predispose an animal to increased amino acid catabolism because dietary amino acids are not stored in labile protein depots, but are deaminated (Hickson and Wolinsky, 1989). The resulting ketoacids are either oxidized for energy directly or converted into fatty acids and/or glucose and then stored as adipose tissue or glycogen. The urea produced from amino acid breakdown is excreted from the body in urine. In healthy animals, the amount of water lost increases with increased urea production.

An optimal food for a working or sporting dog should contain enough high-quality protein to meet the dog's anabolic requirements and enough non-protein energy nutrients to meet its energy requirements. Such a food encourages the use of ingested protein in synthetic rather than energy-generating processes. As non-protein caloric intake increases, less dietary protein is used for energy and more is available for use in anabolic processes. Energy requirements should be met by fat and carbohydrate, leaving the majority of amino acids available for synthetic purposes. During long-duration exercise, DER may increase several-fold whereas protein requirement increases only a few percent. To meet the energy needs of hard-working dogs, either more food must be consumed (increasing both energy and protein intake equally) or a higher energy, lower protein food must be fed (increasing energy intake more than protein intake). Providing sufficient dietary energy by

increasing fat content should limit the use of amino acids for energy production. Because the protein requirement is actually a requirement for available amino acids, the digestibility and essential amino acid content of ingested protein will also determine how efficiently amino acids are incorporated into tissue proteins.

Research attempts that define the optimal dietary protein intake for working dogs have been inconclusive. Several field studies performed on racing-sled dogs in the 1970s and early 1980s found that well-conditioned dogs fed a high-fat, high-protein food maintained higher packed cell volumes and serum albumin concentrations than those fed a relatively high-carbohydrate, low-protein food (Kronfeld et al, 1977; Kronfeld, 1977; Adkins and Kronfeld, 1982). The investigators concluded that the high-fat, high-protein food might offer a performance advantage by maintaining better blood volume and oxygen carrying capacity than the other foods tested. These investigators recommended that 30 to 40% of kcal of a performance ration should come from protein.

Another study examined the effects of feeding isocaloric foods (4.5 kcal [19 kJ] ME/g) containing 16, 24, 32 or 40% of their energy as protein on performance and biochemical parameters (Reynolds et al, 1999). During training and racing, dogs fed only 16% of ME as protein suffered significantly more injuries and had a significant decline in VO_2 max when compared with age-, gender- and ability-matched sled dogs fed 24, 32 or 40% of ME as protein. Additionally in people, long-duration exercise leading to glycogen depletion increases protein requirement more than weight lifting. There were no noticeable differences in performance between the dogs fed 24, 32 or 40% of ME as protein, although the dogs fed 40% of ME as protein maintained a significantly higher packed cell volume and total plasma volume. This study indicated that 16% of ME as protein may be insufficient to meet the needs of extremely hard-working dogs and that such animals should ingest a minimum of 24% of their energy requirement as protein.

Work in greyhounds shows a different response to food protein levels. When raced for 500 m twice/week, dogs ran 0.3 km/hr faster and their hematocrits were higher when fed a lower protein (63 g/1,000 kcal, 24% ME), higher carbohydrate (106 g/1,000 kcal, 43% ME) food vs. a higher protein (96 g/1,000 kcal, 37% ME), lower carbohydrate (75 g/1,000 kcal, 30% ME) food (Hill et al, 2001a). The fat content of the foods was similar. Thus, for sprint athletes, a lower level of food protein appears desirable.

The protein requirement for exercise is only mildly increased (5 to 15%) regardless of exercise type. Protein is used for muscle hypertrophy and muscle maintenance/repair. Furthermore, the branched-chain amino acids can contribute to energy production. Dietary protein should be at least 24% of kcal. Because the energy requirement of some endurance athletes is so high (up to 11 x RER), it may not be feasible to feed even this level of protein and provide adequate kcal. For these dogs, 16% of the ME as protein should be viewed as an absolute minimum. Note that for endurance exercise, energy requirement increases up to 11-fold, whereas protein requirements increase much less (5 to 15%). For a given food, as intake increases to meet energy requirements, protein intake increases proportionally. Because of the disparity between the increase in need for energy and protein for exercise, as total dietary energy requirement increases, the percent of the ME as protein of the food can decrease. **Table 18-9** summarizes protein recommendations by exercise type.

Digestibility

DM digestibility of food is important to canine athletes for two reasons. First, exercise may be limited by a dog's ability to obtain sufficient amounts of nutrients (usually energy). Enhanced digestibility increases the maximum possible delivery of nutrients to tissues. Second, lower digestibility means greater fecal bulk, and therefore a greater handicap. Although increased animal size results in greater running efficiency, increased fecal weight creates a greater energetic cost of running with no benefit. Total DM digestibility of any food for canine athletes should exceed 80% (Downey et al, 1980; Lewis et al, 1987). Foods having a higher energy density are likely to have increased DM digestibility.

Antioxidants

There are at least two questions to consider when discussing antioxidants for working and sporting dogs: 1) do supplemental antioxidants provide a health benefit and 2) do they influence performance.

Exercise is associated with an increase in the rate of oxygen consumption. The extent of the increase depends on the intensity of the exercise. Even normal oxidative metabolism results in the production of highly reactive free radical molecules. Proportionate increases in free radical production appear to accompany exercise-associated increases in oxygen consumption (Hinchcliff et al, 2000). Aerobic, anaerobic and mixed exercise cause varying degrees of free radical production. Besides mitochondrial production of free radicals, such as with endurance exercise, anaerobic and mixed exercise result in ischemia reperfusion, acidosis and catecholamine oxidation that further contribute to oxidative stress. The body's typical adaptive response is increased mobilization of a variety of enzymatic and non-enzymatic antioxidant systems. However, with exercise these innate antioxidant capabilities are oftentimes overwhelmed, which leads to oxidative stress. The consequences of prolonged oxidative stress may contribute to and/or exacerbate a wide variety of degenerative diseases (Chapter 7). In human athletes, unchecked oxidative stress seems to be involved in chronic muscular fatigue and may lead to a condition called "overtraining" (Finaud et al, 2006). It is possible that canine athletes experience a similar phenomenon.

Considerable research into the use of supplemental antioxidants to augment the body's antioxidant capacity during exercise has been done in a variety of species. However, because of the complexity of the associated variables, many of the research results are equivocal making it challenging to apply the knowledge to practice (Finaud et al, 2006). These complexities

include degree of training, positive effects of free radicals, doses of antioxidant supplements and the number of different antioxidant supplements used.

Oxidative stress can be mitigated to a degree through training. In marathon runners, free radicals generated during exercise up-regulated the expression of antioxidant enzyme systems (Gomez-Cabrera et al, 2006). Also, in other studies, endurance, anaerobic and mixed exercise training programs reduced post-exercise oxidative stress. The positive effects of training are seen in antioxidant enzyme systems in muscle, fat, plasma, liver and heart (Finaud et al, 2006; Aksoy et al, 2006). In one study in minimally trained dogs, the antioxidant mechanisms were insufficient to meet the antioxidant needs associated with repetitive endurance exercise (Hinchcliff et al, 2000). Not surprisingly, training matters. Many hunting dogs have a leisurely lifestyle for most of the year, associated with being the family pet. However, on the opening day of hunting season, they are expected to function at peak athletic and olfactory performance. Such dogs should have adequate levels of antioxidants in their food. Better yet, combine that recommendation with a preseason exercise-training program. It should be noted that free radicals appear to also have a physiologic function and total mitigation of reactive oxygen molecules can negatively affect certain types of exercise performance. In human subjects, free radicals have been shown to have a regulatory function at the vascular level, causing vasodilatation (Richardson et al, 2006). Excessive doses of antioxidants have been shown to impair muscle force production (Stone and Yang, 2006). When racing greyhounds were supplemented with high doses (1 g/day) of vitamin C, they ran slower (Marshall et al, 2002). Racing greyhounds also ran slower when supplemented with high doses of vitamin E (1,000 IU/day) but not lower doses (100 IU/day) (Hill et al, 2001).

Besides interfering with normal redox signaling, high doses of antioxidants, particularly of individual antioxidant supplements, can be counterproductive in a different way. Single antioxidant supplementation can have a pro-oxidant effect. For example, as part of its antioxidant function, vitamin E temporarily becomes a radical species known as the α-tocopherol radical. Normally, co-antioxidants, such as vitamin C, reduce the α-tocopherol radical back to α-tocopherol. If co-antioxidants are absent or decreased, the α-tocopherol radical can exhibit pro-oxidant activity (McNaulty et al, 2005). Antioxidant balance is important because supplementation with large amounts of a single antioxidant may change the balance to one of a pro-oxidative state. High doses of vitamin C and selenium may act as pro-oxidants (Atalay et al, 2006). Multi-nutrient antioxidant supplementation using lower doses is a better approach.

Commonly supplemented food-source antioxidants include vitamins E and C, β-carotene and other carotenoids, selenium and thiols. Fruits and vegetables are good sources of flavonoids, polyphenols and anthocyanidins. The following recommendations, however, will focus on vitamins E and C and selenium as antioxidant key nutritional factors because: 1) they are biologically important, 2) they act synergistically and 3) there is published information regarding safety and inclusion levels.

VITAMIN E

Vitamin E is the primary lipid-soluble antioxidant in plasma, erythrocytes and tissues (NRC, 2006). It is transported in plasma proteins and partitions into membranes and fat storage sites where it is one of the most effective antioxidants for protecting polyunsaturated fatty acids from oxidation. The minimum DM requirement for vitamin E for foods for adult dogs is 30 mg/kg (NRC, 2006). Research indicates that a higher level of vitamin E confers specific biologic benefits. In minimally trained sled dogs, 136 IU of vitamin E/kg was not enough to maintain normal vitamin E levels in plasma after three successive 58-km exercise runs (Hinchcliff et al, 2000). In another sled dog study, 400 IU vitamin E/day in conjunction with β-carotene and lutein resulted in increased plasma concentrations of antioxidants and decreased DNA and lipoprotein oxidation (Baskin et al, 2000). In a study that measured plasma vitamin E concentrations in racing-sled dogs during the 1998 Iditarod Race, dogs that had high pre-race vitamin E concentrations were almost twice as likely to finish the race (Piercy et al, 2000). These results could reflect a higher vitamin E intake and/or better fitness and a resultant higher anaerobic threshold. As noted above, unchecked oxidative stress can result in muscle fatigue. Endurance exercise in sled dogs results in considerable oxidative stress (Hinchcliff et al, 2000). Trained subjects present a higher vitamin E status whereas overreaching seems to decrease it (Finaud et al, 2006).

Based on antioxidant biomarker studies in non-exercising dogs, for improved antioxidant performance, dog foods should contain at least 500 IU/kg of DM vitamin E (Jewell et al, 2000). For a 25-kg dog engaged in moderate exercise for several hours/day, this would amount to approximately 250 IU/day. Compared to the amounts in the studies mentioned above, this is not an excessive amount.

VITAMIN C

Vitamin C is the most powerful reducing agent available to cells. As mentioned above, it is an important co-antioxidant because it regenerates oxidized vitamin E. Besides regenerating vitamin E, vitamin C also: 1) regenerates glutathione and flavonoids, 2) quenches free radicals both intra- and extracellularly, 3) protects against free radical-mediated protein inactivation associated with oxidative bursts of neutrophils, 4) maintains transition metals in reduced form and 5) may quench free radical intermediates of carcinogen metabolism.

Dogs can synthesize amounts of vitamin C required for maintenance (Innes, 1931; Naismith, 1958; Chatterjee et al, 1975) and they can rapidly absorb supplemental vitamin C (Wang et al, 2001). However, in-vitro studies indicated that dogs (and cats) have from one-quarter to one-tenth the ability to synthesize vitamin C as other mammals (Chatterjee et al, 1975). Whether or not this translates to a reduced ability in vivo is unknown.

Studies in exercising people and horses have shown improvements in indicators of oxidative stress associated with exercise

Box 18-6. Vitamins, Minerals and Exercise.

Although vitamins and minerals are obviously important for exercise, it is unclear if exercise alters the requirements for these nutrients. Additionally, some vitamins and minerals are believed to be beneficial as ergogenic aids. Unfortunately, little well controlled research has been conducted in this area and current results are conflicting.

Exercise-induced increases in demand have been suggested for nearly all of the B-complex vitamins. Many of these compounds are used as cofactors in key enzymes of energy-generating pathways; others function in tissue synthesis and repair initiated by exercise. Likewise, the demand for vitamin C has been postulated to increase due to its role in L-carnitine and collagen synthesis and its antioxidant functions. Exercise may also hasten the excretion of water-soluble vitamins because exercise increases total body water turnover. Five to 10 times maintenance levels of the water-soluble vitamins have been safely fed to working dogs.

High consumption of polyunsaturated fatty acids (PUFA) and increased oxygen metabolism may also increase a working or sporting dog's risk for oxidative damage of cell membranes. Such damage may induce myodystrophy and decrease endurance. Increased intake of antioxidants is recommended for prophylaxis. At present, there is no evidence to indicate that exercise increases dietary requirements for vitamins D and K.

Metabolic acidosis induced by lactic acidosis associated with strenuous work may increase excretion of calcium, magnesium and potassium. Foods containing low levels of magnesium (but at levels above the minimum Association of American Feed Control Official's allowance) resulted in clinical signs of magnesium deficiency in greyhound dogs. These signs were alleviated when foods containing magnesium at 0.12% of the dry matter (DM) were fed.

Canine athletes fed high-fat foods or those whose food is supplemented with meat (as is common with greyhounds and sled dogs) may require additional calcium. The high level of fat in performance foods enhances the formation of insoluble calcium soaps, thus rendering a portion of the ingested calcium unavailable. Additionally, red meat is rich in phosphorus and nearly devoid of calcium. Meat supplementation may thus require calcium supplementation to maintain a normal calcium content and calcium-phosphorus ratio in the diet. Dietary calcium levels of 1.2 to 2.0% of a food's DM have been successfully fed to working dogs. Very high-fat foods with lower calcium concentrations may be deficient in available calcium. Excessive calcium supplementation may also predispose a dog to zinc deficiency by inhibiting absorption of this nutrient (Chapter 32).

The requirement for iron is also thought to increase with exercise. Commercial performance foods and foods supplemented with substantial quantities of red meat should easily meet this increased demand. In such instances, iron supplementation is contraindicated because it may irritate the lower gastrointestinal tract and predispose canine athletes to develop bloody diarrhea.

Large doses of vitamins and minerals individually or in combination have not been demonstrated to increase the physical capabilities of human or canine athletes. Dietary intake of these nutrients should be aimed at meeting increased physiologic requirements rather than attempting to produce an unproved pharmacologic enhancement of performance.

Several considerations must be weighed when determining the optimal vitamin and mineral content of a performance food. One must estimate the availability and the tolerance levels of these nutrients as well as possible nutrient interactions. For example, iron and zinc must be present in proper proportions; an excess of one may lead to a relative deficiency of the other because they share a common mechanism of absorption. Similarly, a disproportionate supplementation of one fat-soluble vitamin may inhibit absorption of the others. The concentrations and types of energy-producing nutrients in the food can also influence vitamin and mineral requirements. As mentioned, PUFA intake can alter the demand for vitamin E and selenium.

Although dogs have no known dietary vitamin C and L-carnitine requirement, some researchers argue that canine athletes may be unable to synthesize adequate quantities of these nutrients to meet the metabolic demands of extremely hard work. It is also unclear whether requirements for vitamins and minerals increase in proportion to caloric intake or whether they approach an asymptote. Further research is needed to resolve these issues.

Those wishing to supplement with vitamins and minerals are advised to do so carefully. Such supplementation should only be undertaken with knowledge of nutrient availability, interactions and tolerance levels because dietary overcompensation of these nutrients may be as detrimental to performance as dietary deficiencies. One report noted that a mineral mixture solution containing potassium, phosphorus, sodium, magnesium, copper and iron given free-choice to exercising dogs caused diarrhea.

as a result of vitamin C supplementation (Goldfarb et al, 2005; White et al, 2001). However, as mentioned above, a study in greyhounds that were supplemented with high doses of vitamin C resulted in slower racing times. As mentioned previously, multi-nutrient antioxidant supplementation using lower doses is a better approach than using high doses of a single antioxidant supplement. To augment antioxidant protection, in conjunction with recommended levels of vitamin E above, improved antioxidant performance foods for working and sporting dogs should contain between 150 to 250 mg of vitamin C/kg (DM). The upper end of this range would be about 70 to 100 mg/day for a 30-kg dog. This is about 7 to 10% of the amount (1 g/day) that slowed race times in the greyhound study described above.

SELENIUM

Glutathione-peroxidase is a selenium-containing antioxidant enzyme that defends tissues against oxidative stress by catalyzing the reduction of H_2O_2 and organic hydroperoxides and by sparing vitamin E. In people, following eccentric exercise-

Box 18-7. Electrolytes and Exercise.

Electrolytes are integral components of nearly all chemical reactions and transmembrane transport systems. About one-third of basal energy requirement is expended to maintain electrolyte concentration gradients across cellular membranes. The narrow range within which these concentrations are regulated and the high cost of achieving this regulation is evidence of their biologic significance. The electrolytes sodium, potassium and chloride are involved in control of fluid balance, maintenance of normal muscle and nerve excitability and acid-base status.

The electrolytes (primarily sodium) play a major role in regulation of total body water. Hyperosmolality stimulates thirst and causes the kidneys to conserve water. In cases of electrolyte depletion, aldosterone may reduce renal losses by stimulating tubular reabsorption of sodium and water. Sodium depletion occurs commonly in horses, people and other mammals that sweat; however, exercise-related loss of sodium may also be significant in canine athletes. The amount of sodium lost via saliva in exercising dogs depends on salivary flow rate. As salivary flow increases, the osmotic concentration of the initially hypotonic saliva increases; saliva approaches isotonicity with plasma at maximum flow rates. Warm or humid conditions that elicit increased salivary flow rates during exercise may also significantly increase sodium, bicarbonate and chloride losses.

Abnormal electrolyte concentrations impair physical performance by altering membrane potentials across muscle and nerve cells, and altering the functions of catalytic and contractile proteins. These changes hinder performance by diminishing the rate of energy and force generation. They also interfere with heat dissipation, which is particularly impaired by increases in plasma osmolarity.

Either water or an electrolyte solution may be used to maintain or replace fluid-electrolyte losses during and after exercise. Electrolyte solutions, while popular, are of limited value for most dogs eating a balanced food. Additionally, there is much debate about the proper concentration of these solutions. Hypertonic and even isotonic solutions administered orally may not return postexercise plasma osmolarity to normal. These solutions may encourage water transfer into cells if they are more hypertonic than the fluid of the interstitial spaces. Such fluids may lead to gastrointestinal cramping, vomiting and diarrhea and thus exacerbate dehydration. Anecdotally, even isotonic solutions administered before exercise have been associated with snow “dipping” or ingesting snow during sled-dog races. This phenomenon may be caused by the effect of the electrolyte solution on plasma osmolarity and thus thirst. Snow dipping is considered undesirable in racing dogs because it disturbs the rhythm and speed of the team.

Proponents of electrolyte supplementation note that in proper concentrations, such solutions increase fluid palatability and the rate of fluid absorption from the gut. Some argue these solutions may help maintain plasma volume during exercise and may aid in its restoration in the postexercise period. Because diarrhea is a common disorder among working dogs, the use of electrolyte replacement solutions may play a role in the clinical management of these cases.

Clearly, more research is needed before recommendations can confidently be given about the administration of electrolyte solutions to canine athletes before, during and after exercise. Under nearly all conditions, it is more important to replace water losses. Under conditions where electrolyte administration is deemed beneficial, it is safer to err on the side of hypotonic rather than hypertonic oral supplementation.

induced muscle injury, suboptimal selenium status worsens muscle functional decrements (Milias et al, 2006). The minimum requirement for selenium in foods for dogs is 0.10 mg/kg (DM) (Wedekind et al, 2002). Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at much higher levels (five to 10 times) than the human recommended allowance or minimal requirement (Combs, 2001; Neve, 2002). Several mechanisms have been proposed for this effect, including enhanced antioxidant activity via glutathione peroxidase (Neve, 2002). Therefore, for increased antioxidant benefits, the recommended range of selenium for dog foods is 0.5 to 1.3 mg/kg (DM). There are no data to base a safe upper limit of selenium for dogs or cats, but for regulatory purposes, a maximum standard of 2.0 mg/kg (DM) has been set for dog foods in the United States (AAFCO, 2007).

Other Nutritional Factors

Vitamins, minerals and electrolytes play important roles in maintaining homeostasis and chemical reactions during exercise (**Boxes 18-6** and **18-7**). However, they are of secondary concern when feeding canine athletes and are found in adequate amounts in most commercial foods. Likewise, the acid-base composition of the food and base loading may also affect performance (**Box 18-8**); however, these effects are poorly understood in canine athletes. Deficiencies of vitamin A, iodine and zinc have been associated with disturbances of smell in people (Mattes, 1999) but are not of practical concern in dogs being fed commercial foods.

FEEDING PLAN

The feeding plan should be formulated based on realistic and quantifiable nutritional objectives after the patient, food and feeding method have been assessed. The feeding plan guides the selection of foods and feeding methods.

Assess and Select the Food

Although the working or sporting dog's nutritional needs could conceivably be met by many different dietary approaches, all foods for canine athletes (performance foods) should share a few important characteristics. First, the food should be calori-

Jacques Debraekeleer

"The smallest feline is a masterpiece."
Leonardo da Vinci

INTRODUCTION

Cats were probably domesticated between 1600 and 1500 BC. Early Egyptians considered cats sacred and valued them for their natural hunting and predatory behavior, which helped control rodent populations. Little consideration for the nutritional needs of cats was required during the early days of domestication. As domestic cats evolved from mouse catcher to household companion, the need to understand their unique nutritional requirements also increased. Today, it is well accepted that proper nutrition and care throughout life maximizes health, longevity and quality of life. Providing proper guidance about the nutritional management of cats requires an understanding of: 1) the basic principles of nutrition (Chapters 5 and 6), 2) the foods and nutrients commonly fed to cats, 3) how to assess nutrient availability and quality of various foodstuffs and foods, 4) foods and feeding practices that may positively or negatively affect health and 5) the unique nutritional needs of cats throughout the lifecycle.

Demographics

Cats are the most popular pets in the United States, totaling approximately 77 million (APPMA, 2003). More than one-third of the households in the U.S. own cats with an average of 2.1 cats per cat-owning household. In 1996, the ratio of male to female cats was roughly equal and nearly 80% of pet cats in the U.S. were neutered (**Table 19-1**) (Lund et al, 1999). **Table 19-2** lists the 10 countries with the largest pet cat populations. Mixed-breed cats, domestic shorthairs and longhairs, make up an estimated 95% of the world's domestic cat population. They result from random rather than selective breeding. Domestic shorthair and longhair cats display a wide variety of sizes, and coat colors, patterns and lengths. Although most cats in the U.S. are non-pedigreed, the Cat Fanciers Association registered 41 different breeds in 2005. The four most common breeds were Persians, Maine coons, Siamese and Abyssinians (CFA, 2005).

Compared with dogs, cats make up a smaller proportion of the pets seen by veterinarians, but that proportion is increasing. Now, nearly 68% of cat owners in the U.S. regularly use veterinary services. In 2001, cats visited veterinary clinics once per year compared with 0.79 visits per year in 1987 (Center for Information Management, 2002). In 2001, cat owners spent \$6.3 billion toward the health and well being of their cats. Cat food sales followed the upward trend in cat ownership and health care with almost \$4.3 billion of sales in the U.S. in 1997

Table 19-1. Age and gender distribution of cats in the United States (1996).*

	Status	% of population
Gender	Male	9.7
	Neutered male	41.2
	Female	11.7
	Spayed female	34.4
Age (years)	0-1	25.7
	1-4	27
	4-7	17.6
	7-10	12
	10-15	13.4
	15+	4.4

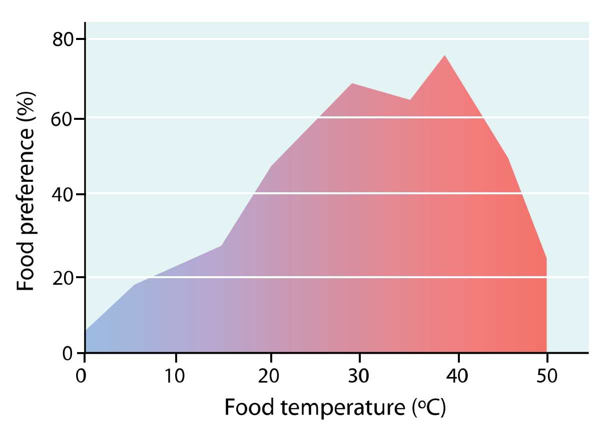

Figure 19-1. Influence of food temperature on food preference in cats (mean food preference demonstrated by 23 cats fed moist food at various temperatures vs. the same food at 20°C [68°F]). Note how preference increases for food served at body temperature but decreases when food is served at temperature extremes. (Adapted from Sohail MA. The ingestive behavior of the domestic cat–A review. Nutritional Abstracts and Reviews Series B 1983; 53: 177-186.)

(Maxwell, 1998). The greatest growth occurred in dry cat foods and treats, whereas sales of moist foods were static, and sales of semi-moist products decreased. Pet owners are very interested in nutritional information. In one pet owner survey, interest in obtaining nutritional information equaled obtaining information about diseases. Furthermore, the pet owners' top two preferred sources of pet health information were the Internet and veterinarians (MAF, 2005).

CATS AS CARNIVORES

Taxonomically, cats and dogs are members of the order Carnivora and are therefore classified as carnivores (Table 12-4). From a dietary perspective, however, dogs are omnivores (Chapter 12) and domestic cats and other members of the superfamily *Feloidea* are strict or true carnivores, along with raptors, mosquitoes and some coldwater fish. This basic difference is supported by specific behavioral, anatomic, physiologic and metabolic adaptations of cats to a strictly carnivorous diet.

Adaptations in Feline Feeding Behavior

Domestic cats share several feeding behaviors with their wild counterparts. Unlike most mammals, cats do not display a regular daily rhythmicity in sleep-wake cycles, activity, feeding and drinking. Cats typically eat 10 to 20 small meals throughout the day and night (Kane et al, 1981; MacDonald et al, 1984). This eating pattern probably reflects the evolutionary relationship of cats and their prey. With the exception of African lions, cats are solitary hunters. Small rodents (e.g., voles and mice) make up 40% or more of feral domestic-type cats' food source; however, young rabbits and hares may compose a large portion of their natural diet (Fitzgerald, 1988). A variety of other prey (e.g., birds, reptiles, frogs and insects) is also eaten, but in smaller amounts. The average mouse provides approximately 30 kcal (125 kJ) of metabolizable energy (ME) (Mugford, 1977). This amount is about 12 to 13% of a feral cat's daily energy requirement. Repeated cycles of hunting throughout the day and night are required to provide sufficient food for an average cat. Thus, meal feeding cats once per day is in conflict with their natural feeding behavior.

The predatory drive is so strong in cats that they will stop eating to make a kill (Adamec, 1976). This behavior may frustrate owners who confuse predatory behavior with hunger (**Box 19-1**). Many owners reason that a fed cat will not hunt and are disappointed when their housecat kills songbirds. Supplemental feeding may reduce hunting time, but otherwise does not alter hunting behavior (Turner and Meister, 1988).

Cats are very sensitive to the physical form, odor and taste of foods. Oral tactile sensation is important to normal feeding behavior and should be considered when feeding novel foods. Unless accustomed to foods with different textures such as dry foods, cats generally prefer solid, moist foods and reluctantly accept food with powdery, sticky and very greasy textures (NRC, 2006, 1986; Kane et al, 1981a). The flavor and texture preferences of individual cats are often influenced by early experience

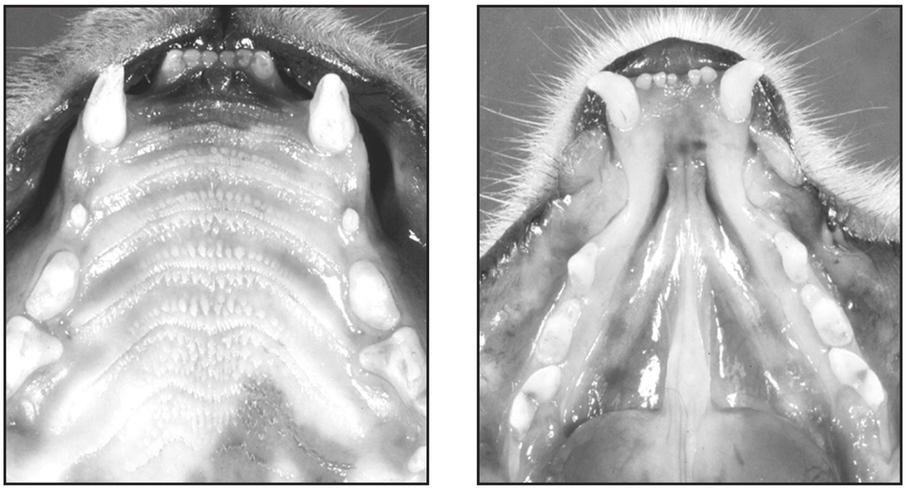

Figure 19-2. Maxillary dentition and hard palate of a cat (Left). Mandibular dentition and sublingual mucosa of the same cat (Right). These photographs demonstrate tooth anatomy associated with a carnivorous eating behavior. The canine teeth are slightly curved and taper to a pointed tip suitable for grasping and puncturing prey. The premolar and molar teeth are conical and sharply pointed, making them suitable for shearing and tearing flesh. There are no grinding (flat, table) surfaces present. (Adapted with permission from Harvey CE, Emily PP, eds. Function, formation, and anatomy of oral structures in carnivores. In: Small Animal Dentistry. St. Louis, MO: Mosby-Year Book, 1993.)

that can affect preferences throughout life. Cats accustomed to a specific texture or type of food (i.e., moist, dry, semi-moist) may refuse foods with different textures. This becomes an important consideration when feeding cats novel foods.

Cats find certain flavors very attractive, which seems to reflect the nutritional characteristics of their natural foods. Cats prefer the tastes of animal fat, protein hydrolysates (digests), meat extracts and certain free amino acids abundant in muscle tissue (i.e., alanine, proline, lysine, histidine and leucine). Cats search out wild prey more often when meat is not in their diet (Robertson, 1998). Even the feeding behaviors of cats in the wild reflect their preference for animal tissues. When ingesting prey, wild cats avoid consuming plant materials contained in the entrails. African lions have been observed to first empty the digesta from the entrails by expressing the contents with their tongues (Leyhausen, 1979). This behavior contrasts with that of a pack of wild dogs or wolves eating similar game. Wolves often first consume the viscera of prey (Mech, 1970). Herbivores are common prey; therefore, the gastrointestinal contents are generally of plant origin and have a high carbohydrate content. Unlike dogs and other omnivores, cats are not attracted to the taste of sugars and are averse to flavors derived from plant products (e.g., glutamic acid and medium-chain triglycerides) (MacDonald et al, 1984). Cats are also sensitive to bitter tastes when compared to tastes of other species (Carpenter, 1956). A great deal of variation in preference is apparent in the cat population; owners often report that cats have an appetite for cantaloupe, pumpkin, bananas or celery.

Food temperature also influences food acceptance by cats (**Figure 19-1**). Cats prefer that moist foods be offered at, or near, body temperature (38.5°C [101.5°F]). This preference is logical considering that in the wild, a cat's food typically consists of freshly killed prey.

Anatomic and Physiologic Adaptations

Sensory Structures

Cat eyes are well adapted to hunting. Their visual acuity is greater than that of dogs because of their larger optic cortex. A cat's ears are upright, face forward and have 20 associated muscles to provide the fine control needed to precisely locate sound. Cats also respond to high-pitched sounds, which represent the range of sound frequencies emitted by typical prey (Tabor, 1983). Finally, the highly sensitive facial whiskers and tactile hairs are thought to help cats hunt in dim light and to protect their eyes.

Limbs

The retractable claws of cats are a unique adaptation to hunting. The sharp tips of the claws with hook-like curves and needle features are ideal for capturing and securing prey, yet they are easily retracted so they do not make noise when cats stalk prey. In contrast, the claws of dogs play only a secondary role in capturing prey.

Oral Cavity

Cats and dogs have the same number of incisor, canine and carnassial teeth (i.e., the enlarged upper premolar and lower molar teeth specialized for shearing flesh); however, cats have fewer premolar and molar teeth, and they do not possess fissured crowns, which are a hallmark of omnivorous animals (**Figure 19-2**). The jaws of cats have limited lateromedial and craniocaudal movement, thereby limiting grinding ability. The scissors-like action of the carnassial teeth is ideal for delivering the cervical bite used to transect the spinal cord and immobilize or kill prey. Cats lack salivary amylase used to initiate digestion of dietary starches. This adaptation reflects the nutritional composition of the typical prey (i.e., low starch content).

Stomach

Because cats evolved to eat small frequent meals, the stomach is less important as a storage reservoir compared with the stomach of dogs. Thus, the stomach of domestic cats is simpler than that of dogs (i.e., relatively smaller with a smaller glandular fundus).

Small and Large Intestine

Intestinal length, as determined by the ratio of intestine to body length, is markedly shorter in cats than in omnivores and herbivores (**Table 19-3**). A greater villus height in cats increases the absorptive surface area. Overall, however, the absorptive capacity is estimated to be 10% less than that of dogs (Kendall et al,

Box 19-1. Alternative Eating Behaviors.

Although there are such things as aberrant eating behaviors, many of the behaviors observed are normal behaviors that owners happen to find objectionable.

COPROPHAGIA

Coprophagia, or consumption of excreta, is normal behavior for queens with kittens less than 30 days of age. The queen stimulates the kittens' elimination reflexes by grooming the kittens' perineal areas and then consumes the products of elimination. This process is important as an aid to elimination in young kittens. In addition, coprophagia maintains sanitation and reduces odors in the nest area. Thus, coprophagia has important survival value in wild or feral cats by reducing factors that could attract predators to the nest site. It is very uncommon for cats to continue coprophagia after the kittens are weaned.

CANNIBALISM/INFANTICIDE

Cannibalism or infanticide is often normal behavior in male and female cats. Queens typically cannibalize aborted, dead and weak kittens. This behavior may serve to reduce the spread of disease to healthy kittens, conserve maternal resources and optimize survival of the fittest kittens and help keep the nest box clean. In addition, the queen derives nutritional benefits from consuming dead kittens. Occasionally, queens will kill an apparently healthy litter. Environmental factors that cause kittens to mimic early signs of illness (e.g., inactivity, hyperthermia or hypothermia) may trigger infanticide and cannibalism. Maternal stress, malnourishment and hormonal insufficiency may contribute to unexplained cannibalism as well. Maternal experience or parity does not appear to play a role.

Tomcats may indiscriminately kill unrelated kittens. This behavior usually occurs when a strange male enters a new territory and encounters a lactating queen and kittens. A queen rapidly returns to estrus after the loss of its kittens. Thus, infanticide optimizes a male's genetic potential because it now has an opportunity to sire subsequent litters. Infanticide is an uncommon behavior by resident male cats.

The health status, dietary management and husbandry practices should be reviewed in queens or catteries experiencing persistent problems with cannibalism. Males should not have access to young kittens to reduce the chance of infanticide. Although resident male cats rarely pose a problem, it is prudent to err on the side of safety. Factors contributing to maternal stress should be evaluated and, if possible, reduced.

PLANT AND GRASS EATING

Plant and grass eating is a natural behavior of both cats and dogs. A variety of explanations have been advanced for grass eating. Because grass is not digested within the cat's gastrointestinal (GI) tract, it acts as a local irritant and sometimes stimulates vomiting. Thus, grass eating may serve as a purgative to eliminate hair or other indigestible material. However, many cats readily seek out grass to eat, appear to enjoy eating it and do not vomit. Other explanations for the behavior include a response to nutritional deficiencies, boredom or a taste preference. In contrast to eating grass, eating other plants, including many indoor ornamental plants, carries risk of toxicity (e.g., lily toxicity).

RESPONSE TO CATNIP

The smell or ingestion of catnip (*Nepeta cataria*) can invoke unusual behavioral changes for five to 15 minutes after exposure. The active ingredient, cis-trans-nepetalactone, is thought to act as a hallucinogen although stimulation of neurologic centers associated with estrous behaviors has also been suggested. Cats may respond to catnip by head rubbing and shaking, salivating, gazing, skin twitching, rolling and animated leaping. Only 50 to 70% of cats exhibit a behavioral response, which may have a genetic basis. Prolonged exposure may lead to a chronic state of partial unawareness. Cats may become refractory for an hour or more after cessation of the initial response.

WOOL SUCKING

A commonly reported behavioral abnormality in cats is wool sucking. The behavior first appears near puberty when cats begin to lick, suck, chew or eat wool or other clothing articles. Although the cause is poorly understood, nutritional deficiencies are unlikely. Affected cats may be seeking the odor of lanolin or human sweat or the behavior may be a manifestation of prolonged nursing. Siamese, Siamese-cross and Burmese cats are primarily affected, suggesting a genetic link. Wool sucking is managed by limiting access to attractive items and through behavior modification. Feeding a high-fiber food or providing a continuous supply of dry food reduces the behavior in some cats.

PROLONGED NURSING

Prolonged nursing may occur in kittens that strive to satisfy a desire for non-nutritional sucking. Non-nutritional sucking normally subsides near weaning. Kittens may develop nursing vices when nursing fails to take place because they were orphaned, prematurely weaned or required bottle feeding. Within the litter, kittens will often nurse tails, ears, skin folds and/or the genitalia of their littermates. After a kitten is separated from its litter, it may transfer sucking vices to people, stuffed toys, clothing or other pets.

1982; Morris and Rogers, 1989). Therefore, dogs can more efficiently use a variety of foods, some of which may require more digestion than animal tissues.

Unlike in omnivores, the sugar transport systems of the small intestine of cats are not adaptive to varying levels of dietary carbohydrate (Buddington and Diamond, 1992). Cats do not waste energy or protein by turning over carriers or enzyme systems of little value because free sugars and complex carbohydrates normally make up a negligible percentage of their food (**Table 19-4**). This lack of adaptability has been noted in other strict carnivores, such as raptors and coldwater fish. Also, cats have low activities of intestinal disaccharidases (i.e., sucrase, maltase and isomaltase) (Kienzle, 1993). This reflects adaptation to foods limited in simple sugars and other carbohydrates. In cats, pancreatic amylase production is about 5% of that in dogs (Kienzle, 1987, 1993a). Pancreatic amylase production is relatively nonadaptive in cats, as would be expected in a species unaccustomed to significant changes in dietary carbohydrate levels. Cats have higher concentrations of bacteria in their small intestine than dogs and other omnivores studied (Johnston et al, 1993, 2001; Gruffydd-Jones et al, 1998). Interestingly, the numbers typical for cats would be diagnostic for small intestin-

ANOREXIA

Although a few days of inappetence is not particularly detrimental to an otherwise healthy cat, prolonged inadequate calorie intake results in malnutrition, reduced immune function and increased risk for hepatic lipidosis. Anorexia may be caused by stress, unacceptable foods or concurrent disease. Most commonly, cats presented to veterinarians for anorexia have a concurrent disease. Cats may endure prolonged starvation rather than eat an unpalatable food. Therefore, advising owners that a cat will "eat when it gets hungry enough" can have deadly results. Anorexia of more than three days duration, even in an otherwise healthy-appearing cat, warrants investigation by a veterinarian.

A thorough history is useful for differentiating potential causes of anorexia. To determine if inadequate food acceptance is the cause, offer a small selection of highly palatable foods along with the typical food. Because improperly stored foods may develop off flavors, bacterial contamination or fungal growth, confirm that the product is fresh and wholesome. Environmental or emotional factors reported to result in stress-mediated anorexia include hospitalization, boarding, travel, introduction of new people or pets to the household, loss of a companion, overcrowding, high temperatures and excessive handling. Stress-mediated anorexia is usually diagnosed from the history and by ruling out other diseases. Providing a quiet secluded area will often allow a cat to relax sufficiently enough to begin eating. Often, increasing the food's palatability will improve food intake. Warming food, changing the food form, adding water or choosing foods high in animal protein and fat can enhance food palatability. If cats are highly stressed or appropriate feeding sites are unavailable, mild tranquilizers or appetite stimulants (e.g., mirtazapine, oxazepam or cyproheptadine) may be beneficial (Chapter 25). Force feeding may be accepted by some cats but others find the process so stressful that any benefit is far outweighed by the additional stress.

FIXED-FOOD PREFERENCES

The food type fed by the owner during a kitten's first six months influences the pattern of food preferences throughout life. Although uncommon, kittens exposed to a very limited number of foods may develop a food fixation, refusing to eat anything but a single food. Adult cats fed highly palatable, single-item foods have been reported to develop fixed-food preferences as well.

Cats with food fixations can be particularly troublesome if dietary modifications are necessary. Cats with strong food preferences should be transitioned to the new food over a prolonged period. Convert to the desired food by replacing 10 to 20% of the old food with an equal amount of the new food on Day 1, then gradually increase the ratio of new to old over the next 14 days. A more gradual transition may be required if food intake drops below 70% of maintenance levels. Cats should be monitored to ensure they are not selecting the preferred food from the food dish and that food intake remains adequate. Feeding kittens and cats a variety of foods (both different forms of food and different brands) and not feeding single-item foods can avoid food fixations. This approach is strongly recommended as disease management later in life often requires a dietary change.

LEARNED TASTE AVERSIONS

Cats may develop learned aversions to certain foods when feeding is paired with a negative GI experience. The negative experience can be physical, emotional or physiologic. Typically, aversions occur when cats consume a food immediately before an episode of nausea or vomiting. Foods that were readily consumed before the negative incident will be avoided subsequently. Clinically, aversions may develop when GI upset is induced by various diseases, drugs or treatment protocols. Foods with high salience (i.e., strong odors or high protein levels) are more likely to become aversive and should not be fed within 24 hours of anticipated GI upsets. Aversions have been documented to last up to 40 days in cats. Learned aversions are considered an adaptive response. By avoiding foods that previously caused gastric distress, cats will avoid eating foods likely to be spoiled or tainted. From a clinical perspective, consideration of food aversions often equates to delaying introduction of a therapeutic food, such as a diet for chronic kidney disease, until the cat's GI signs have been controlled with other medical management.

POLYPHAGIA

Various diseases, drugs and psychological stresses can mediate excessive food consumption. Rarely, polyphagia (hyperphagia) may occur with diseases involving the central nervous system, particularly with lesions of the ventromedial hypothalamus. Presence of weight loss or gain is of key diagnostic importance. Polyphagia with weight loss is almost always associated with an underlying disease process or simple underfeeding. Caloric intake should always be calculated because underfeeding can result in a ravenous appetite that may be misinterpreted as abnormal. Nutritional management of polyphagia requires an accurate diagnosis because treatment is aimed at the primary disease.

al bacterial overgrowth in dogs (NRC, 2006). Although the reason for this finding is unclear, their relatively short small intestine and carnivorous physiology have been suggested as possibilities. Increased numbers of small intestinal bacteria might enhance protein and fat digestion (Zoran, 2002).

Certain amino acid transporters in the small intestines of cats are highly adaptable, particularly the transporter responsible for arginine uptake. This finding underscores the importance of the amount of protein and specific amino acids in foods for cats. Unlike omnivores, cats are unable to synthesize significant quantities of ornithine or citrulline within the intestine. Both are precursors to arginine synthesis. This inability results in the absolute requirement for arginine in cat foods, which is discussed below.

Cats have a vestigial cecum and a relatively short colon (0.4 m). These anatomic features would appear to limit cats' capability to use poorly digestible starches and fiber by microbial fermentation in the large bowel (Morris and Rogers, 1989). The primary end products of bacterial fermentation (i.e., short-chain fatty acids: acetate, propionate and butyrate), however, are present in relatively high concentrations in the large bowel of cats (Brosey et al, 2000). Large intestinal fermentation may be

more important to cats than previously thought.

Feline Nutrient Requirements and Metabolic Adaptations

Energy Metabolism

The liver of most animals has two enzyme systems for converting glucose to glucose-6-phosphate: hexokinase and glucokinase. This conversion is necessary before the liver can use glucose. The glucokinase system operates only when the liver receives a large amount of glucose from the portal vein. Because the typical food source of wild cats is primarily animal not plant tissue, it contains only small amounts of digestible (soluble) carbohydrate and the portal system delivers very little absorbed glucose to the liver. Thus, adult cats have very low hepatic glucokinase activity and a limited ability to metabolize large amounts of simple carbohydrates. Omnivores (e.g., people, dogs and rats) have higher hepatic glucokinase activity (MacDonald et al, 1984).

Kittens ingest digestible carbohydrates (i.e., lactose or milk sugar) before weaning. Adult cats must rely primarily on gluconeogenesis from glucogenic amino acids (ketoacids), lactic acid and glycerol for maintenance of blood glucose concentration. In omnivores, maximal gluconeogenesis occurs in the post-absorptive state when the direct contribution of dietary glucose is absent. In cats, gluconeogenesis is maximal in the absorptive phase immediately after a meal.

Feline liver apparently lacks fructokinase. This finding is compatible with the observations by Kienzle that cats consuming high-sucrose diets (>25%) have significant fructosuria. The fact that cats, unlike many mammals, have no taste preference for sucrose further supports adaptation to a diet devoid of simple carbohydrates (Kienzle, 1993b).

Protein Metabolism

Protein metabolism is unique in cats and is manifested by an unusually high maintenance requirement for protein as compared with canine requirements (**Table 19-5**) and a special need for four amino acids: arginine, taurine, methionine and cystine. The protein requirement for growth in kittens is only 50% higher than that of puppies, whereas the protein requirement for feline maintenance is twice that of adult dogs. The higher protein requirement of cats is not due to an exceptionally high requirement for any specific amino acid (**Table 19-6**); instead, it is caused by a high activity of hepatic enzymes (i.e., transaminases and deaminases) that remove amino groups from amino acids so the resulting ketoacids can be used for energy or glucose production. Unlike omnivores and herbivores, cats have a limited ability to decrease the activity of these enzymes when fed low-protein foods. The cat's strict adherence to a diet of animal tissue likely resulted in a lack of evolutionary pressure to accommodate lower protein food sources. Hepatic enzyme systems are constantly active; therefore, a fixed amount of dietary protein is always catabolized for energy (MacDonald et al, 1984). The gluconeogenic enzymes in feline liver appear to be continuously active, unlike the situation in most other species, including dogs (MacDonald et al, 1984). In addition, an alternate hepatic gluconeogenic pathway common in flesh-eating animals is active in cats (Beliveau and Freedland, 1982). This pathway uses serine as a glucose precursor. Serine is a nonessential amino acid found in large amounts in muscle, milk and egg.

ARGININE

Arginine deficiency in cats causes one of the most dramatic responses of any nutrient deficiency. Cats cannot synthesize sufficient ornithine or citrulline for conversion to arginine, which is needed for the urea cycle. After a cat eats a meal, the highly active protein catabolic enzymes in its liver produce ammonia, which is absorbed from the colon.

Without arginine, the urea cycle cannot convert ammonia to urea and ammonia toxicity occurs (MacDonald et al, 1984). Eating a single meal devoid of arginine may result in hyperammonemia in less than one hour. Affected cats exhibit severe signs of ammonia toxicity (i.e., vocalization, emesis, ptyalism, hyper-

activity, hyperesthesia, ataxia, tetanic spasms, extended limbs with exposed claws, apnea and cyanosis) and may die within two to five hours (MacDonald et al, 1984). Because the diet of wild cats is high in animal protein (that contains arginine), cats have apparently lost the flexibility in protein metabolism seen in other animal species that eat foods with more limited amino acid composition. Arginine deficiency, however, has only been reported to occur in cats fed experimental foods specifically formulated to be arginine deficient or in cats fed certain casein-based human enteral products (Diehl and Wheeler, 1992). Although not necessarily supporting the argument that cats are carnivores, excess dietary lysine does not cause arginine antagonism in cats, as it can in dogs (Fascetti et al, 2004).

TAURINE

Taurine is a β-amino sulfonic acid, abundant as a free amino acid in the natural food of cats, such as small rodents, birds and fish. Taurine is found at lower concentrations in large animal species such as cattle. In cats, dietary taurine is essential and clinical disease results if insufficient amounts are present. Many species can use either glycine or taurine to conjugate bile acids into bile salts before they are secreted into bile. Cats can only conjugate bile acids with taurine. The loss of taurine in bile coupled with a low rate of taurine synthesis contributes to the obligatory taurine requirement of cats (**Box 19-2**).

METHIONINE AND CYSTINE

The sulfur-containing amino acids methionine and cystine are required in higher amounts by cats than most other species, especially during growth. Cystine is the amino acid formed when a pair of cysteine molecules are joined by a disulfide bond. Methionine and cystine are considered together because cystine can replace up to half of the methionine requirement of cats (NRC, 2006). Methionine serves as a precursor to cysteine; therefore, cysteine is not an essential amino acid. Cysteine cannot be converted to methionine; however, a minimal requirement for methionine must be met with methionine. Although these amino acids are present in high amounts in animal flesh, methionine tends to be the first limiting amino acid in many food ingredients. Nutritional deficiencies are possible, especially in cats fed home-prepared or vegetable-based foods. Clinical signs of methionine deficiency include poor growth and a crusting dermatitis at the mucocutaneous junctions of the mouth and nose. Approximately 19% of a food must be composed of animal protein to meet the methionine requirement of kittens (MacDonald et al, 1984). Foods high in plant proteins require additional methionine, which can be supplied as DL-methionine, a crystalline form of the amino acid. Cats appear to prefer foods with added methionine compared to foods deficient in methionine (Rogers et al, 2004).

Numerous theories have been advanced to explain the high methionine and cystine requirement of cats. Methionine needs may be increased because of an increased S-adenosyl methionine requirement, cysteine synthesis, taurine synthesis or because of a high rate of methionine catabolism. Additional cystine may be required for the synthesis of the antioxidant glutathione and the amino acid felinine. Felinine is a branched-chain, sulfur-containing α-amino acid found in the urine of domestic cats. Its biologic function has not been fully elucidated. The most widely accepted possible role for felinine, or its breakdown product in urine, is as a pheromone, which is of importance in territorial marking. Sexually immature kittens have been reported not to excrete felinine and adult males excrete more

Box 19-2. Taurine.

As a β-amino acid, taurine is neither incorporated into proteins nor degraded by mammalian tissues. However, taurine has important functions in virtually all body systems. In addition to its importance in normal bile salt function, taurine is essential for normal retinal, cardiac, neurologic, reproductive, immune and platelet function. Taurine is needed for normal fetal development and may function as an antioxidant, osmolyte and neuromodulator. Most animal tissues, particularly skeletal muscle, heart, viscera and brain, contain high levels of taurine; plants contain none. Taurine is essential in foods for cats because of two factors.

- The feline liver has a limited capacity to synthesize taurine. The rate-limiting enzymes responsible for conversion of methionine and cysteine to taurine (i.e., cysteine dioxygenase and cysteine sulfinic acid decarboxylase) are minimally active.
- Cats have an obligate loss of taurine via the enterohepatic circulation of bile acids. Taurine is important in the conjugation and secretion of bile acids. Many animals conserve taurine by switching to glycine conjugation when dietary taurine becomes scarce. Feline hepatic enzymes do not use glycine, but conjugate bile acids mostly to taurine. Most bile salts secreted into the intestinal lumen are returned to the liver after intestinal uptake. However, once deconjugated, taurine is available for intestinal uptake, fecal excretion or degradation by intestinal microbes. Microbial degradation appears to account for deconjugation and substantial wasting of free taurine. This process also results in an obligate taurine loss.

The requirement for taurine is influenced by dietary factors and the metabolic needs of cats. The protein source, commercial processing, sulfur-containing amino acid content and dietary fiber levels alter taurine requirements. In general, taurine is abundant in animal tissues and absent in plants; thus, homemade vegetarian diets and cereal-based dog foods have long been known to cause taurine deficiency when fed to cats. However, in 1987, taurine deficiency was reported to occur in cats fed commercial foods containing the National Research Council's recommended levels of taurine (400 mg taurine/kg food). This finding underscored the food-dependent nature of the taurine requirement and prompted an increase in taurine recommendations by the Association of American Feed Control Officials to 1,000 mg/kg and 2,000 mg/kg (ppm) food in commercial dry and moist foods, respectively. However, taurine levels of 2,500 ppm are often recommended for moist products. Taurine adequacy is best established through feeding trials.

Because taurine functions throughout the body, signs of deficiency have been demonstrated in virtually all body systems. Three syndromes of taurine deficiency in cats have been well established: 1) feline central retinal degeneration (FCRD), 2) reproductive failure and impaired fetal development and 3) feline dilated cardiomyopathy (DCM). Hearing loss, platelet hyperaggregation and impaired immune function have also been demonstrated although specific clinical disorders have not been recognized.

CLINICAL SIGNS

Clinical signs of taurine deficiency occur only after prolonged periods of depletion (i.e., five months to two years). Typically in non-reproducing adults, taurine deficiency may manifest as FCRD, DCM or both, with only about 40% of taurine-deficient cats exhibiting clinical signs.[a,b]

Clinical signs of FCRD are inapparent until significant visual impairment has occurred. Then, owners may notice their cat bumping into objects or "miscalculating" jumps. Early disease may be detected during ophthalmic examination. Changes in retinal function can be demonstrated by electroretinograms before retinal lesions appear. The development of FCRD apparently requires three or more months of taurine depletion. Initially, lesions appear as dark granular focal defects in the area centralis, slightly temporal to the optic disk. As degeneration progresses, the lesion becomes hyperreflective and extends in a band across the tapetum. Complete blindness ensues with full degeneration of the retina and attenuation of retinal vessels. Structural changes within the retina are permanent. Therefore, a diagnosis of FCRD does not reflect the current taurine status of a cat, but indicates a period of prolonged taurine deficiency has occurred.

Cats with DCM may be clinically normal or present acutely with signs of heart failure. Clinical signs may include lethargy, anorexia and dyspnea. Physical findings may include pleural effusion, pulmonary edema, gallop heart rhythms, systolic murmurs and ventricular dysrhythmias. Cats in severe heart failure are hypothermic, have pale mucous membranes, poor pulse quality and are often too weak to stand. Only about one-third of cats with DCM have concurrent FCRD. DCM is confirmed by echocardiography. Findings most often include dilatation of the left atrium and ventricle and decreased left ventricle contractility.

REPRODUCTION AND FETAL DEVELOPMENT

Reproduction and fetal development are severely impaired in taurine-deficient queens. Conception and implantation appear normal; however, fetal death is frequently observed near 25 days of gestation, followed by abortion or resorption. In a group of taurine-deficient queens, only 38% of 33 matings resulted in term deliveries, with an average of 2.1 live births.

Developmental abnormalities reported to occur in kittens born to taurine-deficient queens include poor survival, cerebellar dysgenesis, abnormal hind-limb development and thoracic kyphosis, which appears as a dorsoventral flattening of the thoracic cavity. Severe hydrocephalus and anencephaly may be present in aborted fetuses. Surviving kittens are often small and weak. Growth is depressed up to 40% in the immediate postnatal period.

DIAGNOSIS

The diagnosis of taurine deficiency is based on clinical signs and low plasma and whole blood taurine concentrations. Care must be used when evaluating plasma taurine concentrations because levels may be altered by sample handling errors and feeding. Fasting may reduce plasma taurine concentrations, whereas poor handling may allow taurine contamination from platelets and white blood cells. Although plasma taurine concentrations reflect the labile taurine pool, whole blood taurine concentrations better reflect tissue taurine status. Normal plasma taurine levels in cats may vary up to fivefold (50 to 250 nmol/ml). Plasma taurine values less than 40 nmol/ml may suggest taurine deficiency. Cats with clinical signs of deficien-

cy typically have plasma taurine values less than 10 nmol/ml. Therefore, taurine deficiency is best evaluated using whole blood taurine concentrations. Whole blood taurine levels are normally greater than 300 nmol/ml, and values less than 160 nmol/ml are considered deficient, whereas values less than 50 nmol/ml are common. Samples should be collected and submitted according to protocols recommended by the individual clinical laboratory. Care should be used when collecting blood and plasma for taurine analysis. Falsely elevated plasma taurine levels may result from even small amounts of clotting, hemolysis or inclusion of platelets and white cells in the plasma sample. Use of serum for determining taurine status is not recommended because the quantity of taurine in serum varies with the procedure and the time allotted for coagulation and retraction of the clot.

PATHOPHYSIOLOGY

A central uniform mechanism of taurine action has not been determined, and may not exist. FCRD represents a disruption and loss of the photoreceptor outer segment. Within the retina, taurine may stabilize cell membranes, possibly acting as an antioxidant. In DCM, taurine is thought to regulate myocardial calcium flux through ionic channels, thereby regulating myocardial contractility and/or mitochondrial energy production. Taurine may act as a neuromodulator or neurotransmitter in fetal development. Finally, taurine appears to influence reproduction at the level of the uterus and placenta by unknown mechanisms.

TREATMENT

Cats with taurine deficiency should be supplemented with 250 to 500 mg of taurine twice daily to rapidly replete tissue stores. Cats with DCM may show clinical improvement within one to three weeks, whereas FCRD and developmental defects are irreversible.

PREVENTION

The taurine requirement of cats depends on diet composition. Poor-quality protein, Maillard reaction products or other factors that enhance bacterial overgrowth in the intestinal tract may increase the requirement two- to sixfold. Cats require approximately 50 mg of available taurine per day, which can be supplied by high-quality animal tissues or as a crystalline amino acid supplement. Commercial foods are typically supplemented with taurine in addition to the taurine provided naturally by ingredients. Animal feeding trials are essential to ensure dietary taurine adequacy.

than adult females (NRC, 2006). Felinine excretion rates of 95 mg/day have been recorded in intact male cats and may significantly increase the daily sulfur amino acid requirement (Hendriks et al, 1995).

Fat Metabolism

Cats have the ability to digest and use high levels of dietary fat (as is present in animal tissue). Like other true carnivores, cats have a special need for arachidonic acid (AA) (20:4n6) because they have a limited ability to synthesize it from linoleic acid (18:2n6), unlike dogs and other omnivores (MacDonald et al, 1984, 1984a). An exogenous source of AA is especially important for more demanding lifestages, such as gestation, lactation and growth. The basis for this additional requirement is the low hepatic delta-6 desaturase activity in cats (Sinclair et al, 1979). Delta-6 desaturase is the rate-limiting factor in the conversion of linoleic acid to γ-linolenic acid, which is further elongated and desaturated to form AA. AA is abundant in animal tissues, particularly in organ meats and neural tissues, but absent in plants. Thus, the dietary requirement for AA has little consequence if cats consume animal tissues (MacDonald et al, 1984).

Vitamin Metabolism

The vitamin needs of cats differ from those of dogs in several ways. Cats do not convert sufficient amounts of tryptophan to niacin (DaSilva et al, 1952). An animal tissue-based diet is well supplied with niacin from NAD and NADP (nicotinamide-adenine dinucleotide phosphate) coenzymes; therefore, cats don't need to produce niacin from tryptophan. Although cats possess all the enzymes needed for niacin synthesis, the high activity of enzymes in the catabolic pathway (picolinic carboxylase) far exceeds the rate of niacin synthesis (Morris and Rogers, 1983). As a result, the niacin requirement of cats is 2.4 times higher than that of dogs (NRC, 2006).

The prosthetic group of all transaminases is pyridoxine (vitamin B_6) (Stryer, 1975). Cats have high transaminase activities, consistent with consuming a diet from which considerable energy is derived from dietary protein. Therefore, it is logical to expect that their pyridoxine turnover and requirement would be higher than that of omnivores. The pyridoxine requirement of cats is estimated to be 1.7 times higher than that of dogs (NRC, 2006).

Vitamin A occurs naturally only in animal tissue. Plants synthesize vitamin A precursors (e.g., β-carotene). Omnivorous and herbivorous animals can convert β-carotene to vitamin A; cats cannot because they lack intestinal dioxygenase that cleaves β-carotene to retinol. In addition, cats have insufficient 7-dehydrocholesterol in the skin to meet the metabolic need for vitamin D photosynthesis; therefore, they require a dietary source of vitamin D (How et al, 1994, 1994a; Morris, 1996). Vitamin D is relatively abundant in animal liver; therefore, the need for dermal production is minimal and alternate pathways rapidly metabolize 7-dehydrocholesterol. Vitamin D is fairly ubiquitous in animal fats and primary vitamin D deficiency has been identified only in cats fed experimental diets.

Water

Water needs of cats also differ from those of dogs, not because of feline feeding behaviors (i.e., carnivorous vs. omnivorous) but because of their ancestors' adaptation to environmental extremes. Domestic cats are thought to have descended from the African wildcat (*Felis silvestris libyca*), a desert dweller. Several unique features of water balance in cats may be explained by adaptation to a dry environment. Cats are able to survive on less water than dogs and may fail to increase water intake at minor levels of dehydration, up to 4% of body weight (Anderson, 1982). Cats compensate for reduced water intake, in part, by forming highly concentrated urine. Unfortunately, this strong concentrating ability coupled with a weak thirst drive may result in highly saturated urine, increasing the risk of crystalluria or urolithiasis, both components of the feline lower urinary tract disease complex.

Cats consume 1.5 to 2 ml of water/g of dry matter (DM). This 2:1 ratio of water to DM is similar to that of typical prey. This ratio represents approximately 0.5 ml water/kcal ME intake. Practical recommendations for water provision are somewhat higher at 1 ml water/kcal ME. Water ingested from moist foods containing 78 to 82% moisture will result in diuresis.

LIFESTAGE NUTRITION

Lifestage nutrition is the practice of feeding foods designed to meet an animal's optimal nutritional needs at a specific age or physiologic state (e.g., maintenance, reproduction or growth). The concept of lifestage nutrition recognizes that feeding either below or above an optimal nutrient level can negatively affect biologic performance and health (Figure 5-2). This concept differs markedly from feeding a single product for all lifestages (i.e., all-purpose foods), whereby nutrients are added at levels to meet the highest potential need (i.e., usually growth and reproduction). For maximum benefit, risk assessment and preventive plans should begin well before the onset of disease. The value of lifestage nutrition is greater if risk factor management is also incorporated into the feeding practice. A narrower range of nutrient recommendations often emerges when age and physiologic needs are reviewed in conjunction with reducing nutritional risk factors for disease.

Box 19-3. Commercial Treats and Table Foods.

An estimated 41 to 60% of cats are regularly fed table foods and 34% of cats are fed commercial treats.[a] Feeding treats and table food allows more social interaction with the owner, increases diet variety and provides additional caloric intake. Some commercial treats claim dental benefits either by mechanical cleansing or through use of an active ingredient (Chapter 47). When fed in excess, treats and table foods may negatively affect a well-balanced food. Because most commercial cat foods contain vitamins and minerals well above the nutritional needs of cats, table foods and treats fed at less than 10% of the total daily intake should be safe. Providing high-calorie treats or table foods can also contribute to obesity and must be considered in the calculation of total calories for a cat.

MILK

One of the most common human foods offered to cats is milk. Milk is highly palatable and small quantities are well tolerated by most healthy cats. However, after weaning, intestinal lactase activity declines unless milk is a regular part of the diet. Undigested lactose is subject to bacterial fermentation and promotes osmotic diarrhea. Feeding milk to cats unaccustomed to receiving it may overwhelm digestive capacity resulting in diarrhea, flatulence or gastrointestinal distress. Although commercial lactase supplements may alleviate signs of lactose intolerance, lactose avoidance is more prudent for affected cats.

NUTRITIONAL SUPPLEMENTS

Although many supplements are legitimate sources of essential nutrients, others represent food fads that reflect current trends in human nutrition. Poor-quality foods are rarely "fixed" by adding a supplement. Changing to a higher quality food is a more appropriate recommendation and often less expensive.

Calcium

Breeders sometimes provide supplemental calcium during pregnancy, lactation or growth. Additional calcium is rarely necessary, except for cats fed a homemade food or queens with eclampsia, and may lead to nutritional excess or nutrient imbalances in cats fed complete and balanced commercial cat foods.

Chromium

Chromium has been called a "glucose tolerance factor" for its role in normal glucose homeostasis and insulin action in experimental animals. Chromium supplementation promotes lean tissue accretion in growing livestock. Thus, health food stores now stock chromium as an "anti-diabetic" nutrient and "fat-burner" for people. Little information exists about the effect of chromium supplementation in cats. Some caution may be warranted given excess chromium has been associated with chromosomal damage.

Brewer's Yeast/Thiamin

Brewer's yeast and thiamin have been promoted as coat conditioners and flea preventives for dogs and cats. Although brewer's yeast is a good source of B vitamins, particularly thiamin, research has not proven its efficacy as a flea repellent.

RAW MEATS

Breeders and owners commonly feed raw meats to cats. Raw muscle and organ meats are highly palatable, digestible and generally nutritious when supplemented with appropriate vitamins and minerals. Cooking destroys some nutrients and increases the availability of others. A benefit to feeding raw meat to cats has not been documented, and the disadvantages far outweigh any advantages. Raw meat, even when "flash frozen," may contain harmful bacteria (e.g., *Salmonella* spp. and *Escherichia coli*) and parasites (e.g., *Toxoplasma*

Nearly all commercial cat foods meet or exceed the minimum nutrient requirements; however, certain nutrients may still be outside of the desired nutrient range for optimal health. For cats fed commercial foods, these nutrients require particular consideration and, thus, are referred to as nutrients of concern. Specific food factors (e.g., digestibility, texture and effect on urinary pH) can also affect health and risk of disease (Chapter 1). Together, nutrients of concern and specific food factors are called key nutritional factors. Cats eating homemade foods are at greater risk for nutrient deficiencies (e.g., calcium) and excesses (e.g., phosphorus) than those eating commercial foods. Therefore, these cats have a longer list of key nutritional factors, which are discussed in Chapter 10. **Box 19-3** includes information about a variety of popular topics regarding foods for cats including commercial treats, table foods, vegetarian foods and dog foods. The key nutritional factors for different lifestages of healthy cats will be discussed in the following chapters, including those factors associated with reducing the risk of specific diseases and those involved with optimizing performance during different physiologic states. In sequence, these chapters cover Feeding Young Adult Cats: Before Middle Age, Feeding Mature Adult Cats: Middle Aged and Older, Feeding Reproducing Cats, Feeding Nursing and Orphaned Kittens from Birth to Weaning and Feeding Growing Kittens: Postweaning to Adulthood. The chapter about feeding young adult cats is presented first because most pet cats are adults and the nutrient needs of adults serve as a good basis for comparing nutrient needs for reproduction, lactation and growth.

gondii, Cryptosporidium parvum) (Chapter 11). Some of these microbes can also be a health risk for people. Unless supplemented with vitamins and minerals, raw meat is nutritionally incomplete and can lead to nutritional secondary hyperparathyroidism, iodine deficiency or both. Meat mixes composed of large percentages of organ meats may provide excessive levels of vitamin A. Finally, cats fed raw meat diets sometimes develop fixed-food preferences, making subsequent food changes difficult.

FEEDING BONES

Bones are a concentrated source of calcium, phosphorus and magnesium. Steamed bone meal is a very good choice for supplying calcium in homemade or all-meat diets. However, feeding whole bones to cats should be discouraged. Bones with jagged or sharp points are often to blame for oral trauma and can become esophageal foreign bodies. Bone feeding is also associated with colitis and constipation in small animals. Commercial foods approved by the Association of American Feed Control Officials (AAFCO) are replete in calcium, phosphorus and magnesium and should not be supplemented.

VEGETARIAN AND VEGAN DIETS

Although the nutritional needs of cats are best met by a carnivorous diet, vegetarian diets can be designed to provide adequate nutrition. Vegetarian formulas are commercially available and several commercial supplements are available to provide nutrients normally missing, inadequate or poorly available in plant-based diets. The commonly reported pitfalls of commercially available feline vegan diets include taurine, arachidonic acid and vitamin A deficiencies. Several nutrients (below) require special attention in vegetarian formulations.

Protein

Plants are typically low in protein relative to the dietary needs of cats. Additionally, the quality of protein, in many cases, is much lower than protein from animal sources. Concentrated sources of plant protein available to supplement feline foods include isolated soybean protein and corn gluten meal. Care must be taken to feed sufficient protein both to meet the overall nitrogen needs and the minimum requirements of available individual amino acids.

Amino Acids

Taurine is not present in plant ingredients. Therefore, cats fed plant-based foods require taurine supplementation. Chemically synthesized sources of taurine are available from pharmacies and health food stores. Similarly, only animal tissues synthesize carnitine, a vitamin-like amino acid. Although healthy cats do not require dietary carnitine, a dietary source may be conditionally essential during growth or under disease conditions. Synthetic supplements are available. The common limiting amino acids in plants are methionine, lysine and tryptophan. Diets must be closely evaluated to ensure the availability of sufficient quantities of these amino acids. Plant proteins contain large amounts of glutamate. Cats may poorly tolerate high-glutamate foods.

Vitamins

Because cats cannot use β-carotene, pre-formed vitamin A must be supplied in the food. Also, many vitamin A supplements contain vitamin D. All sources of vitamin D should be considered to avoid excess. Vegetarian diets also require supplementation with vitamin B_{12}, which is not supplied by plant ingredients. Vitamin B_{12}-enriched yeast and synthetic supplements are commercially available. Finally, the niacin content of vegetarian diets should be closely evaluated. Although niacin is present in high amounts in many plant ingredients, the availability is often poor and additional supplementation may be required.

Box 19-3 continued

Minerals

Providing adequate calcium is a concern in any homemade food. A variety of calcium supplements are available from health food stores and pharmacies. Many plant ingredients contain components (e.g., fibers or phytates) that severely compromise the availability of certain trace elements. The availability of iron, zinc and copper is of particular concern in high-phytate and high-fiber foods (Chapter 5). These minerals should be provided as a highly available source.

Fat

Of the nutrients required by cats, arachidonic acid is the one not commercially available. To provide arachidonate directly, cats must be given animal fat or tissue as a nutritional source. However, cats can convert γ-linolenic acid (18:3n6) to arachidonic acid (20:4n6) via delta 5-desaturase. γ-linolenic acid is available from plant oils (e.g., borage and evening primrose oils). Prolonged feeding and reproductive trials using γ-linolenic acid have not been reported; thus, the suitability of these oils as long-term arachidonic acid supplements is unknown. Because cats fed foods high in polyunsaturated fatty acids may develop steatitis, cats fed vegetarian foods with large quantities of plant oils should be protected with added vitamin E.

DOG FOOD

Most dog foods are not nutritionally adequate for the maintenance, growth and reproduction of cats. Nutrients most likely to be deficient are protein, taurine, niacin, vitamin B_6, methionine and choline. Clinical signs of deficiency depend on which nutrients are deficient and to what degree.

FOOD TOXINS

Food toxicities are relatively infrequent in cats. Most notable is hemolytic anemia caused by onion toxicity. Certain disulfides found in onions promote oxidative damage to cat hemoglobin, resulting in Heinz body production and red cell removal. The toxic compound appears to be highly stable, because it remains active in cooked onion-based broth and onion powder. Hemolytic anemia has been described in a cat fed commercial baby food containing onion powder. Onion toxicity was not proved but the anemia resolved with a diet change. Subsequent studies have demonstrated toxic effects at levels of 2.5% dry matter. Therefore, it is prudent to avoid feeding food or seasonings containing onion powder or onions. Chapter 11 provides more information about foodborne toxins.

Theobromine

Theobromine is a toxic methylxanthine found in chocolate. The clinical signs of toxicity include vomiting, diarrhea, vascular collapse and death. The oral LD_{50} of theobromine is 200 mg/kg body weight. Approximately 40 to 50 g of cocoa would need to be consumed to provide this dose of theobromine, which is undoubtedly why clinical reports of chocolate toxicoses in cats are rare.

Histamine

Histamine is a primary amine arising from the decarboxylation of histidine. Histamine toxicosis has been reported to occur in cats after ingestion of certain species of spoiled fish. Affected cats developed salivation, vomiting and diarrhea about 30 minutes after eating uncooked anchovies. Myosis, lacrimation, tachypnea and tachycardia were evident upon physical examination. A survey detailing the histamine content of North American cat foods found foods were well below the 500 mg/g (wet/weight) level considered hazardous in people. Thus, histamine toxicosis is most likely to occur in cats fed improperly handled fish that has undergone spoilage.

water intake. When allowed free access to water, the total water intake of cats eating dry food is only half that of cats eating moist food (Burger et al, 1980; Seefeldt and Chapman, 1979).

Energy

Determination of DER for a population of cats results in a bell-shaped curve (Figure 1-5). Individual cats may have energy requirements 50% or more above or below the average requirement. This range is not surprising considering that the DER of a particular cat is influenced by differences in lean body mass, gender, neuter status, environmental temperature, genetic traits, housing and activity level. Despite the relative uniformity of size within the domestic cat population, there are size-associated differences in energy requirements. Generally, smaller cats consume more calories per kg body weight than larger cats (Earle and Smith, 1991; Finke and Lutschaunig, 1995). Thus, it is important to remember that calculated energy requirements are only estimates for individual cats. The true caloric requirement for an individual cat is what is needed to maintain an ideal body condition (BCS 2.5/5 to 3.5/5) and stable weight.

Data in the literature indicate that, under a variety of conditions, the DER of young adult cats ranges widely from 31 to 100 kcal/kg body weight/day (129 to 418 kJ/kg body weight/day) (NRC, 2006). However, the DER of average young adult pet cats is more likely to range between 40 to 75 kcal/kg body weight/day (167 to 314 kJ/kg body weight/day) or approximately 1.0 to 1.6 x RER, where RER in kcal = $70(BW_{kg})^{0.75}$ or RER in kJ = $293(BW_{kg})^{0.75}$. A simple linear formula can also be used to estimate RER for cats weighing more than 2 kg: RER is approximately 70 kcal + 30 kcal x BW_{kg} (293 kJ + 125.5 kJ x BW_{kg}) (Lewis et al, 1987). Table 5-2 lists RER values for body weights greater than 1.5 kg. Caloric requirements for active neutered cats are calculated using the lower end of the range (1.2 x RER), whereas the upper end of the range (1.4 to 1.6 x RER) is used for active and sexually intact cats. Most housecats are neutered and are minimally active (NRC, 2006) and, therefore, are more prone to overweight and obesity. Thus, it is prudent to use 1.0 x RER or 39 to 66 kcal/kg body weight/day [163 to 276 kJ/kg body weight/day]) (Earle and Smith, 1991) as a starting point for most housecats and increasing their energy intake, if necessary, to maintain ideal body condition. This same starting point, 1.0 x RER, is recommended when calculating the energy needed for maintenance at ideal body weight for an obese cat. Obese cats may require as few as 0.8 x RER or 44 to 54 kcal/kg ideal body weight (184 to 226 kJ/kg ideal body weight/day) to achieve an average weight loss of 1% of body weight per week (LaFlamme and Jackson, 1995) (Chapter 27). After obese cats have returned to their original lean weight, as few as 24 kcal/kg body weight (100 kJ/kg body weight) may be needed for maintenance (Hoenig et al, 2007). Controlling energy intake is important for managing and preventing obesity. Approximately 35% of adult cats seen by veterinarians in the United States are overweight or obese (Lund et al, 2005). The prevalence is highest in seven- to eight-year-old cats; nearly 50% of this age group are overweight or obese (BCS 4/5 or 5/5) (Scarlett et al, 1994; Lund et al, 1999). Obesity increases the risk of death in young to middle-aged cats 2.7 times above that of lean cats (Scarlett and Donoghue, 1997); thus, preventing obesity has important consequences for long-term health (Chapter 27). Risk factors associated with obesity include: 1) middle age, 2) male gender, 3) neutering, 4) low activity/indoor/apartment dwelling and 4) feeding high-fat, high-calorie foods free choice (Lund et al, 2005; Scarlett et al, 1994). Food digestibility and energy density may influence the risk for FLUTD. Energy-dense foods reduce overall DM intake. Lower DM intake decreases stool volume, which subsequently reduces fecal water loss. Both features reduce total magnesium intake and increase urine volume. Food intake should be controlled when feeding high-calorie foods. Excessive intake of calorically-dense foods coupled with free-choice feeding can induce obesity, also a risk factor for urolithiasis.

The recommended range of energy density in foods for inactive/obese-prone young adult cats is 3.3 to 3.8 kcal/g (13.8 to 15.9 kJ/g) (DM). The recommended range for foods for normal weight young adult cats is 4.0 to 5.0 kcal/g (16.7 to 20.9 kJ/g).

Fat

Cats use dietary fat for energy, as a source of essential fatty acids and to facilitate absorption of fat-soluble vitamins. A minimum requirement for fat has not been established for cats although foods containing less than 5% DM fat have been fed successfully to hyperlipidemic cats. The minimum recommended DM allowance of fat in adult cat foods is 9% (NRC, 2006). Fat levels above 9.0% DM are recommended for most cats. Fat enhances the palatability of food; cats prefer foods with levels near 25% DM fat vs. foods containing 10 or 50% DM fat (Kane et al, 1981). High-fat foods have been associated with an increased incidence of obesity in cats (Scarlett et al, 1994). Most cats do well when fed foods containing 10 to 30% DM fat. Cats prone to obesity, however, should be fed foods with lower levels of dietary fat (9 to 17% DM).

Current AAFCO allowances for the essential fatty acids, linoleic acid and arachidonic acid (AA), are appropriate for adult cats (2007). Therefore, commercial foods that have AAFCO label statements acknowledging that a food is appropriate for adult maintenance should provide adequate amounts of linoleic acid and AA. **Box 20-1** discusses the role of omega-3 (n-3) fatty acids in foods for adult cats.

Fiber

Although cats do not require dietary fiber, small amounts in commercial foods enhance stool quality and promote normal gastrointestinal (GI) function. The natural foods of cats typically contain less than 1% dietary fiber although much higher levels are well tolerated (Vondruska, 1987; Dimski and Buffington, 1991). Fiber concentrations less than 5% DM are recommended for normal young adult cats. Because increased levels of dietary fiber reduce energy density and can induce satiety, obese-prone cats may benefit from foods that contain from 5 to 15% DM crude fiber (Chapter 27). Fiber supplementation may also benefit cats that are prone to develop hairballs.

Box 20-1. The Emerging Role of Omega-3 Fatty Acids in Feline Nutrition.

Fatty acids of the omega-3 (n-3) series (linolenic acid, 18:3n-3) are probably required in the food of all animals. However, studies establishing requirements for omega-3 fatty acids in adult cats have not been performed. Cats would normally consume omega-3 fatty acids when eating the neural tissues of their prey. The role of omega-3 fatty acids in companion animal medicine has focused mostly on their pharmacologic-like properties and ability to modulate the immune response and inflammation associated with dermatitis, arthritis, cancer and obesity. Although these effects may benefit some animals, untoward effects are possible. In one study, cats developed increased bleeding times and decreased platelet function when fed foods supplemented with high levels of omega-3 fatty acids. However, no adverse effects were found in similar studies. The current understanding of omega-3 fatty acid metabolism in cats is limited; thus, aggressive omega-3 fatty acid supplementation should be used judiciously. The recommended dry matter allowance for omega-3 fatty acids in foods for healthy adult cats is 0.01% (total eicosapentaenoic and docosahexaenoic acids).

The Bibliography for **Box 20-1** can be found at www.markmorris.org.

Clinical evidence and field trials have demonstrated a reduction in the frequency of hairball vomiting with fiber supplementation (Hoffman and Tetrick, 2003; Dann et al, 2004).

Protein

The protein requirements of adult cats have generally been established using experimental foods containing essential amino acids at or above the minimum requirement for growth. From these studies, the National Research Council (2006) suggested the minimum protein requirement for adult cats is 16% and the minimum recommended allowance is 20% (DM, food energy content of 4 kcal/g [16.7 kJ/g]). Commercial foods prepared from natural ingredients and processed may have lower protein digestibility than the experimental foods used to establish these minimums. To provide a margin of safety and account for differences in protein quality, the Association of American Feed Control Officials (AAFCO) has suggested a minimum dietary protein level of 26% DM for adult maintenance (2007). Protein and amino acid requirements vary with the energy content of a food. The minimum protein allowance suggested by AAFCO is based on foods containing 4.0 kcal/g (16.7 kJ/g) DM and should be corrected for foods with energy densities greater than 4.5 kcal/g (18.8 kJ/g). (See Chapter 1 for the correction method.)

Meeting the minimum protein needs of cats is critical because they have minimal capacity to adapt to low levels of dietary protein. Protein in excess of the requirement is rapidly catabolized and used to provide energy and maintain blood glucose levels. Any excess energy will be stored as fat; therefore, there appears to be little benefit to feeding large excesses of protein to cats. Furthermore, dietary protein excess may increase proteinuria and the progression of subclinical renal disease (Adams et al, 1994; Brown et al, 1997; Ross, 1992). Similar to findings in people and dogs, the role of protein in the progression of renal disease in cats is controversial. There is, however, strong (Grade 1, [See Chapter 2]) evidence to support the recommendation to feed a veterinary therapeutic food designed for kidney disease to cats with serum creatinine concentrations in excess of 2 mg/dl (stage mid-II through IV chronic kidney disease [CKD]) (Polzin et al, 2008; Ross et al, 2006; Elliot et al, 2000). The point being that, among other things, these foods are typically lower in protein.

Although cats can be fed vegetable-based foods, most protein in the food should be derived from animal tissues. The amino acid profile of most animal tissues better reflects the nutritional requirements of cats. Moist products should list animal-based ingredients within the first two ingredients (excluding water), whereas dry products should list animal-based ingredients in the first three ingredients. The recommended DM protein allowance for both normal weight and inactive/obese-prone young adult cats is 30 to 45%. Current AAFCO allowances for taurine are appropriate for adult cats (2007). Foods that have AAFCO label statements acknowledging that a food is appropriate for adult maintenance should provide adequate amounts. Therefore, taurine, although a very important nutrient for cats, is considered an "other" nutritional factor and is discussed under that heading below.

Phosphorus

Dietary phosphorus levels of 0.5 to 0.8% DM are recommended for young adult cats. The minimum recommended allowance for phosphorus in foods for adult cats is 0.26% DM (NRC, 2006). Deficiencies of phosphorus are rare in cats fed commercial foods. Phosphorus excess appears to be of greater concern. Dietary phosphorus is a key nutrient in the management of two common feline diseases: struvite-mediated FLUTD and CKD. The mineral constituents of struvite are magnesium, ammonium and phosphate. Although the primary objectives for preventing FLUTD due to struvite precipitates are to increase urine volume, reduce urinary pH and, to a lesser extent, restrict dietary magnesium, limiting dietary phosphorus may be beneficial (Chapter 46). The kidneys excrete excess dietary phosphorus. The risk of clinically apparent struvite crystalluria and urolithiasis is highest in cats from two to five years of age. Controlling phosphorus intake in combination with appropriate reductions in dietary magnesium concentrations and urinary pH, and increasing water intake, if possible, should help reduce the risk of struvite-associated FLUTD in cats of this age group.

Excess dietary phosphorus is not considered a cause of renal damage but may accelerate the progression of renal disease towards failure and death (Ross et al, 1982). High levels of dietary phosphorus (1.2 to 1.8% DM) reduce creatinine clearance values and possibly reduce renal function in young, healthy cats (Pastoor et al, 1995). Excess phosphorus should be avoided in the early nutritional management of renal disease in cats

to decrease the renal excretory workload and avoid phosphorus retention (Chapter 37). The evidence for recommending a phosphorus-restricted food for cats with CKD, however, is weak. Studies in dogs on the specific effect of phosphorus intake on clinical outcome in induced CKD have shown that dietary phosphorus restriction slows progression and improves survival. Similar studies have not been reported in cats. Phosphorus restriction has been shown, however, to reduce renal mineralization in cats with induced CKD (Polzin et al, 2008). Dietary phosphorus may be reduced as low as 0.3% DM in cats with overt renal disease.

Sodium and Chloride

The minimum sodium requirement for adult cats is 0.065% DM; the minimum recommended allowance is not much greater (0.068%) (NRC, 2006). The average sodium content of prey is relatively low (i.e., approximately 0.25% DM in whole rat carcasses) (Vondruska, 1987). Sodium concentrations from 0.2 to 0.6% DM satisfy the needs of healthy young adult cats without providing excessive levels. In people, limiting sodium intake to levels that meet the requirement without significant excess reduces the risk of hypertension and is considered important to long-term health (Stamler, 1995). This same nutritional practice has been advocated for cats. In a study involving feline hypertension, nearly 50% of hypertensive cats fed a low-sodium food had a significant reduction in blood pressure (Littman, 1994). This response is similar to that seen in people in that not all people are "salt-sensitive." In cats, hypertension is commonly associated with diseases such as renal failure, hyperthyroidism and cardiac disease (Cowgill and Kallet, 1986; Kobayashi et al, 1990). High blood pressure has been associated with significant end-organ damage in hypertensive cats. Blindness, retinal hemorrhage, stroke, cardiac dilatation and murmurs and renal damage were common findings among cats studied (Littman, 1994). Thus, as it relates to cats with hypertension, avoiding excess sodium chloride seems prudent because: 1) hypertension has significant deleterious health effects, 2) diagnostics to detect hypertension are not commonly performed and 3) the medical conditions associated with hypertension are common in cats.

Dietary sodium chloride supplementation is used in commercial cat foods to reduce the occurrence of FLUTD by increasing water intake. Sodium chloride added at concentrations of 4% DM or greater markedly enhanced water intake and increased urine volume (Burger et al, 1980). Short-term studies have shown adult cats tolerate a wide range of dietary sodium intakes (i.e., 0.04 to 2.0%) (MacDonald et al, 1984; NRC, 2006; Burger et al, 1980). A longer-term study (three months) evaluated the safety of salt supplementation (0.35% vs. 1.1% sodium and 0.7% vs. 2.06% chloride, DM) in normal, obese, aged cats and cats with pre-existing CKD. In this study, none of the cats were hypertensive at the beginning of the study and blood pressure was unaffected when they were fed the high-salt food. Cats with pre-existing kidney disease fed the salt-supplemented food, however, experienced increased serum urea nitrogen, phosphorus and creatinine concentrations, suggesting progressive deterioration of renal function. Because apparently healthy cats can have a significant degree of undetected renal dysfunction when screened routinely with biochemistry profiles, it would follow that the risks associated with feeding high-sodium chloride foods to reduce the occurrence of FLUTD outweigh the benefits (Kirk et al, 2006).

Furthermore, in addition to possibly exacerbating hypertensive disorders and contributing to the progression of pre-existing renal disease, high dietary sodium levels reportedly enhance urinary calcium excretion (Osborne et al, 1992), particularly in cats with impaired renal function (Kirk et al, 2006). This may explain the common occurrence of calcium oxalate uroliths in cats with kidney disease. Thus, sodium excess, particularly in the form of sodium chloride, should be avoided in adult cats.

Chloride has been implicated more recently as a major determinant in the development of hypertension in salt-sensitive people. The interaction of sodium with chloride appears to cause the greatest increase in blood pressure compared with sodium combined with other anions (Kurtz et al, 1987) (Chapter 36). The minimum chloride requirement has been determined for kittens but not adult cats. The NRC recommended allowance for adult cats (0.096% DM) is based on kitten data (2006). Typically, dietary chloride recommendations are 1.5 times dietary sodium recommendations.

Magnesium

The minimum magnesium requirement for adult cats is 4.1 mg/100 kcal (9.7 mg/MJ or 0.016% DM) (Pastoor, 1993). The NRC minimum requirement is 0.02% (DM, 4 kcal/g) and the minimum recommended allowance is 0.04% (DM, 4 kcal ME/g [16.7 kJ/g]) (2006). Excessive magnesium restriction may be associated with the prevalence of calcium oxalate uroliths in cats (Thumchai et al, 1996). Therefore, excessive restriction of magnesium (i.e., <0.04% DM) is not recommended. For practical purposes, a magnesium content between 0.04 to 0.1% DM is recommended in foods for young adult cats (**Table 20-3**). These levels are similar to those found in the natural food of cats. Magnesium concentrations of 0.08% DM were measured in whole rat carcasses (Vondruska, 1987). Magnesium is an essential nutrient, but is also a major constituent of struvite crystals. To reduce the risk of FLUTD due to struvite, dietary magnesium concentrations should be less than 20 mg/100 kcal of food (<0.10% DM) and the food should be formulated to produce the appropriate urinary pH (Chapter 46).

Urinary pH

Food ingredients and feeding methods contribute to the urinary pH produced by cats. The normal urinary pH of cats eating mice and rats is 6.2 to 6.4 (Hand et al, 1988). Thus, 6.2 to 6.4 is considered the "normal acidic urinary pH" of cats fed a wild-type food and the recommended range for healthy young adult cats.

The risk of struvite precipitation and FLUTD is greatly reduced at urinary pH values less than 6.5 (Buffington, 1991). Many cats develop metabolic acidosis when the urinary pH

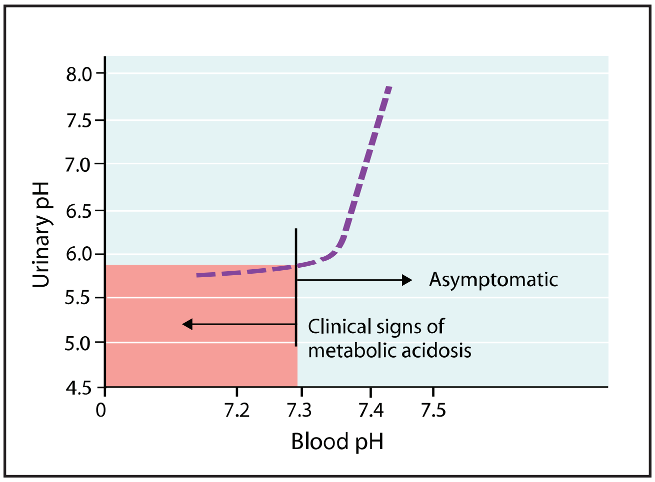

Figure 20-1. Correlation between urinary and blood pH in cats. Many cats develop metabolic acidosis when urinary pH is consistently less than 6.0. (Adapted from Allen TA, Bartges JW, Cowgill LD, et al. Colloquium on Urology. Feline Practice 1997; 25: 32.)

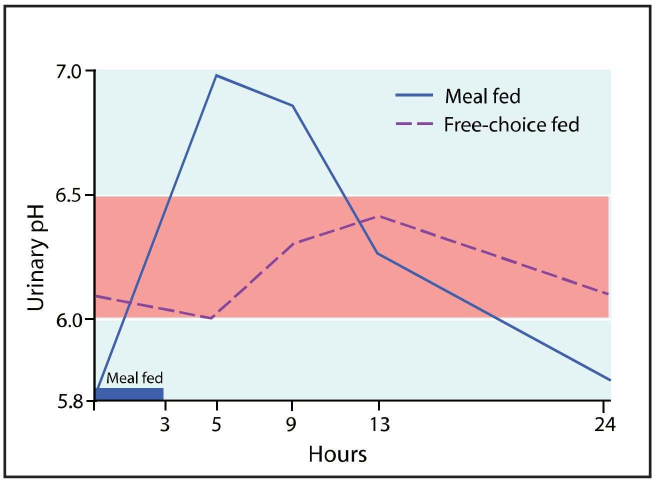

Figure 20-2. Effect of feeding method on urinary pH in cats. Note the significant increase in urinary pH after a single meal (meal fed). This effect is termed "postprandial alkaline tide." Food provided free choice modulates urinary pH by dampening the postprandial alkaline tide that occurs three to six hours following ingestion of larger meals. The shaded area represents the acceptable urinary pH range for adult cats. (Adapted from Taton GF, Hamar D, Lewis LD. Evaluation of ammonium chloride as a urinary acidifier in the cat. Journal of the American Veterinary Medical Association 1984; 184: 433-436.)

is less than 6.0 (**Figure 20-1**) (Dow et al, 1990). Metabolic acidosis may promote bone demineralization, urinary calcium and potassium loss (Ching et al, 1989, 1990) and increase the risk of calcium oxalate urolithiasis (Thumchai et al, 1996; Kirk et al, 1995). Free-choice food intake modulates urinary pH by dampening the postprandial alkaline tide that occurs three to six hours following larger meals. Meal feeding promotes a much greater alkaline tide and higher average urinary pH (**Figure 20-2**). Commercial foods commonly balance dietary cations and anions to achieve an appropriate urinary pH. Animal proteins, corn gluten meal, certain mineral salts, methionine and phosphoric acid are common ingredients that reduce urinary pH when added to feline foods (Hand et al, 1988).

Foods that produce average urinary pH values of 6.2 to 6.4 when fed free choice reduce the risk of struvite-mediated FLUTD, avoid metabolic acidosis and reduce the risk of calcium oxalate urolithiasis in most young adult cats.

Antioxidants

The body synthesizes many antioxidants (e.g., superoxide dismutase) but relies on food for others (e.g., vitamin E). Common food-source antioxidants include vitamins E and C, β-carotene and other carotenoids, selenium and thiols. Fruits and vegetables are good sources of flavonoids, polyphenols and anthocyanidins. The following discussion will focus on vitamins E and C and selenium as antioxidant key nutritional factors in foods for young adult cats because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C and selenium-containing glutathione peroxidase regenerate vitamin E after it has reacted with a free radical), 3) of safety concerns and 4) information regarding inclusion levels in pet foods is usually readily available.

The consequences of prolonged oxidative stress (i.e., free radical damage) to cell membranes, proteins and DNA contribute to and/or exacerbate a wide variety of degenerative diseases. A partial list includes cancer, diabetes mellitus, kidney and urinary tract disease, heart disease, liver disease, inflammatory bowel disease and cognitive dysfunction (Ames et al, 1993; Kesavulu et al, 2000; Ha and Le, 2000; Thamilselvan et al, 2000; Freeman et al, 1999; Cheng et al, 1999; Center, 1999; Knight, 1999).

The consequences of free radical damage to cells and tissues have also been associated with the effects of aging. Although aging is a complex, multifactorial process, one possible explanation for many of the degenerative changes is the free radical theory of aging (Harman, 1956). This theory proposes that free radicals produce cell damage and that age-dependent pathologic alterations may, at least in part, be the cumulative result of these changes. Examples of research supporting this theory include invertebrate studies that found the normal endogenous production of reactive oxygen species limits lifespan (Melov et al, 2000) and studies involving superoxide dismutase-deficient mice that died within the first week of life (Melov, 2000).

Many phenomena initiate free radical formation within the body. Although such things as environmental pollutants and radiation are direct and indirect sources of free radicals, the primary source is endogenous from normal oxidative metabolism in mitochondria. The body defends itself against the effects of free radicals through a complex of protective antioxidant compounds. These compounds protect biomolecules by scavenging free radical compounds, minimizing free radical production and binding metal ions that might increase the reactivity of poorly reactive compounds. Besides these classic mechanisms, many antioxidants exhibit second messenger regulatory function, cell cycle signaling and control of gene expression (Chapter 7 covers antioxidants in detail).

VITAMIN E

Vitamin E (α-tocopherol) is the main lipid-soluble antioxidant present in plasma, erythrocytes and tissues (NRC, 2006). It is transported in plasma proteins and partitions into membranes and fat storage sites where it is one of the most effective antioxidants for protecting polyunsaturated fatty acids (PUFAs) from oxidation. It functions as a chain-breaking antioxidant that prevents propagation of free radical damage in biologic membranes. Vitamin E inhibits lipid peroxidation by scavenging lipid peroxyl radicals much faster than these radicals can react with adjacent fatty acids or with membrane proteins (Gutteridge and Halliwell, 1994).

Research indicates that a level of vitamin E higher than the requirement confers specific biologic benefits. The minimum recommended allowance of vitamin E in foods (DM) for adult cats is 38 mg/kg (NRC, 2006). The concentration of vitamin E in a food necessary to protect against lipid peroxidation of PUFAs in cell membranes depends on the concentration of PUFAs in the food. Foods high in PUFAs, such as foods containing fish oils, may require four or more times increased vitamin E concentration to prevent steatitis (NRC, 2006). Besides helping to prevent chronic diseases associated with oxidative stress, increasing dietary intake of vitamin E to 272 and 552 IU/kg of food (DM) in aged cats improved immune function (Hayes et al, 1969; Hall et al, 2003; Meydani et al, 1998). Furthermore, increased vitamin E intake is also directly related to increased vitamin E content of skin in cats (and dogs), which may help prevent certain skin diseases (Jewell et al, 2002). No safe upper limit has been established for cats. One antioxidant biomarker study suggested that cat foods should contain 600 IU/kg DM for improved antioxidant function (Jewell et al, 2000). Based on these data, foods for young adult cats should contain at least 500 IU/kg DM.

VITAMIN C

Vitamin C (ascorbic acid) is the most powerful reducing agent available to cells. As such, it is important for regenerating oxidized vitamin E. Ascorbic acid also: 1) regenerates glutathione and flavonoids, 2) quenches free radicals intra- and extracellularly, 3) protects against free radical-mediated protein inactivation associated with oxidative bursts of neutrophils, 4) maintains transition metals in reduced form and 5) may quench free radical intermediates of carcinogen metabolism (Chapter 7). Dogs and cats can synthesize required amounts of vitamin C (Innes, 1931; Naismith, 1958) and, while not shown in cats, dogs can rapidly absorb supplemental vitamin C (Wang et al, 2001). In vitro studies, however, indicated that cats (and dogs) have from one-fourth to one-tenth the ability to synthesize vitamin C as other mammals (Chatterjee et al, 1975). Whether or not this finding translates to a reduced ability in vivo is unknown.

Excessive vitamin C supplementation can be a problem. In people, high vitamin C intake increased urine oxalate excretion and risk for urolithiasis (Massey et al, 2005). Vitamin C supplementation resulted in a small progressive reduction of urinary pH in cats and 1,000 mg vitamin C per day induced diarrhea in some cats (Kienzle and Maiwald, 1998). Moderate supplementation of foods with vitamin C (193 mg/kg of food, DM) did not appear to increase the risk of urinary oxalate production in healthy adult cats (Yu and Gross, 2005).

Foods for young adult cats should contain 100 to 200 mg vitamin C/kg DM. This is based on the recommendation for vitamin E and data that show that vitamin C regenerates vitamin E at about a 1:1 molar ratio (Barclay et al, 1985). Also, this range is not a risk for urinary oxalate production (Yu and Gross, 2005).

SELENIUM

Glutathione peroxidase is a selenium-containing antioxidant enzyme that defends tissues against oxidative stress by catalyzing the reduction of H_2O_2 and organic hydroperoxides and by regenerating vitamin E. The minimum recommended allowance for selenium in foods for adult cats is 0.3 mg/kg DM (NRC, 2006). The minimum requirement for selenium in foods for cats is 0.13 mg/kg DM (Wedekind et al, 2003, 2003a). Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at much higher levels (five to 10 times) than the recommended allowances for people or the minimum requirements for animals (Combs, 2001; Neve, 2002). Several mechanisms have been proposed for this effect, including enhanced antioxidant activity via glutathione peroxidase (Neve, 2002). Therefore, for increased antioxidant benefits, the recommended range of selenium for cat foods is 0.5 to 1.3 mg/kg DM. There are no data on which to base a safe upper limit of selenium for cats, but for regulatory purposes, a maximum of 2 mg/kg DM has been set for dog foods in the United States (AAFCO, 2007). In the absence of cat data, the safe upper limit for dogs may provide a working guideline for cat foods.

Texture

Food texture influences oral health (Chapter 47). Dry foods specifically designed to promote oral health can help reduce accumulation of dental plaque and calculus and the severity of gingivitis. If the labels of such foods carry the Veterinary Oral Health Council (VOHC) Seal of Acceptance, they have been successfully tested, according to specific protocols, to clinically reduce plaque (Chapter 47).

Generally, dry foods result in less plaque accumulation in cats than do moist and semi-moist foods (Logan, 1996; Studer and Stapley, 1973). This effect appears not to be clinically important because most cats eat dry foods and dental disease is the most prevalent disease of adult cats (Lund et al, 1999). Food texture also influences the palatability and acceptability of foods for cats. A sudden change in texture may result in reduced food intake or food refusal. Cats accustomed to eating only dry foods may refuse moist foods and vice versa.

Other Nutritional Factors

In addition to the key nutritional factors for commercial foods for young adult cats discussed above, the following nutritional

factors are of concern for young adult cats fed homemade foods (Chapter 10). Occasionally, these factors also become important for cats that are intentionally, or unintentionally, fed commercial dog foods.

Taurine

The AAFCO allowances for taurine are appropriate for adult cats (2007). Therefore, commercial cat foods that have AAFCO label statements acknowledging that a food is appropriate for adult maintenance should provide adequate amounts. However, sporadic cases of taurine depletion continue to be diagnosed. Therefore, dietary taurine concentrations should be evaluated in cats with signs of deficiency or disease (Chapter 19). The minimum recommended allowance for taurine in foods depends on the form of the food. Dry and moist foods should provide 0.1 and 0.17% DM taurine, respectively (NRC, 2006). Taurine is not required in commercial dog foods and is usually not added, yet another reason cats should not be fed dog foods.

Essential Fatty Acids

Signs of essential fatty acid deficiency in cats include fatty degeneration of the liver, kidneys and adrenal glands. Scaly skin, mild hyperkeratosis and hair loss have also been noted. Linoleic acid and α-linolenic acid are essential for normal membrane structure and function, including growth, lipid transport, maintenance of the epidermal permeability barrier and normal skin and coat (MacDonald et al, 1984a). Definitive studies about the essentiality of α-linolenic acid have not been conducted in cats. AA, on the other hand, is important for functions that rely on eicosanoid synthesis. In cats, AA deficiency is associated with impaired platelet aggregation, inflammatory skin lesions and reproductive failure in queens (MacDonald et al, 1984b, 1984c). Male cats are capable of converting linoleic acid to AA within the testes, resulting in normal spermatogenesis (MacDonald et al, 1984c). The minimum DM recommended allowances for linoleic acid and AA are 0.55 and 0.006%, respectively (NRC, 2006). The AAFCO allowances for linoleic acid and AA, however, are appropriate for adult cats (2007). Thus, provision of adequate amounts of these essential fatty acids via commercial foods is usually not a problem.

Calcium

Calcium deficiencies are uncommon in cats fed commercial foods. Most cases of calcium deficiency occur in cats fed only meats, in which the calcium concentration is excessively low, particularly relative to the moderately high phosphorus concentration. The recommended DM allowance for calcium in foods for growing kittens is 0.8% of the diet (NRC, 2006). Adult needs are typically less than those for growth. The recommended DM allowance for calcium in foods for adult cats is 0.29% (NRC, 2006). Typical commercial foods contain calcium levels well in excess of these guidelines.

Daily calcium intakes of 200 to 400 mg result when adult cats are fed foods with a calcium-phosphorus ratio of 0.9:1 to 1.1:1 (Scott and Scott, 1967). Although foods with much

broader ratios of calcium to phosphorus have been fed successfully, ratios near 1:1 calcium to phosphorus optimize the availability of phosphorus (Kienzle et al, 1998). When the calcium-phosphorus ratio is increased to 2:1, phosphorus availability declines by 41%. Calcium-phosphorus ratios between 0.9:1 to 1.5:1 appear optimal for most cat foods.

Potassium

The potassium requirement of cats varies with the dietary protein concentration and the effect of the food on urinary pH. High-protein foods and foods that result in an acidic urinary pH increase the potassium requirement (Hills et al, 1982; Ching et al, 1989, 1990; Dow et al, 1990; DiBartola et al, 1993). Previously recommended levels of 0.4% DM potassium (NRC, 1986) resulted in hypokalemia in adult cats and kittens when combined with dietary acidification. Dietary potassium levels in foods for adult cats should be at least 0.52% DM (NRC, 2006) and ideally between 0.6 to 1.0% DM to prevent hypokalemia. The current AAFCO allowance for potassium is 0.6% DM (2007). Therefore, foods that have AAFCO label statements acknowledging that a food is appropriate for adult maintenance should provide adequate amounts of potassium.

Negative potassium balance may occur in cats with certain metabolic abnormalities (e.g., renal insufficiency, renal tubular acidosis, diabetes mellitus and enteritis). Supplementation may be necessary to maintain normal potassium balance in cats with these conditions, even when they are fed a food containing 0.6% DM potassium.

FEEDING PLAN

Assess and Select the Food

After the nutritional status of the cat has been assessed and the key nutritional factors and their target levels have been determined, the adequacy of the food being fed can be assessed. The steps to assessing foods include: 1) determining if the nutritional adequacy of the food has been assured by a credible regulatory agency such as AAFCO and 2) comparing the food's key nutritional factors with recommended levels.

In the U.S., commercial foods approved by AAFCO will usually have a nutritional adequacy statement on the label (Chapter 9). Commercial cat foods that have received AAFCO or other credible regulatory approval provide reasonable assurance of nutritional adequacy. Few homemade recipes have been formulated according to such protocols. Even foods bearing nutritional adequacy statements, however, are not infallible. Nutritional adequacy statements do not assure the food will be effective in preventing certain important long-term health problems (**Table 20-1**). Therefore, in addition to having passed nutritional adequacy protocols, the food should be evaluated to ensure that the key nutritional factors are at levels appropriate for delivering the feeding goal of promoting long-term health through disease prevention. Besides providing recommended levels of key nutritional factors for young adult cats, **Table 20-4** lists key nutritional factor profiles for selected commercial foods. The manufacturer should be contacted if the food in question cannot be found in this table. Manufacturers' addresses, websites and toll-free customer service numbers are listed on pet food labels. If the manufacturer cannot provide the necessary information, consider switching to a food for which this information is available. Because of the propensity for developing food fixations, feeding a combination of food forms (dry and moist) is sometimes recommended. It is unnecessary to change foods if the food currently fed supplies the correct amounts of the key nutritional factors and the food has a nutritional adequacy statement appropriate for adult cats. However, a new food should be selected if discrepancies were determined. The new food should, as closely as possible, provide the recommended levels of the key nutritional factors.

Snacks are either human foods (table foods) or commercial treats and are offered to cats for a variety of reasons. Small amounts of snacks will not have an important effect on the overall food regimen. Excessive feeding of treats, however, can markedly affect the cumulative nutritional profile. Therefore, it is important to assess the impact of treats with respect to the dietary needs of individual cats. The impact of treats on daily nutrient intake depends on three factors: 1) the nutrient profile of the treat, 2) the number of treats provided daily and 3) the nutrient composition of the cat's regular food. Meeting nutrient requirements is not the primary goal of feeding treats; consequently, many commercial treats are not complete and balanced. Similarly, most table foods are not nutritionally complete and balanced and may contain high levels of fat or minerals. If snacks are fed, it is simplest to recommend commercial treats that best match the nutritional profile recommended for young adult cats. Generally, snacks should not be fed in excessive amounts (<10% of the total dietary regimen on a volume, weight or calorie basis). Otherwise, the nutritional composition of the snack and food should be combined and assessed as the total food regimen.

Assess and Determine the Feeding Method

Veterinarians should evaluate the feeding method, including how the food is fed, the feeding frequency and the amount of food offered. It is also useful to know how the food is prepared (e.g., heated, water added, etc.) and by whom and where the cat is fed. This information may help explain any apparent discrepancies between the dietary history and the physical findings and help identify risk factors associated with various feeding methods. For example, a thorough evaluation of an obese cat includes verification that an appropriate feeding method is being used (Chapters 1 and 27).

No single feeding method is optimal for all cats. The preferred method of feeding an individual cat is often determined by non-nutritional factors (i.e., food type, owner preference, owner schedule and feeding environment including whether there are other pets [cats, dogs] in the household). Nutritional considerations for selecting an appropriate feeding regimen include the cat's body condition, health status/disease risk factors and the food's energy density and palatability.

There are basically two ways to feed cats: 1) free choice in

Chapter 21

Feeding Mature Adult Cats: Middle Aged and Older

Kathy L. Gross
Iveta Becvarova
Jacques Debraekeleer

"Every life should have nine cats."
Anonymous

CLINICAL IMPORTANCE

More pet cats are getting older. Thirty-five percent of cats in the United States are at least seven years of age (Lund et al, 1999). The number of pet cats older than six years in the U.S. nearly doubled (from 24 to 47%) over a recent decade (Stratton-Phelps, 1999). Similarly, in Europe, the number of cats older than seven years increased by 100% between 1983 and 1995 (Kraft, 1998). For the purposes of this chapter, the term "mature" indicates cats that are seven to eight years old and older. It includes cats that could be considered "middle-aged," "senior" and "geriatric."

Age-related diseases begin to increase in prevalence around seven or eight years of age; this prevalence is coupled with the gradual onset of behavioral, physical and metabolic changes related to aging (Lund et al, 1999). Instituting appropriate changes in nutritional management and preventive care at this point are important to reduce risk factors for common age-associated diseases (Table 20-1), thereby helping to maintain good health and maximize longevity. Furthermore, a cat's chronologic age may not accurately reflect its physiologic age (e.g., an eight-year-old cat with kidney disease and poor nutritional status is likely to be "physiologically older" than a healthy 11-year-old cat).

This chapter builds on many of the recommendations in Chapter 20 for feeding young adult cats. The minimum nutrient requirements of mature adult cats are similar to those of young adult cats. The few studies evaluating the effects of aging on the nutritional needs of cats have shown minimal changes in nutrient requirements. Therefore, nutritional recommendations for mature adult cats are based on risk factor management, extension of learning from other species and prudence. Several key nutritional factors for mature adult cats, however, are lower than the recommended upper range for young adults. To date, the only nutritional modification proven to slow aging and increase the lifespan is caloric restriction. Reducing caloric intake by 20 to 30% of normal, while meeting essential nutrient needs, slows the aging process and decreases susceptibility to cancer, renal disease, arthritis and immune-mediated diseases in animal models studied (Sheffy and Williams, 1981; Kealy et al, 2002). This level of caloric restriction is difficult to achieve in the long term and has not been incorporated into mainstream nutritional advice.

Older mature cats become less active and have reduced lean body mass. Together, these changes reduce their basal metabol-

Table 21-1. Common physiologic changes and diseases associated with aging in cats.*

Body systems/functions	Age-related changes	Associated conditions and diseases
Metabolism	Decreased thirst sensitivity	Dehydration
	Decreased thermoregulation	Hypothermia or hyperthermia
	Decreased immunocompetence	Susceptibility to infections, disease and cancer
	Decreased rate of drug metabolism	Drug intolerance
	Increased sleep	Irritability
	Decreased activity and metabolic rate	Loss of body mass, reduced BMR and obesity
Special senses	Decreased olfaction	Reduced food intake and weight loss
	Decreased taste perception	Reduced food intake and weight loss
	Decreased hearing	
	Decreased visual acuity	
Oral cavity	Decreased salivary secretion	Increased oral disease
	Increased tooth loss, dental calculus	Painful or difficult prehension
	Increased periodontal disease	Reduced food intake and weight loss
		Susceptibility to sepsis and end-organ damage
Gastrointestinal	Decreased liver function	Reduced nutrient assimilation
	Increased cellular infiltrates	
	Decreased digestive function	Reduced nutrient digestibility
	Decreased colonic motility	Constipation
	Decreased pancreatic function	Reduced nutrient digestibility
Endocrine	Decreased pancreatic function	Glucose intolerance and diabetes mellitus
	Decreased adrenal function	Reduced ability to respond to stress
	Alterations in thyroid structure and function	Hyperthyroidism
Integumentary	Loss of elasticity, dry, thin coat, hyperplasia of sebaceous glands with decreased sebum and increased waxy secretions	Dermatitis Intradermal cysts Dry, flaky coat
Urinary	Decreased total renal function	Chronic renal failure
		Hypokalemia
	Alterations in acid excretion	Decreased acid-base regulation
		Metabolic acidosis
Reproductive	Testicular tumors and atrophy, mammary gland nodules	Reproductive gland neoplasia
	Irregular estrous cycles	Reproductive failure
	Decreased conception rates	Pyometra
	Cystic endometrial hyperplasia	
Musculoskeletal	Decreased lean mass and tone	Decreased BMR, weakness, decreased activity
	Decreased bone mass	Osteoarthritis, spondylosis
	Degenerative joint changes	
Cardiovascular	Decreased cardiac output, increased peripheral resistance, hypertension	Cardiomyopathy, valvular regurgitation Hypertension and end-organ damage
	Valvular thickening	
Respiratory	Reduced vital capacity and compliance	Chronic respiratory disease
	Increased respiratory rate and residual air capacity	
Nervous	Alterations in neurotransmitter levels	Senility
	Progressive decline in cellularity of nervous tissues	Decline in special senses
	Decreased reactivity to stimuli and cognition decline	Behavioral changes

Key: BMR = basal metabolic rate.
*As in any biologic system there is much individual variation. An individual aging animal may have few to many of these changes. Also, the age at which changes occur, and their severity, is quite variable.

ic rate. Additionally, changes occur in virtually all body systems. Age-associated changes in physiologic function include reduced digestive function, immune response, glucose tolerance, renal function, smell, taste perception and numerous other changes (**Table 21-1**) (Harper, 1996; Markham and Hodgkins, 1989; Cowan et al, 1998). Not all cats develop all age-associated changes nor will the changes that develop necessarily occur in any predictable sequence. Aging cats become less adaptable and have reduced physiologic reserve to withstand perturbations in their health and environment, including changes in their food. Older cats age at different rates; thus, greater diversity exists in individual needs than at any other lifestage. Individualization of nutritional management becomes even more important because of the reduced adaptability of older mature adult cats. The goals for nutritional management of mature adult cats are:

- Maintenance of optimal nutrition (i.e., maintenance of ideal body condition and weight, adequate intake of a nutritious food and good hydration).
- Risk factor management (i.e., minimization of associated disease risks [Table 20-1]).
- Disease management (i.e., amelioration of clinical signs of common diseases, slowing progression of certain chronic diseases).

• Improvement in the quality and length of life.

This chapter describes how to assess mature adult cats and how to determine and meet their nutritional needs.

PATIENT ASSESSMENT

History and Physical Examination

A complete history should be taken and physical examination performed as described for young adult cats (Chapter 20). Physiologic changes associated with aging and age-related diseases are of particular interest. Note any changes in appetite, food or water intake, activity, oral health and body condition. Abnormalities in these parameters are often early indicators of underlying disease. Oral disease is the most prevalent disease in adult cats; however, weight loss, cancer, renal disease, cardiac disorders, diabetes mellitus and hyperthyroidism are frequently diagnosed in this age category. Kidney disease may affect nearly 30% of older mature adult cats and is a major cause of death (MAF, 1998; Lulich et al, 1992). Physical evaluation of renal size, shape and firmness may uncover kidney abnormalities, whereas thoracic auscultation may expose cardiac disease. Hyperthyroidism may be detected by palpating enlarged thyroid glands or may be suspected based on the history and other physical findings. A fundic examination may help detect hypertension, which is often secondary to renal, cardiac or thyroid disease in older mature adult cats. Retinal hemorrhage was a common finding in a group of older hypertensive cats (Littman, 1994).

Laboratory and Other Clinical Information

Specific abnormalities in the physical and historical examination should be pursued further using appropriate diagnostic procedures. A geriatric-type blood panel to screen for common age-associated diseases should be performed at least annually. The minimum database should include a complete blood count, urine specific gravity and sediment examination and a serum biochemistry profile. The biochemistry panel should include measurements of albumin, globulin, urea nitrogen, creatinine, glucose, alkaline phosphatase, alanine aminotransferase, calcium, potassium, phosphorus, sodium, chloride and bicarbonate. Serum total thyroxine (T_4) concentrations should be assessed if clinical or biochemical abnormalities suggest hyperthyroidism. Feline leukemia and feline immunodeficiency virus testing should be current and repeated if potential exposure has occurred or suspicious clinical signs are present. Specialized diagnostics may be indicated by physical and/or biochemical findings (e.g., electrocardiography, ultrasonography, radiography, blood pressure monitoring).

Key Nutritional Factors

The recommended range of nutrient allowances can be optimized to support changes in physiologic function and reduce risk factors for common age-related diseases. **Table 21-2** summarizes key nutritional factors for mature adult cats.

Table 21-2. Key nutritional factors for foods for older cats.

Factors	Recommended food levels*	
	Normal and underweight	Inactive/ obese prone
Energy density (kcal ME/g)	4.0-4.5	3.5-4.0
Energy density (kJ ME/g)	16.7-18.8	14.6-16.7
Fat (%)	18-25	10-18
Fiber (%)	≤5	5-15
Protein (%)	30-45	30-45
Calcium (%)	0.6-1.0	0.6-1.0
Phosphorus (%)	0.5-0.7	0.5-0.7
Sodium (%)	0.2-0.4	0.2-0.4
Potassium (%)	≥0.6	≥0.6
Magnesium (%)	0.05-0.1	0.05-0.1
Average urinary pH	6.4-6.6	6.4-6.6
Antioxidants		
Vitamin E (IU/kg)	≥500	≥500
Vitamin C (mg/kg)	100-200	100-200
Selenium (mg/kg)	0.5-1.3	0.5-1.3
VOHC Seal of Acceptance	Plaque control	Plaque control

Key: ME = metabolizable energy, VOHC = Veterinary Oral Health Council (Chapter 47).

*Dry matter basis. Concentrations presume an energy density of 4.0 kcal/g. Levels should be corrected for foods with higher energy densities. Adjustment is unnecessary for foods with lower energy densities.

Water

Water is an often overlooked but critical nutrient in the health of mature adult cats. Aging impairs thirst sensitivity, which is already low in cats compared with other species (MacDonald et al, 1984; Markham and Hodgkins, 1989). Additionally, the decline in renal function observed in many mature adult cats may increase water losses due to impaired urine concentrating ability. Together, these characteristics predispose older cats to dehydration. Chronic dehydration can impair normal metabolic processes and exacerbate subclinical disease. Dehydration also reduces a cat's ability to thermoregulate. Water intake in healthy cats without increased losses is 200 to 250 ml per day (Burger and Smith, 1987). This intake comes from a combination of free water, metabolic water and water contained in food. Changing to a moist food or adding water to the food (moist or dry) can increase water intake. Offering low-salt broth, meat juices and "pet drinks" have been advocated to enhance water consumption; however, the long-term effectiveness of these strategies is unknown. Clean fresh water should be available at all times and readily accessible to further encourage water intake.

Energy

Reductions in lean body mass, basal metabolic rate and physical activity decrease energy requirements as animals age (Sheffy and Williams, 1981; Taylor et al, 1995). In many species, the decrease in lean body mass is counterbalanced by an increase in total body fat such that obesity becomes more prevalent with age (Armstrong and Lund, 1996; Sheffy and Williams, 1981). However, studies reveal the prevalence of obesity plateaus and then declines in cats after seven years of age, whereas the preva-

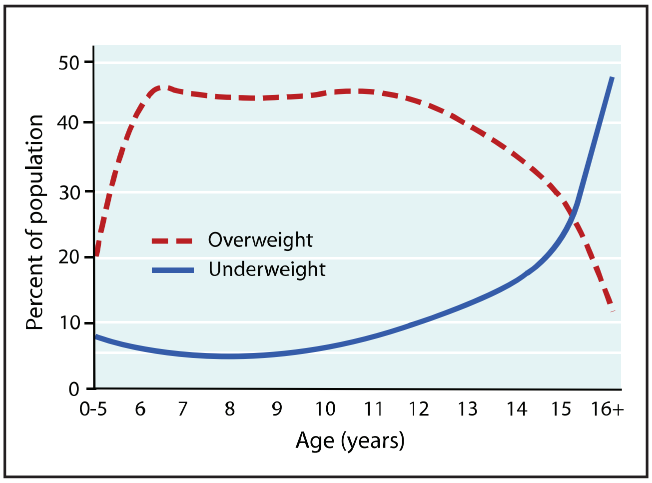

Figure 21-1. Proportion of overweight (body condition score [BCS] 4/5 or 5/5) and underweight (BCS 1/5 or 2/5) cats. Note that six- to 12-year-old cats are commonly overweight, whereas cats over 12 years old are at greater risk of being underweight. (Adapted from Armstrong PJ, Lund EM. Changes in body composition and energy balance with aging. Veterinary Clinical Nutrition 1996; 3: 83-96.)

lence of underweight cats increases dramatically after 11 years of age (**Figure 21-1**) (Scarlett et al, 1994; Armstrong and Lund, 1996). This observation may be explained by the high occurrence of disease in this age group, reduced food intake due to impaired appetite or sensory function, an age-related decline in food digestion or assimilation or a combination of these factors. Although the prevalence of obesity declines after seven years, a significant proportion of mature adult cats remain overweight (**Figure 21-1**). Both obesity and cachexia significantly increase the risk of mortality in cats over eight years of age, with obese cats nearly three times as likely to die as cats of optimal weight (Scarlett and Donoghue, 1997). Therefore, it is critical to recommend foods and feeding methods that will achieve optimal weight and body condition in individual mature cats.

In a study of healthy cats, energy intake declined slightly until approximately 10 years of age. However, a sharp increase in food intake was observed in cats 12 years and older (Taylor et al, 1995). In another study, the energy requirement of cats also decreased with age through approximately 11 years; likewise, the energy needs of these cats increased at approximately 12 years onward (Laflamme and Ballam, 2002). A 10% reduction in fat digestibility was responsible for a similar reduction in total food digestibility in the cats 12 years and older mentioned in the first study (Taylor et al, 1995). The digestibility of dietary fat declined significantly with age, whereas protein and carbohydrate digestibility remained unchanged. Thus, reduced fat digestibility in these mature cats was offset by increased food intake; as a result, digestible energy intake was not different between age groups (Harper, 1996). A later study also found an age-related decrease in ability to digest fat that involved about one-third of cats over 12 years of age (Perez-Camargo, 2004). From these studies, it is unclear if changes in the metabolic rate of older cats are compensated for by a reduction in fat digestion, or if older cats simply compensate for impaired digestion by consuming more food. The latter seems more likely based on observations that weight loss is more prevalent than obesity in very old cats. A decline in pancreatic enzyme secretion is a common physiologic change associated with aging in many species and could be expected to reduce digestibility of dietary fat. In addition, hepatic changes seen in older mature cats may influence nutrient assimilation (Armstrong and Lund, 1996). Based on these studies, the energy density of foods formulated for mature cats should be between 3.5 to 4.5 kcal/g (14.6 to 18.8 kJ/g) dry matter (DM), depending on their predisposition to be overweight and caloric intake may have to be restricted. Inactive/obese-prone cats should be fed foods with lower energy density (3.5 to 4.0 kcal/g [14.6 to 16.7 kJ/g] DM). Normal and underweight cats should be fed energy-dense foods (4.0 to 4.5 kcal/g [16.7 to 18.8 kJ/g] DM) and caloric intake should not be restricted, except to prevent or treat obesity.

Reasonable estimates of caloric needs in mature adult cats are 1.1 to 1.4 x resting energy requirement (RER) (55 to 70 kcal/kg body weight [230 to 293 kJ/kg body weight]), with more active or underweight cats needing up to 1.6 x RER (80 kcal/kg body weight [344 kJ/kg body weight]) (Taylor et al, 1995). Obese cats can be managed with standard weight-control programs appropriate for adult maintenance (Chapter 27).

Fat

Although weight loss is prevalent in very old cats, obesity still affects a large portion of the mature adult cat population (**Figure 21-1**) (Armstrong and Lund, 1996; Lund et al, 2005). Certain diseases associated with obesity are also common in these cats (e.g., diabetes mellitus, hypertension and heart disease). Additionally, the risk of death increases nearly threefold in older obese cats (i.e., eight to 12 years) (Scarlett and Donoghue, 1997; Markham and Hodgkins, 1989; Kirk and Toll, 1996). Moderate to low levels of fat are indicated to reduce the risk of obesity (Scarlett et al, 1994; Hand et al, 1989). However, very old cats need energy-dense foods and ample levels of essential fatty acids. Essential fatty acids (i.e., linoleic, arachidonic and possibly linolenic) help maintain normal skin and coat condition. As animals age, they tend to lose skin elasticity, develop epidermal and follicular atrophy and have reduced sebum secretion (Markham and Hodgkins, 1989). Markedly reducing dietary fat (i.e., calorie-restricted or "light" foods) is not recommended for older mature adult cats unless they are obese prone. Fat should be highly digestible in foods intended for older cats. As discussed above, fat digestion declines with age, which may account for the weight decline noted in very old cats (Taylor et al, 1995). Dietary fat improves food palatability and contributes significantly to energy density. Therefore, maintaining moderate fat concentrations improves food and caloric intake in older mature adult cats and enhances absorption of fat-soluble vitamins (Kane et al, 1981). The recommended range for fat content in foods for mature adult cats is 10 to 25% DM, depending on whether or not they are prone to obesity. Foods for cats that are inactive or prone to obesity should contain 10 to 18% DM fat and foods for cats that are normal or underweight should contain 18 to 25% DM

fat. Foods with lower fat levels are recommended for obese-prone cats, and foods with higher fat levels should be fed to thin cats (body condition score <2.5/5) and cats with poor appetites. Essential fatty acids should be provided at levels at or above those recommended for young adult cats (Chapter 20).

Fiber

Fiber facilitates gastrointestinal health by a variety of mechanisms. Dietary fiber promotes normal intestinal motility and provides nutrition (i.e., volatile fatty acids) for colonocytes due to fermentation by colonic microbes. Feeding small amounts (i.e., <5%) of soluble and insoluble fiber can attain these desirable effects. Promoting intestinal motility may benefit cats with constipation (Markham and Hodgkins, 1989). Constipation is common in older cats due to reduced water intake, limited activity and reduced colonic motility. Although fiber should not be the sole factor for managing constipation, it is beneficial when provided regularly. Dietary fiber also benefits the management of obesity, diabetes mellitus and hyperlipidemia (Hand et al, 1989; Nelson and Lewis, 1990; Nelson et al, 1994; Bauer, 1992) (Chapters 27 through 29).

Increased levels of dietary fiber (5 to 15%, DM) reduce food DM digestibility and dilute caloric density; such levels are recommended for foods for inactive cats and cats that are prone to obesity. Normal and underweight cats should receive foods with increased energy density; thus, lower levels (≤5% DM) of dietary fiber are recommended.

Protein

Dietary protein should not be restricted in apparently healthy mature adult cats. Adequate protein and energy intake are needed to sustain lean body mass, protein synthesis and immune function. Besides increasing protein intake, another approach to influencing body composition (i.e., preventing loss of lean body mass in older cats), is increasing the dietary lysine-calorie ratio (**Box 21-1**). Although controversial, the protein needs of older patients may be somewhat greater than those of young adults (Wannemacher and McCoy, 1966; Carter, 1991). The recommended daily protein allowance for elderly people is increased by 25% above that for adult maintenance. The minimum recommended allowance for DM protein for adult cats is 20% (NRC, 2006). The equivalent increase in the minimum protein allowance for cats results in 25% DM protein. The minimum recommended protein allowance for healthy older cats fed commercial foods is further increased to 30% of the food DM to allow for variable digestibility and protein quality of food ingredients. An additional benefit to maintaining this moderate protein concentration in foods for older mature adult cats is the palatability-enhancing effect of animal protein, which may conceivably improve food intake and weight maintenance in very old cats. However, the long-term effects of feeding foods with high dietary protein levels to healthy cats are still largely unknown. High-protein foods have been associated with increased bone loss and increased formation of urinary calcium oxalate crystals in people (Barzel and Massey, 1998; Reddy et al, 2002). In cats, high-protein foods have been implicated in the progression of renal failure (Polzin et al, 1996). Protein restriction in foods for older cats has been advocated because of the high prevalence of renal disease in this age group (Taylor et al, 1995; Lulich et al, 1992) and the knowledge that renal failure is rarely diagnosed until at least three-fourths of renal function is lost. The potential benefits of this restriction include a delay in age-related renal impairment and slowed progression of subclinical renal disease. In one study, investigators examining the effect of protein-calorie restriction in cats following five-sixths nephrectomy observed a reduction in proteinuria and glomerular injury in cats fed reduced-protein foods (27.6% DM) compared with high-protein foods (51.7% DM) (Adams et al, 1993). A secondary finding was an increased occurrence of hypokalemia in cats fed the high-protein food (Adams et al, 1993). However, a subsequent study demonstrated no change in renal pathology following protein restriction and a slight benefit (i.e., reduced cellular infiltrates and tubular lesions) to caloric restriction (i.e., 56 kcal/kg body weight [low-calorie group] vs. 75 kcal/kg body weight [high-calorie group]) (Finco et al, 1998). Unfortunately, these studies may not be directly comparable because the dietary protein sources were markedly different. Thus, there is no clear consensus about the role of protein reduction in slowing progression of clinical or subclinical feline renal disease (Polzin et al, 2005). Healthy older cats should receive sufficient protein to adequately meet protein needs and avoid protein-calorie malnutrition. Improving protein quality without increasing protein intake can fulfill any additional protein needs of older cats. Until further research defines an optimal range of dietary protein for older cats, moderate levels of dietary protein (30 to 45% DM) are recommended.

Calcium and Phosphorus

After skeletal growth is complete, the nutritional requirement for calcium and phosphorus declines to levels needed by adult

Box 21-1. The Dietary Lysine-Calorie Ratio and Lean Body Mass of Geriatric Cats.

Besides increasing protein intake, another approach to influencing body composition (i.e., preventing loss of lean body mass) in older cats is the dietary lysine-calorie ratio. The lysine-calorie ratio affects body composition in swine and appears to do so in older cats. In a study involving older mature adult cats (>12 years old), increasing the dietary lysine-calorie ratio was correlated with variation in lean body mass. As the lysine-calorie ratio increased, loss of lean body mass was reduced. Cats fed a food with 36% dry matter (DM) protein and a lysine-calorie ratio of 6.30:1 maintained body weight and lean mass similar to that seen with a higher protein food (45% DM) that had a lower lysine-calorie ratio (4.38:1). Such nutritional technologies might hold promise for foods for older mature adult cats.

The Bibliography for **Box 21-1** can be found at www.markmorris.org.

Table 21-3. Most common causes of mortality in cats.*

Cause of death	Proportion of deaths (%)
Cancer	35
Kidney disease	24.9
Heart disease	10.7
Diabetes mellitus	7.6

*MAF (Morris Animal Foundation). Animal health survey: Top four causes of death as reported by owners. Denver, CO. 1998.

cats and is thought to remain relatively constant for life. Unlike the situation in people, osteoporosis is not commonly diagnosed in old cats. Nevertheless, the bone mass of adult cats remains stable until seven years of age and then declines (Jewell et al, 1996). The reason for the decline has not been elucidated but is presumably related to the loss of lean and total body mass that occurs with aging. With loss of body mass, less bone mass is required for structural support. Alternatively, bone loss resulting from buffering chronic elevations of metabolic acids cannot be ruled out. Older cats have been reported to maintain a greater metabolic acid load and a significantly lower urinary pH compared with young adult cats (Lawler and Ballam, 1996; Smith et al, 1997). Interestingly, a lower urinary pH (i.e., higher metabolic acid load) is also a risk factor for development of calcium oxalate urolithiasis, which is most prevalent in older cats (Thumchai et al, 1996; Kirk et al, 1995). Mature adult cats should receive foods with moderate levels of available dietary calcium (0.6 to 1.0%, DM) to help maintain bone mass and possibly reduce the risk of calcium oxalate urolithiasis.

In contrast to the moderate calcium needs during aging, reduction of dietary phosphorus is commonly recommended in foods designed for mature adult cats. The recommendation is predicated on the fact that nearly 30% of older cats may have kidney disease (Lulich et al, 1992). Furthermore, in a survey of pet owners, kidney disease was the second leading cause of nonaccidental death in cats (**Table 21-3**) (MAF, 1998). Renal insufficiency is rarely diagnosed until significant loss of renal function has occurred. Thus, large proportions of older cats have subclinical renal damage and may benefit from reduced dietary phosphorus. It is commonly accepted that phosphorus restriction slows the progression of renal disease in cats (Chapter 37). Phosphorus reduction helps decrease: 1) the renal excretory workload, 2) phosphorus retention, 3) renal secondary hyperparathyroidism and 4) the subsequent renal mineralization in cats with chronic renal insufficiency (Ross et al, 1982; Polzin et al, 1996). Therefore, in the early nutritional management of renal disease in cats, phosphorus levels should be reduced from those typically found in commercial foods (Brown et al, 1997). Slowing progression of early renal disease in affected older cats should increase longevity (Ross et al, 2006). Phosphorus may be reduced to as low as 0.3% of the food DM for cats with overt renal disease, otherwise the general population of mature adult cats should be fed foods containing 0.5 to 0.7% DM phosphorus. Although adult cats appear to be remarkably tolerant to perturbations in dietary calcium-phosphorus ratios (Kealy et al, 1996), a ratio between 0.9:1 to 1.1:1 maximizes availability (Scott and Scott, 1967) and ratios between 0.9:1 to 1.5:1 are recommended.

Sodium and Chloride

Avoiding excessive sodium intake to reduce risk factors appears even more important in older cats than in young adult cats. Although the sodium and chloride requirements of older cats are not likely to be different from those of young adults, the prevalence of chronic diseases associated with hypertension (e.g., renal disease, hyperthyroidism, cardiac disease) increases with age. The exact prevalence of secondary hypertension in the feline population is unknown, but it appears highest in older cats. In one study, systolic arterial pressures were significantly higher in older cats (Lawler et al, 1996). Furthermore, hypertension affects 60 to 65% of cats with renal disease and 23% of cats with hyperthyroidism (Ross, 1992; Kobayashi et al, 1990; Stiles et al, 1994). Chronic hypertension results in end-organ damage and progression of renal and cardiac disease; therefore, control of risk factors for "salt-sensitive" individuals is desirable. Unfortunately, accurate monitoring of blood pressure in all feline patients is uncommon and hypertension is rarely diagnosed until clinical signs are evident. Therefore, nutritional needs for sodium and chloride should be met, but excesses should be avoided.

Supplemental sodium chloride is used in commercial foods to reduce the occurrence of feline lower urinary tract disease (FLUTD) by increasing water intake. A long-term study (three months) evaluated the safety of salt supplementation (1.1 vs. 0.35% sodium and 0.7 vs. 2.06% chloride, DM) in normal, obese, aged cats and cats with preexisting kidney disease. In this study, none of the cats were hypertensive and blood pressure was unaffected when they were fed the high sodium chloride food. However, cats with preexisting kidney disease fed the salt-supplemented food had increased serum urea nitrogen, phosphorus and creatinine concentrations, suggesting progressive deterioration of renal function. Because many apparently healthy cats can have undetected renal dysfunction based on results of routine serum biochemistry screening, the risks associated with feeding high-salt foods to reduce the occurrence of FLUTD outweigh the benefits (Kirk et al, 2006).

Furthermore, in addition to possibly exacerbating hypertensive disorders and contributing to the progression of preexisting renal disease, high dietary sodium reportedly enhances urinary calcium excretion (Osborne et al, 1992), particularly in cats with impaired renal function (Kirk et al, 2006). This may explain the common occurrence of calcium oxalate uroliths in cats with kidney disease. Thus, sodium excess, particularly in the form of sodium chloride, should be avoided.

Regulation of acid-base homeostasis and normal plasma osmolality depends, in part, on adequate sodium and chloride intake. Deficiencies of sodium and chloride can have deleterious effects in older cats; therefore, over restriction should be avoided. The minimum dietary allowance of sodium for adult cats is 0.068% DM (NRC, 2006). The Association of American Feed Control Officials (AAFCO) recommends an

intake of 0.2% of the food DM, or almost threefold the minimum recommended allowance (2007). Some commercial moist foods exceed 1.0% DM sodium or almost 15 times the minimum recommended allowance. Sodium intake at this level is markedly above that needed for optimal health. The recommended range for dietary sodium for mature adult cats is 0.2 to 0.4% DM.

Chloride is now recognized as a co-determinant in salt-sensitive hypertension; thus, control of dietary excess is also important (Kurtz et al, 1987; Kotchen et al, 1987) (Chapter 36). Unfortunately, little information is available about the chloride requirement of cats. The minimum recommended allowance for dietary chloride is 0.096% DM (NRC, 2006); however, more typically, chloride values are approximately 1.5 times the concentration of sodium.

Potassium

The potassium requirement for older cats is thought to be greater than that for young adult cats. This impression comes from anecdotal reports of low serum potassium levels and improved attitude, appetite, muscle strength and renal function following oral potassium supplementation in older cats. However, the potassium requirement of healthy older cats has not been determined and an increased need remains speculative. Nevertheless, factors common in mature adult cats that support the need for increased dietary potassium include: 1) kaliuresis as a result of kidney disease, high dietary protein or high metabolic and/or dietary acid load, 2) reduced food intake and 3) increased intestinal loss. Mature adult cats with normal appetite and renal function probably do not benefit significantly from increased dietary potassium levels. However, hypokalemia can cause signs ranging from mild lethargy to marked polymyopathy and nephropathy. Thus, increasing dietary potassium to support moderate losses may benefit some older cats. Levels as low as 0.3% resulted in hypokalemia when provided in high-protein or acidified foods (DiBartola et al, 1993). The minimum recommended allowance for potassium in foods for adult cats is 0.52% DM (NRC, 2006). Dietary potassium levels for foods for mature adult cats should be at least 0.6% DM.

Magnesium

Increased losses of magnesium, similar to those seen with potassium, may affect magnesium balance in older cats. Hypomagnesemia has also been associated with refractory hypokalemia, particularly in cats with diabetes mellitus (Dhupa, 1995). The benefit of limiting dietary magnesium in cats is a reduced risk of struvite-mediated lower urinary tract disease. However, the risk of struvite-mediated disease is low in older cats (**Figure 21-2**) (Bartges, 1996). Furthermore, foods containing very low levels of magnesium have been associated with the development of calcium oxalate uroliths in an epidemiologic survey of cats (Thumchai et al, 1996) and deficiency increases risk of urolith formation in rats (Su et al, 1991). Therefore, magnesium should be provided at moderate levels (0.05 to 0.1% DM) and severe magnesium restriction should be avoided (<0.04% DM). The minimum recommended allowance for foods for adult cats is 0.04% DM (NRC, 2006).

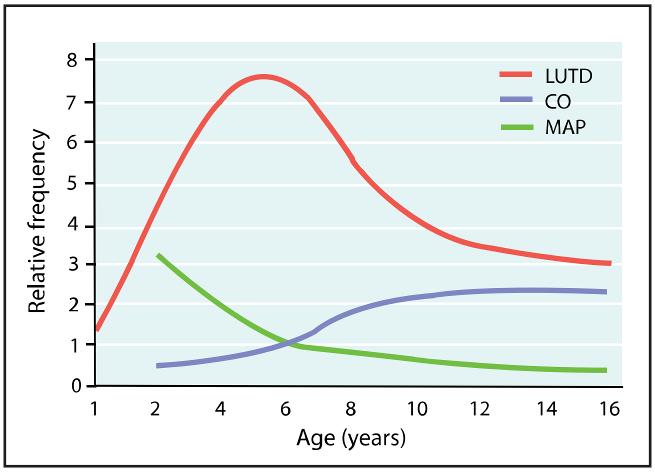

Figure 21-2. Relative frequency of feline lower urinary tract disease (LUTD), struvite (magnesium ammonium phosphate, MAP) urolithiasis and calcium oxalate (CO) urolithiasis in cats of varying age. Note that LUTD is most common in adult cats, struvite urolithiasis is most common in adult cats less than six years old and calcium oxalate urolithiasis is most common in cats over six years old. (Adapted from Bartges JW. Lower urinary tract disease in older cats: What's common, what's not. Veterinary Clinical Nutrition 1996; 3: 57-62. Thumchai R, Lulich JP, Osborne CA, et al. Epizootiologic evaluation of urolithiasis in cats: 3498 cases (1982-1992). Journal of the American Veterinary Medical Association 1996; 208: 547-551.)

Urinary pH

Older cats frequently have clinical or subclinical renal disease that may impair their ability to compensate for acid-base alterations resulting from metabolic and dietary influences. In a study in which cats were fed a food with higher urinary acidifying potential (pH 6.39 vs. 6.6 in the control food), older cats lost more weight, had lower red cell counts and had greater systemic acid loads than younger cats (Lawler and Ballam, 1995). This observation, combined with the reduced risk of struvite urolithiasis, increased risk of calcium oxalate urolithiasis and high frequency of kidney disease in older cats, supports the theory that foods fed to older cats should have a lower urine acidifying potential (i.e., higher published urinary pH averages) than foods for young adult cats. A safe range of measured urinary pH values in mature adult cats is between 6.4 and 6.6.

The acidifying potential of commercial foods for older cats is not typically tested despite the fact that older cats generate a significantly lower urinary pH than younger cats fed the same foods (Smith et al, 1997). To achieve a normal urinary pH, the acidifying potential of foods for mature adult cats should be lower than that of foods for young adult cats. Published urinary pH averages should be greater for foods for older cats than for foods for young adults, unless the foods have been specifically tested in old or very old cats and found to be safe. Providing food with less acidifying potential helps avoid metabolic acidosis and its complications in older cats (Thumchai et al, 1996; Kirk et al, 1995).

Antioxidants

The consequences of prolonged oxidative stress (e.g., free radical damage) to cell membranes, proteins and DNA contribute to and/or exacerbate a wide variety of degenerative diseases including several of those listed in Table 20-1. The consequences of free radical damage to cells and tissues have also been associated with the effects of aging. Although aging is a complex, multifactorial process, the free radical theory of aging may account for many of associated degenerative changes (Harman, 1956). This theory proposes that free radicals produce cell damage and age-dependent pathologic alterations may be the cumulative result of some of these changes.

Many phenomena initiate free radical formation. Although environmental pollutants and radiation are direct and indirect sources of free radicals, the primary source is normal oxidative metabolism (McMichael, 2007). The body defends itself

against the effects of free radicals through a complex network of protective antioxidants. Antioxidants protect biomolecules by scavenging free radical compounds, minimizing free radical production and binding metal ions that might increase the reactivity of poorly reactive compounds. Besides these classic mechanisms, many antioxidants exhibit second messenger regulatory function, cell cycle signaling and control of gene expression (Chapter 7). Combinations of antioxidants work synergistically to reduce oxidative stress and are more effective than individual antioxidants.

The following key nutritional factor recommendations focus on vitamins E and C and selenium. Selenium is an essential component of the antioxidant enzyme glutathione peroxidase. These antioxidants are key nutritional factors because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C regenerates vitamin E after it has reacted with a free radical), 3) of safety and 4) information regarding inclusion levels in pet foods is usually available. Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at much higher levels (five to 10 times) than the recommended allowances for people or the minimum requirements for animals (Combs, 2001; Neve, 2002). For improved antioxidant performance, foods for older cats should contain at least 500 IU vitamin E/kg DM, 100 to 200 mg vitamin C/kg DM and 0.5 to 1.3 mg selenium/kg DM. The antioxidants discussion in Chapter 20 reviews the basis for these recommendations.

Palatability and Digestibility

Reduced smell or taste, oral disease or metabolic disturbances, medication use or a combination of factors can impair appetite and food intake in older cats (**Table 21-1**). Foods for very old cats should be highly palatable and highly digestible to lessen concerns about weight loss and inadequate food intake. Foods with an energy density greater than 4 kcal/g (16.7 kJ/g) DM are more likely to be highly digestible because they are likely to be lower in fiber and higher in fat.

Texture

Oral disease is the most common disease of mature adult cats (Lund et al, 1999). Age-related changes include an increased prevalence of dental calculus, periodontal disease, loss of teeth and oral neoplasia (Guilford, 1996). Cats with poor oral health have more difficulty eating, and pathologic lesions may act as a portal for bacteria into the body. Additionally, decreased salivary secretions and immune function may exacerbate oral infection and disease (Hefferren et al, 1996). Food texture can play an important role in the well-being of older cats. As in young adult cats, the texture of dry foods fed to older cats may result in less calculus and plaque accumulation than if moist foods are fed (Logan, 1996; Studer and Stapley, 1973). However, the dental efficacy afforded by most commercial dry foods appears not to be clinically important and such claims should generally be regarded with skepticism. Dry foods designed with dental cleansing benefit improve oral health by reducing accumulation of dental plaque and the severity of gingivitis (Logan, 1996; Logan et al, 1997). If the labels of such foods carry the Veterinary Oral Health Council (VOHC) Seal of Acceptance, they have been successfully tested, according to specific protocols, to clinically reduce plaque (Chapter 47). Conversely, hard dry foods (e.g., bones) may cause oral pain if fed to cats with gingivitis or periodontitis. Dry foods with softer texture, semi-moist foods or moist foods may be easier to chew. The optimal texture depends on

Table 21-5. Feeding plan summary for mature adult cats.

1. Select a food from **Table 21-4** that most closely matches the recommended levels of key nutritional factors; for foods not in **Table 21-4**, contact the manufacturer for key nutritional factor content.
2. Select a food with an appropriate energy density.
   Inactive/obese-prone mature adult = 3.5 to 4.0 kcal (14.6 to 16.7 kJ) ME/g dry matter.
   Underweight/low body condition mature adult = 4.0 to 4.5 kcal (16.7 to 18.8 kJ) ME/g dry matter.
3. The selected food should be approved by a credible regulatory agency (e.g., AAFCO).
4. Determine the preferred feeding method (Table 20-5); food-restricted meal feeding is best for obese-prone cats.
5. For food-restricted meal feeding, estimate the initial quantity of food based on DER calculation (DER ÷ food energy density, as fed); food energy density as fed (the amount/8-oz. measuring cup or can may be obtained from **Table 21-4** or from the manufacturer's information).
6. Body condition and other assessment criteria will determine DER. DER estimate is calculated by multiplying RER by an appropriate factor (Table 5-2). Remember, DER calculations are estimates and should be used as guidelines or starting points for individual cats and not as absolute requirements. Body condition and other assessment criteria are used to refine the amount to feed.
7. RER can be calculated from Table 5-2.
   Inactive/obese-prone mature adult (eight to 11 years) = 1.1 to 1.4 x RER
   Normal or underweight mature adult (≥12 years) = 1.1 to 1.6 x RER
8. Regularly monitor body condition, body weight and general health.

Key: ME = metabolizable energy, AAFCO = Association of American Feed Control Officials, DER = daily energy requirement, RER = resting energy requirement.

the oral health and food texture preference of individual mature adult cats.

FEEDING PLAN

Older cats are more prone to weight loss, cardiac disease, renal disease, cancer and metabolic aberrations and usually have a decreased activity level than younger cats. The feeding plan should be based on the information obtained in the assessment and any detected risk factors. Nutritional surveillance and therefore the number of contacts per year should be increased for older cats. Although general feeding goals remain the same as those listed in Chapter 20 for young adult cats (maximize health, longevity and quality of life), each patient should be evaluated individually. The feeding plan includes assessing and selecting the best food and feeding method for the individual patient as described for young adult cats.

Assess and Select the Food

Foods currently being fed should be evaluated to:

- Ensure the food was formulated according to the guidelines of a competent regulatory agency (e.g., AAFCO). Review product labels for nutritional adequacy statements (Chapter 9).
- Compare the key nutritional factor levels of the current food with key nutritional factor targets. **Table 21-4** lists selected foods for mature adult cats and key nutritional factor levels for those foods and compares them to the key nutritional factor recommended levels.
- Identify discrepancies between the key nutritional factor targets and those in the food currently fed. A different food should be selected if important discrepancies are found between the recommended levels of key nutritional factors and those in the current food.

It may not always be necessary to change the food and feeding method when managing healthy mature adult cats. However, a thorough evaluation includes verification that an appropriate food and feeding method are being used. Older cats should be reevaluated at each examination because nutrition and health needs change with disease status, risk factors and overall health.

An important goal when managing the nutrition of mature adult cats is to ensure adequate food intake. There is little need to change the form of food a cat eats well because of age. In fact, some cats will refuse to eat a new food with a different form or texture. However, cats with inadequate food intake may benefit from changing food forms if the new food is more palatable and easier to chew.

Assess and Determine the Feeding Method

The feeding method includes how much to feed and how it is fed. Healthy mature cats may be fed free choice, meal fed or fed by a combination of methods. Overweight cats should be offered measured amounts of food. The measured quantity may be fed in meals or dispensed at one time to allow continuous access throughout the day. Underweight cats should be allowed to eat free choice. Only dry and semi-moist foods may be fed free choice and these foods are generally less palatable than moist foods. Table 20-5 summarizes advantages and disadvantages of feeding methods. Older cats may have reduced olfaction and taste perception; therefore, it may be preferable to feed moist and warm foods to encourage food intake. Providing dry foods free choice and several moist food meals throughout the day may optimize food intake. Adding broth or canned meat juices to dry foods may enhance food and water intake in older cats. However, when considering broths or meat juices to improve palatability, evaluate the product for excessive sodium chloride content. (See Key Nutritional Factor discussion, above.) **Table 21-5** summarizes a feeding plan for mature adult cats.

Although most cats do not experience digestive upsets with typical food changes, a gradual transition to a new food may benefit mature adult cats. Progressively exchanging the new food for the usual food over four to seven days will minimize untoward effects and food refusal (Chapters 1 and 20 provide exact details).

REASSESSMENT

Veterinarians should examine older cats and conduct a nutritional assessment regularly. The frequency of monitoring

"The greatness of a nation and its moral progress can be judged by the way its animals are treated."
Mahatma Gandhi

INTRODUCTION

Domestic cats generally reach puberty by six to nine months of age. However, the best age for breeding is between one and one-half to seven years of age (Feldman and Nelson, 1996). Queens 10 to 12 months of age are still growing and must meet nutritional demands for their own growth as well as for their fetuses. Queens older than seven years should not be bred due to reproductive complications, irregular estrous cycles and reduced litter size (Feldman and Nelson, 1996). The reproductive stage of the queen can be divided into four periods: 1) estrus and mating, 2) gestation, 3) lactation and 4) weaning. In general, reproducing queens have increased nutritional needs compared with maintenance requirements, especially during late pregnancy and lactation. During reproduction, energy requirements increase and the minimum requirements for certain nutrients exceed even those required for growth.

The objectives of a good feeding program for reproduction are to optimize: 1) the health and body condition of the queen throughout the various reproductive periods, 2) reproductive performance and 3) kitten health and development through the weaning period. Key indicators of optimal reproduction are ease of conception, a low rate of fetal and neonatal deaths, normal parturition, maximum litter size, adequate lactation and an optimal growth rate of healthy kittens. Providing adequate nutrition throughout reproduction has long-range health implications for the offspring. Immune function is impaired for life in animals born to nutritionally deficient dams (Burkholder and Swecker, 1990). Meeting the nutritional needs of reproducing queens is critical to successful conception, delivery and weaning of healthy kittens.

Lactation begins at parturition and lasts six to 12 weeks depending on breed, kitten growth rates and management practices. Most kittens are sufficiently mature at eight weeks of age to maintain adequate food intake for optimal development. Purebred kittens are typically weaned later than domestic shorthair kittens. Lactation is the most demanding stage of reproduction. The queen must maintain its own nutritional needs and provide nutritionally complete, nutrient-dense milk to support the needs of growing kittens. Consequently, queens should enter lactation with sufficient energy stores to support needs above those supplied by daily food intake. Poor lactation performance is common without these reserves. Thus, successful lactation depends on appropriate nutritional management during the pre-breeding period, gestation and lactation.

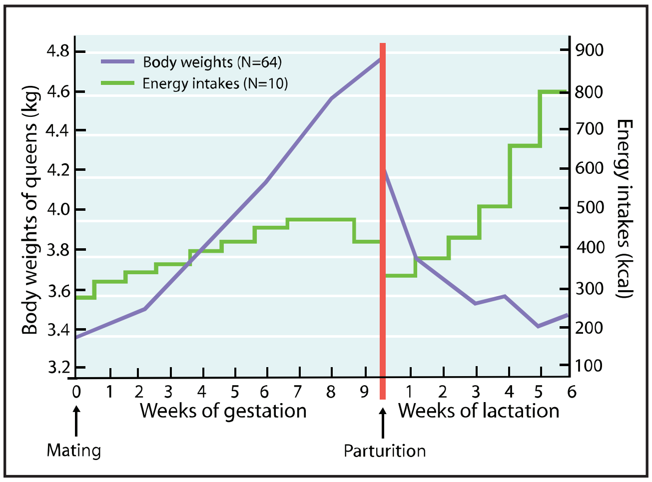

Figure 22-1. Body weight and energy intake during gestation and lactation in queens. Unlike bitches, which have a dramatic increase in energy intake and body weight during the last trimester, queens have a regular linear increase in both body weight and energy intake throughout gestation. Mobilized stores of body fat provide needed energy during lactation, which accounts for weight loss during this period. Food intake parallels lactation and peaks during the sixth to seventh week. (Adapted from Loveridge GG. Body weight changes and energy intake of cats during gestation and lactation. Animal Technology 1985; 37: 7-15.)

PATIENT ASSESSMENT

Estrus and Mating

Optimal nutrition for reproducing cats should precede mating and conception, and ideally start when the animal is a kitten. Female cats are seasonally polyestrous. Repeated estrous cycles occur throughout the breeding season, which typically occur from January through September in the northern hemisphere. Light duration and intensity are major determinants for the estrous period. Therefore, artificial lighting and latitude variation alter the breeding period for individual cats. Vocalizing, rolling, rubbing and treading characterize estrus in the queen; these behaviors culminate in acceptance of the male. Behavioral estrus averages seven to nine days (range one to 21). Cats are induced ovulators (i.e., coital contact is typically required for a luteinizing hormone surge and ovulation).

Queens should have a current vaccination history and be treated for internal and external parasites before breeding. A history and physical examination should precede breeding to assess problems that may interfere with conception, parturition and lactation. Queens should be at ideal body weight at mating (body condition score [BCS] 3/5). Small variations in body condition can be corrected during pregnancy; however, cats that are significantly under- or overweight (BCS <2/5 or >4/5) should not be bred. Both obesity and undernourishment can be detrimental to reproductive performance. Malnourished queens may fail to conceive, abort or bear small, underweight kittens and have a markedly reduced lactation. Lactating queens normally lose weight, but their body weight should return to normal before the next breeding. Obese cats reportedly have a greater incidence of dystocia (Lawler and Monti, 1984). Historical or physical evidence of a narrow pelvic canal, whether due to trauma, genetics or nutritional deficiency warrants careful assessment. Mammary tissue and teat development should be evaluated. Although congenital defects (e.g., multiple teats or teat malformation) rarely prevent queens from raising normal-sized litters, genetic selection away from such traits is advisable. Only cats in excellent health should be considered for breeding.

Tomcats should also be healthy and in optimal body condition (BCS 3/5); however, decreased reproductive performance associated with moderate deviations from ideal (BCS <2/5 to >4/5) have not been reported. In addition to a standard physical examination, the penis, prepuce and testes should be evaluated for anatomic defects. Previous reproductive performance including a weight history should be reviewed. The level of activity required during the breeding period should be ascertained. Single matings result in minimal changes in energy needs, whereas multiple matings may require an increase in the amount of food provided, based on body condition.

Pregnancy

The first assessment step is to diagnose pregnancy. Abdominal palpation is used most commonly to diagnose pregnancy in cats. The fetal vesicles can be reliably palpated from 14 to 25 days of gestation (Feldman and Nelson, 1996). An enlarged uterus is palpable from Day 25 to parturition. Ultrasound can detect pregnancy by Day 11 of gestation and fetal heartbeats are typically heard at 22 days (Davidson et al, 1986). Radiographic diagnosis requires calcification of the fetal skeleton and is most reliable after Day 45 of gestation. Gestation usually lasts 63 to 65 days (range 58 to 70 days) in queens, thus radiography is not useful for early pregnancy diagnosis, but is useful for determining litter size. In addition to the diagnosis of pregnancy, an assessment should include a dietary history, physical examination and any indicated laboratory analyses. Evaluations of body condition, weight gain and food intake are most important. Minimal diagnostics are usually required if the pelvic structures and mammary glands were evaluated and parasite, feline leukemia virus/feline immunodeficiency virus and vaccination status were determined before breeding.

One of the early indicators of successful breeding and conception is a steady gain in body weight. Weight gain increases linearly from conception to parturition in queens (**Figure 22-1**). This pattern is different from that of most other species, which experience small increases in body weight until the last third of gestation when weight gain and energy intake greatly increase. Weight gain in early pregnancy is not associated with significant growth of reproductive tissues or conceptuses but appears to be stored in energy depots (presumably as fat) to support lactation (Loveridge and Rivers, 1989). Mean weight gain during gestation is approximately 40% of the pre-mating weight (900 to 1,200 g for a litter of average size) and has been described by the equation (Loveridge and Rivers, 1989):

Weight gain (g) = 888.9 + (106.5)n (where n = number of neonates).

At parturition, only 40% of the weight gained by queens during gestation will be lost (Loveridge and Rivers, 1989), whereas bitches should return to pre-breeding weight (Feldman and Nelson, 1996a). The remaining 60% of prepartum weight gain will be used during lactation to sustain milk production. Poor nutrition may lead to failure to conceive, fetal death, fetal malformations and underweight kittens. Queens underweight at parturition may subsequently experience poor lactation performance and inability to maintain body condition. Poor maternal nutrition may impair the kittens' immunocompetence for life.

Overnutrition or obesity (BCS 5/5) has an equally negative effect on pregnancy outcome. Stillbirths, dystocia and cesarean sections occur more frequently in obese queens than in cats at ideal body condition (Lawler and Monti, 1984; Bilkei, 1990). Ensuring the queen is at ideal weight (BCS 3/5) before breeding is preferable to limiting food intake during gestation. Therefore, good nutritional management is important to optimal reproductive performance.

If queens are listless or have a poor appetite, the physical examination should closely evaluate uterine size and shape and any vaginal discharges. Laboratory evaluation should include a complete blood count and measurement of serum concentrations of glucose, calcium, protein, urea nitrogen, creatinine, phosphorus and potassium. The abdomen and uterus should be evaluated by ultrasound to evaluate fetal viability or if pyometra is suspected.

Lactation

Unless difficulties arise during parturition or lactation, a veterinarian will not examine most queens. Thus, pre-lactation counseling of the breeder or owner is important because most of the assessment will be performed without veterinary supervision. The queen and kittens should be weighed within 24 hours after parturition. The queen should weigh 700 to 900 g above the pre-breeding weight and each kitten should weigh approximately 100 g. The queen should be evaluated for vaginal discharges, body temperature and maternal behavioral characteristics. A dark reddish vaginal discharge is normal. Bright red discharges indicate hemorrhage, whereas foul-smelling, greenish, gray or brown discharges may indicate a retained fetus, retained placenta or infection. The queen's appetite, which is reduced 24 to 48 hours before parturition, should return to normal or to an increased level within 24 hours of parturition (Lawler and Bebiak, 1986). All kittens should nurse soon after parturition and within the first six to eight hours to ensure transfer of colostral antibodies. Neonatal kittens may not absorb immunoglobulins after 12 hours postpartum. This window of absorption is much shorter in kittens than in puppies and livestock (Casal et al, 1996).

Milk production should begin at parturition. Colostrum is produced during the first 24 to 72 hours of lactation. Milk yield depends on litter size and stage of lactation, with peak lactation occurring at three to four weeks. Investigators measured average milk yields of 1 to 3% of the queen's body weight/day during Week 1 (Dobenecker et al, 1998). Yields increase to 1.3 to 5.9% of the queen's body weight/day at peak lactation then decline slightly until weaning. Although mammary glands should be closely evaluated to ensure health and ready access for the kittens, expressing milk from each gland does not ensure adequate milk production. Continuous weight gain by the kittens is the best indicator of the queen's lactation performance. Neonatal kittens should gain between 10 to 15 g daily. Gains less than 7 g/day are inadequate (Lawler and Bebiak, 1986).

A veterinarian should immediately evaluate the queen and litter if health problems arise during lactation or kitten growth rates are suboptimal. A complete physical evaluation, anamnesis and review of the reproduction records and the nutritional plan should be performed. Blood and urine should be collected from the queen; a minimum database should include a complete blood count, urinalysis and serum biochemistry analysis including electrolytes. Ancillary tests should be performed as indicated.

Table 22-1. Key nutritional factors for foods for reproducing cats.

Factors (units)*	Mating**	Gestation/lactation
Energy density (kcal ME/g)	4.0-5.0	4.0-5.0
Energy density (kJ ME/g)	16.7-20.9	16.7-20.9

Ca:P ratio	-	1:1-1.5:1
Sodium (%)	0.2-0.5	0.3-0.6
Average urinary pH	6.2-6.4	6.2-6.5

Key: ME = metabolizable energy, DHA = docosahexaenoic acid.
*Units expressed on a dry matter basis. Concentrations presume an energy density of 4.0 kcal/g. Levels should be corrected for foods with higher energy densities. Adjustment is unnecessary for foods with lower energy densities.
**Foods for most breeding males and females are usually similar to those for young adult cats (Chapter 20).
***Important for lactation.

Key Nutritional Factors

Few studies establish the minimum nutritional requirements for reproducing queens and breeding male cats. Most nutrient recommendations are extrapolated from growth studies, results from other species and clinical experience. Although most commercial foods appropriate for growing kittens are deemed adequate for female reproduction, ideally, complete and balanced foods specifically designed to support gestation/lactation should be fed. Key nutritional factors for tomcats and queens during mating do not appear to be significantly different from those of young adults (Chapter 20). Exceptions will be noted below. **Table 22-1** summarizes key nutritional factors for reproducing cats eating commercial foods. The following section describes these key nutritional factors in more detail.

Water

Water is important for normal reproduction. Expansion of extracellular fluid compartments and maternal and fetal tissues

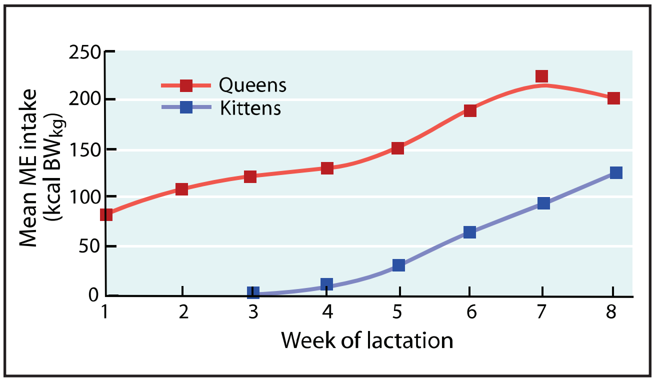

Figure 22-2. Food energy intake during lactation of queens and their kittens. Kittens begin eating the queen's food in increasing amounts from about four weeks of age until weaning. Energy intake peaks for queens at seven weeks and then decreases as kittens consume a larger percentage of their energy from food rather than milk. (Adapted from Munday HS, Earle KE. The energy requirements of the queen during lactation and kittens from birth to 12 weeks. Journal of Nutrition 1991; 121: S43-S44.)

during pregnancy increases the need for water. Water is particularly important for milk production during lactation. Water needs for lactating queens vary according to maintenance needs, type of food (moist vs. dry) and the rate of milk production. Although specific levels of water intake have not been established, reproducing queens should be provided with ample potable water at all times. Some queens are reluctant to leave the nest box during the first few days after parturition. Water intake should be encouraged by placing water very near the enclosure to allow easy access. Feeding moist foods or adding water to food can improve water intake.

Energy

ENERGY NEEDS DURING ESTRUS AND MATING

The energy requirements of most queens during mating do not appear to be significantly different from those of young adults (Chapter 20). The recommendation for energy density for foods for normal weight young adult cats is 4.0 to 5.0 kcal/g (dry matter [DM]) (16.7 to 20.9 kJ/g [DM]). However, during behavioral estrus, queens typically reduce food intake and body weight may decline. Food intake and body weight rebound upon cessation of estrus. In some queens, it may be advisable to feed a highly palatable food with an energy density at the upper end of the recommended range (4.5 to 5.0 kcal/g food [18.8 to 20.9 kJ/g food]) before mating to ensure optimal body condition at conception. Intact female cats typically require more calories than neutered housecats. The daily energy requirement (DER) for sexually intact cats is 1.4 to 1.6 x resting energy requirement (RER).

Breeding male cats that are used infrequently or in small catteries have energy needs similar to those of intact young adult cats (4.0 to 5.0 kcal/g or 16.7 to 20.9 kJ/g [DM]) (1.4 to 1.6 x RER). Tomcats that are used extensively for breeding may have difficulty maintaining proper body condition due to increased energy expenditure or, more often, reduced food intake. The stress of travel, new environments, social interactions and preoccupation with breeding may contribute to inappetence. These tomcats should be managed similarly to cats that are very active or under stress. Foods at the upper end of the recommended range of energy density for young adult cats (4.5 to 5.0 kcal/g food [18.8 to 20.9 kJ/g food]) with above average palatability should help these cats maintain ideal body condition (BCS 3/5) and activity.

ENERGY NEEDS DURING PREGNANCY

One of the most important changes in nutrient requirements of gestating cats is an increase in energy requirement. Although many essential nutrients are required at increased levels during gestation, dietary energy is often the most limiting "nutrient."

As mentioned previously, energy intake and weight gain increase linearly from conception to parturition in queens (**Figure 22-1**). However, food intake normally fluctuates slightly throughout gestation. Reduced food intake occurs approximately two weeks after mating and is thought to occur in association with fetal implantation at about Day 15 postconception (Feldman and Nelson, 1996). Energy intake increases then peaks between six to seven weeks of gestation. A second decline in food intake occurs during the last week of gestation. These transient declines in food intake do not appear harmful. However, inadequate food intake over the course of gestation may impair weight gain, the subsequent lactation and kitten health. The recommended energy allowance for gestation is 25 to 50% above maintenance levels or approximately 90 to 110 kcal/kg body weight/day (376 to 460 kJ/kg body weight/day), although total caloric intake may increase as much as 70% above maintenance (NRC, 1986; Loveridge and Rivers, 1989). The increased need for energy can be met by providing 1.6 x RER at breeding with a gradual increase to 2 x RER at parturition. Energy requirements sometimes exceed the recommended energy allowance due to individual cat variation and increased energy needs of queens with large litters. Therefore, free-choice feeding allows queens to adjust food intake as needed to meet the energy requirement for gestation. **Table 22-2** lists energy requirements of gestating queens at various body weights.

Feeding energy-dense foods (metabolizable energy [ME] = 4.0 to 5.0 kcal/g DM [16.74 to 20.9 kJ/g DM]) helps meet the energy needs of pregnant queens, especially during late gestation when the gravid uterus reduces stomach capacity.

ENERGY NEEDS DURING LACTATION

Lactation is the most energy-demanding stage of a cat's life. Peak milk production typically occurs at three to four weeks of lactation and, theoretically, peak energy demand should occur concurrently. However, actual peak energy demand occurs at six to seven weeks postpartum when energy requirements may exceed 250 kcal/kg body weight/day (1.05 MJ/kg body weight/day) or 2 to 6 x RER (**Table 22-3**). Observed energy intakes of queens and their litters during lactation increase from 90 kcal/kg body weight/day (376 kJ/kg body weight/day) at

parturition to 270 kcal/kg body weight/day (1.13 MJ/kg body weight/day) at Week 7 (Loveridge, 1985). The discrepancy in the timing of peak lactation and peak energy demand is due to combined food consumption by kittens and the queen. Kittens begin eating the queen's food in increasing amounts from three weeks of age until weaning. Therefore, the above estimates of energy requirement for the lactating queen include energy consumed by the queen and its kittens (**Figure 22-2**). When energy intake was measured for the queen alone, the energy requirement at Week 6 of lactation was 229 kcal/kg body weight/day (962 kJ/kg body weight/day) (Munday and Earle, 1991). Within large litters, up to 50% of the total energy was consumed by kittens, increasing the total energy consumption (i.e., kittens and queens) to as high as 306 kcal/kg body weight/day (1.28 MJ/kg body weight/day). Even with these large increases in energy intake, queens will continue to lose weight during lactation and return to pre-mating weight by weaning. Queens that lose excessive weight are prone to lactation failure. **Table 22-3** estimates the energy requirements of lactating queens. However, it is preferable to feed lactating queens free choice because the wide variation in energy needs makes accurate prediction difficult.

The high-energy demands during lactation require a marked increase in total food intake. Feeding an energy-dense food (4.0 to 5.0 kcal ME/g DM, [16.7 to 20.9 kJ ME/g]) helps meet these demands without overwhelming gastric capacity.

If kittens are encouraged to eat a solid food beginning at three weeks of age, the energy demands placed on the lactating queen will decline as kittens increasingly obtain nutrition from solid food. Maintenance energy levels are sufficient for queens at ideal body condition after the kittens are weaned. Queens that have lost excess body weight during lactation should be provided additional food to restore body condition.

Table 22-2. Energy requirements of pregnant queens.*

Body weight		kcal ME per day		kJ ME per day	
		At 90 kcal/kg BW	At 100 kcal/kg BW	At 375 kJ/kg BW	At 420 kJ/kg BW
kg	lb				
2	4.4	180	200	750	840
3	6.6	270	300	1,125	1,260
4	8.8	360	400	1,500	1,680
5	11.0	450	500	1,875	2,100
6	13.2	540	600	2,250	2,520
7	15.4	630	700	2,625	2,940
8	17.6	720	800	3,000	3,360

Key: ME = metabolizable energy, BW = body weight.

Table 22-3. Daily energy requirements of lactating queens over the lactation period.*

Weeks of lactation	Daily energy requirements		
-	Factor x RER	kcal/kg BW**	kJ/kg BW
1	2.3	115	481
2	2.5	125	523
3	3.0	150	628
4	3.5	175	732
5	4.0	200	837
6	5.0	250	1,046

Key: RER = resting energy requirement, $70(BW_{kg})^{0.75}$ or $30(BW_{kg}) + 70$, BW = body weight.
*Based on average queen at parturition (3.8 kg) nursing four to five kittens. These values represent average energy requirements for lactating queens. Individual animal variation and litter size may alter total daily energy needs.
**Adapted from the National Research Council. Nutrient Requirements of Cats. Washington, DC: National Academy Press, 1986.

Protein

Protein synthesis in the queen is greatly increased during gestation. Additionally, protein quality and quantity are important to provide essential amino acids for healthy fetal growth and development. Protein levels of 20% DM have sustained adequate gestation in gestating queens fed energy-dense (4.8 kcal/g [20 kJ/g]) purified foods. The minimum recommended allowance is 21.3% DM (NRC, 2006). However, 30% DM dietary protein results in near optimal weight gain in queens during gestation and kittens during lactation (Piechota et al, 1995). Considering the varying nutrient availability in typical pet food ingredients compared with purified foods, protein levels at or above 35% DM are recommended for gestating queens (range of 35 to 50%, DM). Animal-based proteins are preferred as the major source of dietary protein because they are usually more digestible and have more desirable amino-acid profiles. Protein deficiency during pregnancy may result in lower birth weights, higher neonatal mortality and impaired immunocompetency in kittens (Burkholder and Swecker, 1990). Additionally, when queens are fed protein-restricted foods during late gestation and lactation, their kittens can have delayed home orientation (i.e., ability to orient to and return to the nest), aberrant locomotor development and decreased emotional responsiveness (Gallo et al, 1984).

During lactation, queens increase protein synthesis to provide milk with adequate protein content for kitten growth (i.e., approximately 36% DM milk protein). Milk protein output for a 4-kg queen nursing a large litter may reach 19 g crude protein/day (Dobenecker et al, 1998). Thus, it is not surprising that protein needs during lactation exceed even gestational requirements.

The minimum recommended allowance for protein for peak lactation is 30% DM (NRC, 2006). Inadequate protein concentrations result in poor lactation and kitten growth. Queens fed foods containing 20% DM protein had lower hematocrit values at Week 6 of lactation compared with queens fed foods with higher protein levels (Piechota et al, 1995). Providing 25% DM crude protein to lactating queens results in satisfactory reproductive performance (Piechota et al, 1995). However, near optimal performance is achieved with foods containing 30% DM crude protein. Queens fed foods with 30% protein lose less body weight than those fed foods with levels of 20 or 25% DM protein. Additionally, food intake and kitten growth rates are

higher at dietary protein levels of 30% DM (Piechota et al, 1995). Because of variations in food digestibility and ingredient quality and the goal to promote optimal reproductive performance, the recommended crude protein allowance for lactation is at least 35% DM (range of 35 to 50%, DM). The protein sources in commercial foods should be highly digestible and have high biologic value. Animal-based protein ingredients should provide the major source of amino acids and protein for lactating queens.

For breeding males, the range recommended for young adult non-breeding cats is adequate (30 to 45%, DM).

Fats and Essential Fatty Acids

Fat delivers 2.25 times the number of calories as the same amount of protein or digestible (soluble) carbohydrate; therefore, increasing dietary fat increases a food's energy density. Thus, smaller amounts of food can be consumed to meet the queen's energy demands. The minimum recommended allowance for queens for late gestation and peak lactation is 9% DM (NRC, 2006). However, as discussed above, higher-energy foods are beneficial because of the increased energy demand during gestation and lactation and because such foods improve reproductive performance. For example, in one study, increasing dietary fat from 15 to 27% of the food DM: 1) increased the number of kittens per litter, 2) decreased kitten mortality from more than 20 to 9% and 3) improved reproductive efficiency in queens (more litters per year) (Olovson, 1986). For optimal reproductive performance, foods for gestating and lactating queens should contain at least 18% DM fat (range of 18 to 35%, DM), although foods with lower levels of fat have been successfully fed during gestation. Nutrients in the food should be balanced to the higher energy content of energy-dense foods (>4.5 kcal/g DM [18.8 kJ/g DM]). The fat content in foods for mating cats is typically between 10 to 30% DM.

Minimum essential fatty acid requirements for lactation do not differ significantly from those of gestation. However, a dietary source of docosahexaenoic acid (DHA, 22:6n-3) is required for normal development of retinal function in nursing kittens (Pawlosky et al, 1997). In children, during periods of early growth, DHA is needed to support retinal and auditory development (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003). Furthermore, brain development and learning ability were enhanced in infants supplemented with DHA (Birch et al, 2002; Hoffman et al, 2003). Similar to findings in other species, the inclusion of fish oil as a source of DHA in puppy foods improved trainability (Kelley et al, 2004). The need for DHA during growth in foods for kittens may be even more important than in foods for puppies considering the cat's reduced ability to convert shorter chain fatty acids to DHA. Milk concentrations of DHA parallel dietary intake. Therefore, DHA should be included in foods fed to lactating queens. Common ingredients such as fish and poultry meal represent a source of DHA in the food of queens. For foods for queens in late gestation and peak lactation, the minimum recommended allowance of DHA plus eicosapentaenoic acid (EPA) is at least 0.01% DM (NRC, 2006). Thus, DHA needs to be at least 40% of the total DHA plus EPA, or ≥0.004% DM.

Long-term deficiency of dietary arachidonic acid (AA) results in reproductive failure in cats (MacDonald et al, 1984). However, Association of American Feed Control Officials (AAFCO) allowances for AA are appropriate for gestating cats (AAFCO, 2007). Therefore, foods with AAFCO label statements acknowledging that a food is appropriate for growth or reproduction should provide adequate amounts (See the Essential Fatty Acid discussion in Other Nutritional Factors, below).

Digestible Carbohydrate

Although a true digestible carbohydrate requirement for cats has not been demonstrated, digestible carbohydrates apparently protect against weight loss in queens during lactation (Piechota et al, 1995). Digestible carbohydrates spare protein necessary to sustain blood glucose concentrations in queens and provide a substrate for lactose during milk production. Providing some digestible carbohydrate improves lactation performance even with an abundant supply of dietary protein (Piechota et al, 1995). Until further studies define optimal levels of digestible carbohydrates for lactation, at least 10% DM digestible carbohydrate should be included in foods for lactating queens.

Calcium and Phosphorus

Calcium and phosphorus are required at levels greater than maintenance to support fetal skeletal development and lactation. The minimal recommended DM allowances for dietary calcium and phosphorus for queens in late gestation and peak lactation are 1.08 and 0.76%, respectively (NRC, 2006). Recommended levels for foods for feline gestation and lactation should be within the ranges of 1.1 to 1.6 for calcium and 0.8 to 1.4 for phosphorus DM. Levels at, or greater, than these recommendations are typically found in commercial cat foods. The calcium-phosphorus ratio should be between 1:1 to 1.5:1. Although eclampsia is uncommon in cats, it does occur pre- and postparturiently (**Box 22-1**). The calcium and phosphorus recommendations for mating cats are the same as for young adult cats (Chapter 20).

Sodium

Reproducing queens, particularly during lactation, consume increased quantities of food to meet their energy and protein needs. In doing so, they consume considerably more sodium than in the non-reproducing state. Some women are predisposed to hypertension during pregnancy, but it is unknown whether or not there is a population of queens predisposed to hypertension during gestation.

There is no direct information to support a minimum recommended allowance for dietary sodium for gestation in queens but it is estimated to be about four times the amount recommended for adult maintenance (NRC, 2006). The minimal recommended DM allowance for foods for late gestation and peak lactation (0.27%) (NRC, 2006) is six to seven times the amount recommended for maintenance. Thus, an upper limit of 0.6%

Box 22-1. Eclampsia in the Queen.

Eclampsia, or periparturient hypocalcemia, is uncommon in cats. Clinical signs result from severe hypocalcemia, with or without other biochemical abnormalities. Predisposing factors may include improper perinatal nutrition, inappropriate calcium supplementation and heavy lactation demands. Whereas dogs typically present within the first four weeks of lactation, cats more commonly are presented during the last three weeks of pregnancy. Affected cats exhibit nonspecific clinical signs of lethargy, depression, weakness, tachypnea and mild muscle tremors. Additional signs may include vomiting, anorexia, and hypothermia, flaccid paralysis, hyperexcitability and other signs of malaise. Eclampsia should be considered as a diagnostic rule-out in queens with vague signs of illness late in gestation.

The pathophysiology of periparturient hypocalcemia in cats is not well understood. Some investigators have implicated excessive prenatal calcium intake. High calcium intake may down-regulate parathyroid gland secretion and impair normal mobilization of calcium from skeletal stores. As demand for calcium increases during late gestation and lactation, calcium homeostasis is unable to maintain critical serum levels. Although high calcium intake is an accepted cause of periparturient tetany in cattle, it remains speculative as the cause of the disease in cats.

Serum total calcium and ionized calcium concentrations usually are decreased. Ionized calcium is the biologically active form. In-hospital serum chemistry and point-of-care analyzers allow veterinarians to obtain serum total calcium and ionized calcium concentrations rapidly. Diagnosis of hypocalcemia is based on low serum ionized calcium concentrations. Blood glucose should be measured as well, because hypoglycemia may be present concurrently.

Treatment is aimed at immediate correction of hypocalcemia with a slow intravenous infusion of 10% calcium gluconate (1.0 to 1.5 ml/kg body weight over 10 to 30 minutes), given to effect. Heart monitoring (e.g., auscultation, electrocardiography) should be performed during intravenous calcium gluconate infusion. If bradycardia or dysrhythmias develop, the infusion must be slowed or discontinued. Dextrose may be administered by intravenous bolus (50% solution) or intravenous infusion (5% dextrose in saline solution) to correct hypoglycemia, if present. After acute signs are corrected, oral supplementation of calcium carbonate (10 to 30 mg/kg body weight every eight hours) is begun and continued throughout gestation and lactation.

If eclampsia is diagnosed following queening, the litter should be removed from the queen for 24 hours, during which time, the kittens should be fed kitten milk replacer by bottle or orogastric tube feeding. In contrast to dogs, it is rarely necessary to wean kittens early. Recurrence of periparturient hypocalcemia has not been reported in cats.

The Bibliography for **Box 22-1** can be found at www.markmorris.org.

DM is recommended for foods for queens in late gestation/peak lactation. The recommendation for sodium in foods for mating cats is the same as for young adult cats (Chapter 20).

Urinary pH

Highly acidified foods should be avoided during gestation because metabolic acidosis may impair bone mineralization in adult cats and kittens, which can be especially detrimental to developing fetuses (Ching et al, 1989, 1990; Dow et al, 1990; Buffington, 1988; Hardardottir et al, 1997). Foods designed to produce average urinary pH values between 6.2 to 6.5 appear to be safe (Allen et al, 1997). Foods for mating cats should produce average urinary pH values between 6.2 to 6.4, as for young adult cats.

Digestibility

For reproducing queens, foods with above average DM digestibility are better suited than less digestible foods because: 1) nutrient needs increase as pregnancy progresses 2) increased abdominal fullness as the pregnancy progresses may impair the queen's ability to ingest adequate amounts of nutrients, especially if the food is poorly digestible and 3) the nutritional demands of lactation are even greater than for gestation.

DM digestibility information for commercial foods marketed for reproduction is not readily available. However, energy density indirectly indicates digestibility. Foods with an energy density of 4 kcal ME/g (16.7 kJ/g) or higher have more fat and less fiber. Fat is typically highly digestible and fiber is poorly digestible. Thus, high-fat, low-fiber foods are usually more digestible.

Other Nutritional Factors

In addition to the key nutritional factors for commercial foods discussed above, the following nutritional factors may be important in some instances, especially when homemade foods are fed (Chapter 10).

Phenylalanine and Tyrosine

Tyrosine is not an essential amino acid but is made from phenylalanine. Also, tyrosine spares about half of the need for phenylalanine. Therefore, it is appropriate to consider the amount of phenylalanine required as the sum of phenylalanine plus tyrosine. Although phenylalanine and tyrosine are not the most limiting amino acids in commercial food, at least twice as much phenylalanine, or phenylalanine plus tyrosine, are required for maximal black hair color as for growth (Yu et al, 2001; Anderson et al, 2002). Other metabolic needs for phenylalanine and tyrosine include protein synthesis and synthesis of thyroid hormones and catecholamines (NRC, 2006). The minimal recommended DM allowance for foods for queens during late gestation/peak lactation for phenylalanine plus tyrosine is 1.91%. To maximize black hair color, 50% or more of this amount must be from phenylalanine (NRC, 2006).

Taurine
Taurine is required for normal reproduction and fetal development (Chapter 19). Taurine deficiency in gestating queens may result in fetal death near the 25th day of gestation, abortions throughout gestation, fetal deformities and delayed growth and development (Sturman, 1991). However, the taurine requirement for gestation is similar to that for other lifestages (i.e., a minimum of 0.1% DM taurine in dry foods and 0.17% DM in moist foods) (NRC, 2006; Kirk et al, 1995). Current AAFCO allowances for taurine are appropriate for reproducing cats (2007). Therefore, foods that have AAFCO label statements acknowledging appropriateness for growth or reproduction should provide adequate amounts.

Essential Fatty Acids
Linoleic and AA and possibly α-linolenic acid are required in foods for cats. Signs of linoleic acid deficiency in cats are similar to those in other animals (Chapter 32). However, the long-term deficiency of dietary AA also results in reproductive failure. Queens with an AA deficiency appear unable to bear live kittens (MacDonald et al, 1984). In contrast to queens, male cats do not appear to require AA for reproduction. Spermatogenesis remains normal in males with an AA deficiency possibly because testes convert linoleic acid to AA. AA at 0.04% of the dietary energy supports normal reproduction in queens. However, lower levels have been used when interference from omega-3 fatty acids is avoided (MacDonald et al, 1984). Current AAFCO allowances for linoleic and AA are appropriate for gestating cats (2007). Therefore, foods that have AAFCO label statements acknowledging that a food is appropriate for growth or reproduction should provide adequate amounts.

Magnesium
Magnesium should not be overly restricted in foods for reproducing queens. Most cat foods intended for prevention of struvite urolithiasis have magnesium levels above the minimum recommended allowance for late gestation and peak lactation (0.05%, DM) (NRC, 2006). Dietary magnesium levels of 0.08 to 0.15% DM are recommended in foods for reproducing queens.

Copper
Copper is required for normal iron metabolism and as an enzyme cofactor in several key metabolic pathways, including those responsible for myelin, melanin and connective tissue production. Copper requirements for growth and reproduction are thought to be approximately 5 mg/kg food (Doong et al, 1983). However, copper deficiency has been reported to occur in queens fed a food containing 15 mg copper/kg food, supplied, in part, by copper oxide (Morris and Rogers, 1994). Copper from copper oxide is poorly available. The combination of poorly available copper from food and competition from high levels of dietary zinc, iron, calcium and phytate significantly impair copper availability. Clinical signs of copper deficiency include fetal death and abortions, achromotrichia, arthrogryposis, fusion of digits, craniofacial deformities and cerebral dysgenesis.[a] For this reason, DM copper levels of 15 mg/kg food from an available source have been recommended for queens eating dry foods (AAFCO, 2007). The minimum recommended DM allowance for foods for late gestation and peak lactation in queens is 8.8 mg/kg (NRC, 2006).

A previous report of experimental copper deficiency cited histochemical defects of the aorta (Doong et al, 1983). Hematologic abnormalities are not a typical feature of copper deficiency in cats, as in other species. Supplemental copper in feline foods should be highly available. Copper sulfate and copper chelates appear to be good dietary sources.

FEEDING PLAN

Generally, feeding plan recommendations are based on information from populations of cats at similar lifestages. However, the feeding plan for reproducing cats should be tailored to meet the needs of the individual cat based on unique variations in genetics, environment, litter size and health status. The feeding plan includes the food to be fed and the feeding method (how much food is fed and how it is offered).

Assess and Select the Food
The process of food assessment includes comparing the current food's key nutritional factor content with the key nutritional factor recommendations for reproduction. **Table 22-4** lists the key nutritional factors in selected commercial foods and compares them to the recommended levels. For foods not listed, the same information can usually be obtained from pet food manufacturers (see pet food labels for toll-free numbers or websites). The comparison discloses potential discrepancies between the key nutritional factors and the cat's current food. Also, the food should be shown to be appropriate for reproduction based on AAFCO or other credible regulatory agency guidelines or feeding trials. Generally speaking, commercial growth-type foods are also intended for feeding to queens for gestation/lactation.

Food assessment during lactation also includes assessment of lactation performance. Evaluation of kitten growth rate and rate of weight loss in the queen can point to nutritional inadequacies in the queen during late gestation and lactation. Nursing kittens should gain approximately 100 g/week or 10 to 15 g/day. Weight gains less than 7 g/day require immediate evaluation of the food, the queen and the kittens. Queens normally lose some weight during lactation but should return to within 2% of their pre-breeding body weight by weaning (**Figure 22-1**). Weight loss is also related to litter size. The anticipated weight loss of queens from Week 0 to 3 can be approximated by the following equation (Loveridge and Rivers, 1989):

Total queen's body weight loss (g) = 339.2 + (58.8)n (where n = number of kittens).

If either the queen's rate of weight loss is excessive, or the kittens' growth rate is inadequate, the food and feeding method

Chapter 23

Feeding Nursing and Orphaned Kittens from Birth to Weaning

Kathy L. Gross
Iveta Becvarova
Jacques Debraekeleer

"Kittens are angels with whiskers."
Author Unknown

INTRODUCTION

Kittens usually depend on the queen to provide food during the neonatal or nursing period. Proper nutrition of the queen during gestation and lactation, the behavior and health of the queen and good neonatal care are important to achieving a successful transition from fetal life to the nursing period. The transition from queen's milk to solid food (weaning) is a gradual process and is an integral part of the nursing period. This chapter includes feeding normal nursing kittens, feeding orphaned kittens and integrating the weaning process.

Kittens are considered orphaned if they lack sufficient maternal care for survival from birth to weaning. Several physiologic needs normally provided by the queen must be met to ensure survival of neonates: heat, humidity, nutrition, immunity, elimination, sanitation, security and social stimulation. A foster queen or the caregiver must meet these needs for orphaned kittens (**Box 23-1**).

PATIENT ASSESSMENT

History

Clients should be encouraged to keep logbooks of all data that may provide information about the health and nutritional status of kittens (i.e., orphaned, fostered and normal) and the reproductive performance of the queen. Records should include food intake, body weight, body temperature and stool characteristics, especially during the first two weeks postpartum. Changes in kitten behavior, activity and other indicators of normal development (e.g., opening of eyes, eruption of teeth and coat quality) may prove useful as well (**Table 23-1**). In some instances, it may be helpful to differentiate individual kittens (**Box 23-1**).

It is particularly important that good records be maintained for orphaned and foster kittens. Orphaned kittens are hand-raised kittens, whereas foster kittens are those raised by a queen other than their mother. Successful management of these kittens depends on the quick recognition and correction of health and management problems. Parameters such as weight gain, daily food intake, stool characteristics and kitten vigor (i.e., muscle tone, activity and alertness) should be recorded. Kittens should be observed for suckling activity in addition to the above parameters.

Orphaned kittens should have consistent weight gains similar to those of suckling kittens (**Figure 23-1**) (Remillard et al, 1993). Orphans, in particular, should be examined for common problems such as hypothermia, hypoglycemia, dehydration and congenital defects. The current nutritional and hydration status

Box 23-1. General Good Husbandry Practices for Neonatal Kittens.

Kittens should be housed in warm draft-free enclosures. Incubators are ideal, particularly for newborn kittens. Pet carriers, shoeboxes or cardboard boxes are suitable substitutes. The bedding should be soft, absorbent and warm. Thread-free cloth, fleece and shavings are appropriate materials and help kittens feel secure as they snuggle into them.

Neonates demonstrate a certain degree of poikilothermy and are unable to regulate body temperature well during the first four weeks of life. Kittens huddle together close to the queen, which generates an optimal microclimate, protects them against changes in environmental temperature and decreases the rate of heat loss. Orphans cannot seek protection near the queen and are more sensitive to suboptimal environmental conditions.

Without the queen, neonates can quickly become hypothermic, which leads to circulatory failure and death. Artificial heat should provide age-optimal environmental temperatures (**Table 23-2**). It is best to set the heating source to establish a gradation of heat in the nest box. A gradation of environmental temperatures allows neonates to move toward or away from the heat source as needed to avoid hyperthermia, which can be as detrimental as hypothermia. Kittens can rapidly become dehydrated secondary to overheating. Maintaining humidity near 50% helps reduce water loss and maintains the moisture and health of mucous membranes.

To fulfill non-nutritive nursing needs, hand-reared kittens often nurse other littermates in the nest box. To avoid skin trauma related to excessive nursing, kittens can be housed individually or separated by dividers. Although beneficial for alleviating problems due to non-nutritive nursing, separation of the litter reduces temperature and humidity in the immediate environment and social stimulation by littermates. Brief, but regular handling, provides social stimulation. The stress associated with regular handling increases neural development and improves weight gain in kittens. Kittens raised without social stimulation develop abnormal behavior patterns (i.e., kittens reduce normal exploratory behavior and become more suspicious and aggressive as adults). Peer contact can compensate for maternal deprivation. Therefore, benefits of separating neonates must be weighed against the potential for development of abnormal behavior and increased risk for hypothermia. Kittens should interact with littermates as much as possible until weaning.

Kittens obtain passive systemic immunity from colostrum and passive local immunity from continued ingestion of queen's milk. If possible, neonates should receive colostrum or queen's milk within the first 12 hours of birth. This is particularly critical for kittens fed only milk replacers because they lack systemic and local immune protection.

Normally the queen will sever the umbilical cord. If not, it should be cut to 1.5 in. (3.5 to 4 cm) and an appropriate topical antiseptic applied. Orphaned kittens are at greater risk for infectious disease; thus, sanitary husbandry practices are important. To reduce risk for diseases, kittens should not be exposed to older animals or grouped within multiple litters. Feeding equipment and bedding should be kept clean and sanitized frequently. Caretakers should wash their hands before handling neonates and after stimulating elimination.

Kittens cannot voluntarily urinate or defecate until about three weeks of age. Until that time, they rely on the queen to stimulate the urogenital reflex to initiate elimination. Caretakers should stimulate kittens after feeding by gently swabbing the perineal region with a warm moistened cotton ball or cloth.

Often, kittens within a litter look similar; therefore, it may be difficult to tell them apart when hand rearing, especially in large litters. Different colored nail polish can be applied to the claws to help differentiate individuals; ask clients to paint a different paw for each kitten (e.g., blue front left paw, blue right rear paw, pink right front paw, etc.).

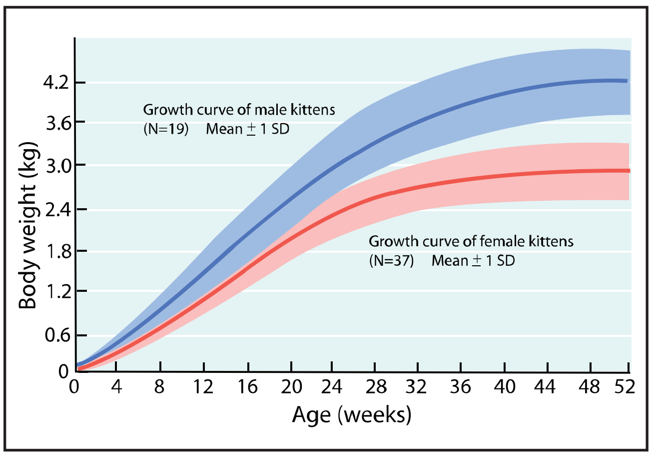

Figure 23-1. Growth curve for female and male kittens. Note after four weeks of age there are significant gender differences in growth rates; female kittens grow at a slower rate and are normally smaller than males. (Adapted from National Research Council. Nutrient Requirements of Cats. Washington, DC: National Academy Press, 1986; 2.)

should also be noted. Kittens fostered onto another queen should be supervised initially to detect any behavioral problems between the foster parent, its young and the orphans. Ideally, kittens should be accepted immediately and allowed to nurse. Ask clients to watch for signs of rejection or impending cannibalism by the foster queen.

Queens should also be monitored for signs of impending cannibalism (e.g., extreme nervousness, aggressiveness toward the kitten(s) and kitten rejection). Unfortunately, cannibalism often occurs without warning. In the case of orphans, the queen, if available, should be examined to detect the potential cause for abandonment.

Additionally, housing and environmental hygiene should also be evaluated. Improper housing and hygiene are important risk factors for poor kitten development and impaired health.

Physical Examination

The goals of the neonatal physical examination are to: 1) establish baseline data for future reference, 2) assess overall health and development of the kittens and 3) detect abnormalities that

Table 23-1. Normal physiologic values for neonatal kittens and data for neonatal care.

Litter size	-	Average: 3-5 (1-7)
Body weight	Birth weight	90-120 g
	Weeks 1-2	Double
	Weeks 3-4	Triple
Daily weight gain	Weeks 1-4	Average: 10-13 g/day
Body temperature	24 hr after birth	33.3-35.5°C (92-96°F)
	End of Week 1	36.6°C (98°F)
Heart rate	Weeks 0-4	>220 beats/min.
Respiratory rate	Weeks 1-2	15-35 breaths/min.
Shivering reflex develops	-	Week 1
Eyes	Eyelids open	8 days (5-14)
	Pupillary light response	24 hr after eyelids separate
Ears	Reaction to auditory stimuli	3 days
	External ear canals open	6-14 days (completely open by 17 days)
	Development functional hearing	21 days
Locomotion	Forelimbs start to support weight	3-4 days (1-10)
	Ability to stand	
	Sitting	10 days (5-25)
	Walking unsteadily	20 days
	Start climbing	21-22 days
Micturition and defecation	Voluntary control	3 weeks
Energy requirements	At birth	380 kcal/kg
	At 4 weeks	250 kcal/kg
Eating solid food	-	28-50 days
Deciduous teeth eruption	Incisors	2-3 weeks
	Canines	3-4 weeks
	Premolars	3-6 weeks
Permanent teeth eruption	Incisors	3-4 months
	Canines	4-5 months
	Premolars	4-6 months
	Molars	4-5 months

may impair normal development and health. During the physical examination, particular attention should be given to kitten behavior, body weight, body temperature and oral cavity health. Additionally, the umbilicus of each kitten should be closely evaluated. Normally, the queen will cut the umbilicus leaving approximately one and one-half inches. Occasionally, queens will remove excessive cord resulting in an umbilicus flush with the abdomen or an open hernia (**Figure 23-2**). Careful wound management and antibiotic therapy are often required to prevent omphalitis and/or septicemia. Umbilical cords left too long may wrap around the kitten's legs or paws cutting off circulation to the affected limb.

Kitten Behavior

Normal kittens are vigorous and have good muscle tone. They should nurse immediately or soon after parturition and have a strong sucking reflex. Well-fed kittens should have a distended abdomen and be quiet after feeding. Kittens that are hungry, cold, hot or in discomfort will cry continuously and should be closely monitored. Nursing behavior and milk intake should be carefully observed because some kittens develop rounded abdomens as a result of aerophagia. Kittens may have difficulty nursing queens of longhaired breeds due to hair accumulation or matting around nipples. In these cases, abdominal hair can be clipped to allow easier access to the queen's nipples. Care should be taken not to damage the queen's nipples during this process.

The behavioral response of kittens to the queen is also important. Poor maternal-kitten interaction may result in cannibalism or neglect. Kittens depend on the queen for food, antibodies, warmth and hygiene; therefore, serious metabolic alterations (e.g., hypoglycemia, hypothermia, dehydration and malnutrition), infectious disease and death are common sequelae to abnormal behavior and maternal neglect.

Body Weight

Monitoring initial and subsequent body weight is a good way to evaluate milk intake and health status of nursing and orphaned kittens. Healthy nursing kittens should be weighed at birth and weekly thereafter using a gram scale. Daily weighing is important to evaluate the queen's milk production and to help assess sick, weak and underweight kittens. Weight loss or slow weight gain in individuals or entire litters may indicate: 1) disease in kittens or the queen, 2) inability of kittens to suckle or 3) inadequate milk production.

Birth weights are normally between 85 to 120 g with mean weights of approximately 100 g. Kittens weighing less than 75 g have very high mortality rates and require extra care and monitoring if they are to survive. Low birth-weight kittens should be weighed every 24 to 48 hours for the first one to three weeks of life to ensure proper weight gain. Kittens gain an average of 100 g/week for the first six months of life. Minimally, they should gain 7 g/day (Lawler and Bebiak, 1986).

Body Temperature

Kittens regulate body temperature poorly during the first four

Table 23-2. Optimal environmental temperature for orphaned kittens.

Age	°C	°F
Immediate environment/incubator for orphans		
Week 1	32-34	89.5-93
Week 2	27-29	81-84
Week 3	24-27	75-81
Weeks 4-12	24	75
Environment around litter		
Week 1	24-27	75-81

Figure 23-2. A neonatal kitten with an open umbilical hernia following excessive umbilical cord removal by the queen after parturition.

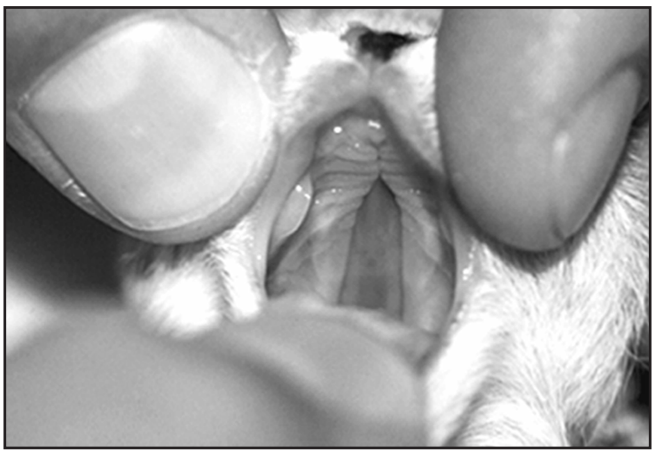

Figure 23-3. Cleft palate in a neonatal kitten. This is a common birth defect in kittens and may be associated with malnutrition of the queen during gestation. Nutrients commonly associated with a cleft palate include deficiencies of zinc and copper, as well as, vitamin A toxicosis during gestation.

weeks of life. Normal body temperature is approximately 36.0°C (96.8°F) at birth and increases to 37.5°C (100.0°F) by one week of age (Lawler and Bebiak, 1986). Extreme environmental conditions or abandonment by the queen may lead to hypothermia, which may quickly result in circulatory failure and death.

Normally the queen maintains the temperature and humidity in the nest box. Without the queen, kittens can quickly become hypothermic. Artificial heat should provide age-optimal environmental temperatures (**Table 23-2**). It is best to set heat sources to establish heat gradation in the nest box. This allows kittens to move away from the heat source as needed to avoid hyperthermia. Hyperthermia can be as detrimental as hypothermia; hyperthermic kittens can rapidly become dehydrated. Maintaining humidity near 50% helps reduce water loss in kittens and maintains the moisture and health of mucous membranes.

Oral Cavity

Examination of the oral cavity should include careful evaluation of the mucous membranes and hard palate. The mucous membranes should be light pink and moist. Cleft palates are relatively common defects in kittens (**Figure 23-3**). Vitamin A toxicity and trace mineral deficiencies (i.e., copper and zinc) during gestation have been associated with the development of cleft palates in kittens. However, in most cases, a cause is not identified. Most kittens with a cleft palate are unable to nurse effectively. Affected kittens must either be tube fed until the time of surgical correction or spontaneous closure, or they should be humanely euthanized.

Laboratory Evaluation

Laboratory tests should be performed as needed to assess any abnormalities noted during the physical examination. Particular attention should be given to hydration status and serum glucose and electrolyte concentrations. When evaluating laboratory data in kittens, age-appropriate reference values should be used because concentrations of certain analytes (e.g., phosphorus, hematocrit, serum proteins) vary markedly from adult values (Hoskins, 1990).

Key Nutritional Factors

Colostrum and Milk

Colostrum is milk provided by the queen during the first 24 to 72 hours after parturition. Colostrum provides nutrients, water, growth factors, digestive enzymes and maternal immunoglobulins, all of which are critical to survival of neonatal kittens. Colostrum differs from mature milk in water and nutrient composition (**Table 23-3**). The dry matter (DM) content of colostrum is high, which accounts for its sticky, concentrated appearance compared with mature milk. The DM concentration declines as water content increases from Day 1 to 3 of lactation (Adkins et al, 1997). Lactose concentrations are low in colostrum (29.9 g/l or 23 mg/kcal) and increase as milk matures. Protein and lipid levels decline markedly from Day 1 to 3; however, this decline likely reflects the initial change in water content because nutrient levels rebound after Day 3 and increase slightly over the course of lactation. Like protein and lipid levels, the calculated gross energy of colostrum is high on Day 1 of lactation (1,300 kcal/l or 5.44 MJ/l) and falls significantly by Day 3. However, the energy content then increases throughout lactation. Changes in mineral content also vary with time. Calcium and phosphorus concentrations increase up to Day 14, whereas iron,

copper and magnesium concentrations decline. Early studies reported very low calcium concentrations and calcium-phosphorus ratios of 0.5:1 in queen's milk. These values likely represent colostral milk (calcium-phosphorus ratio = 0.4:1) (Baines, 1981). Recent studies of queen's milk report calcium-phosphorus ratios between 0.8:1 to 1:1 on Day 7; ratios reach 1.2:1 by late lactation (Dobenecker et al, 1998; Adkins et al, 1997). The variation in nutrient content with time probably explains the discrepancy in milk composition published by different investigators. Different values probably represent milk from different stages of lactation.

In addition to providing complete nutrition for nursing kittens, queen's milk also supplies non-nutritive factors that enhance food digestion, neonatal development and immune protection. The immunoglobulin concentration of cat colostrum and mature milk may not be significantly different as they are in most species (Casal et al, 1996). More studies are needed to further evaluate this difference; a decline in immunoglobulin concentrations and an increased casein-whey ratio with time contradict this finding (Adkins et al, 1997). Regardless, kittens acquire passive systemic and local immunity from ingesting either colostrum or mature milk (Casal et al, 1996). Kittens should receive colostrum within the first 12 hours of life to obtain adequate systemic immunity; after 16 hours, passive immunoglobulin transfer does not occur in kittens (Casal et al, 1996). During this time, kittens absorb intact immunoglobulins across the intestine. Failure to ingest colostrum or queen's milk during this absorptive window leaves kittens immunologically compromised and susceptible to infections and sepsis. Passive transfer of systemic immunity is particularly important to orphaned and hand-raised kittens that are fed only milk replacers. Consumption of queen's milk provides local concentrations of immunoglobulins within the gastrointestinal (GI) tract and helps prevent invasion of microorganisms into the bloodstream (passive local immunity). Local immunity persists as long as kittens receive queen's milk. Both systemic and local immunity are important in maintaining kitten health until maturation of the kittens' immune system.

Mature milk is a complete food for nursing kittens. Water, protein, fat, lactose, minerals and vitamins are provided in amounts sufficient for normal growth and development. As mentioned previously, mature milk may sustain high immunoglobulin levels similar to those provided by colostrum. Continued nursing provides high immunoglobulin levels for passive local immunity. Thus, the major feature differentiating mature queen's milk from colostrum is the nutrient content (**Table 23-3**). As lactation progresses, milk energy, protein, lactose, calcium and phosphorus levels increase whereas copper, iron and magnesium concentrations decrease (Adkins et al, 1997). The amino acid profiles of colostrum and mature milk also differ. Notable features include the relatively high concentrations of arginine and taurine in queen's milk, which likely reflect the unique metabolism of cats.

The nutrient requirements of nursing kittens have not been well studied. Although the nutrient profile of queen's milk is thought to provide optimal nutrition, faster growth rates are typically observed in kittens fed milk replacers (Remillard et al, 1993). Nevertheless, nutrient recommendations for neonates are based on the composition of queen's milk and growth studies in weaned kittens. Despite discrepancies in published nutrient values, queen's milk varies markedly from milk of other species (**Table 23-3**). Consequently, milk from other species is unsuitable for nursing kittens.

Table 23-4. Daily energy intake recommendations for orphaned kittens as a basis for determining food dose.*

Age (days)	kcal ME/100 g BW	kJ ME/100 g BW
1-3	15	60
4-6	20	85
>6	20-25	85-105

Key: ME = metabolizable energy, BW = body weight.
*Clients should not overfeed orphan formulas initially; the energy amounts listed for the first six days of the feeding period intentionally underfeed but then gradually increase so that the orphans' energy requirements are being met after about one week. Adapted from Mundt H-C, Thomée A, Meyer H. Zur Energie- und Eiweißversorgung von Saugwelpen über die Muttermilch. Kleintierpraxis 1981; 26: 353-360. Schaefers-Okkens AC. Pediatrie Post University Course, Ghent, Belgium, January 14, 1993. Sheffy BE. Nutrition and nutritional disorders. Veterinary Clinics of North America: Small Animal Practice 1978; 8: 7-29. Monson WJ. Orphan rearing of puppies and kittens. Veterinary Clinics of North America: Small Animal Practice 1987; 17: 567-576. Hoskins JD. Clinical evaluation of the kitten from birth to eight weeks of age. Compendium on Continuing Education for the Practicing Veterinarian 1990; 12: 1215-1225.

Replacement formulas with a nutrient profile similar to that of mature milk should be used for orphans and supplemental feedings. Thus, the nutrient content of queen's milk in **Table 23-3** provides a summary of the key nutritional factors for nursing kittens. For nutrients in which the concentration in mature milk is unknown, values recommended by the Association of American Feed Control Officials (AAFCO) for growth should suffice (2007). Also, the key nutritional factor discussion (Chapter 24) for postweaning kitten growth provides information that could be extrapolated to neonates, in lieu of other information.

Water
Kittens contain 78.8% body water at one week of age (Halle, 1992). Total body water decreases to 70.1% at weaning. By comparison, adult cats are composed of only 61.7% water (Halle, 1992). Water is one of the most important nutrients in orphan feeding. The normal water intake of kittens is relatively high. A normal kitten needs about 155 to 230 ml water/kg body weight/day (i.e., 4.4 to 6.5 ml water/oz. body weight). On average, orphaned kittens should receive about 180 ml of liquid/kg body weight to make orphan feeding successful. Water should be given until a total intake of 180 ml/kg body weight/day is reached if the milk replacer doesn't provide this much water at the recommended dilution.

Energy
Queen's milk typically meets the energy requirements of nursing kittens. Newborn kittens require about 24 kcal (100 kJ) metabolizable energy (ME)/100 g body weight for the first four weeks of life. **Table 23-4** provides recommended levels of energy intake for orphaned kittens from one to four weeks of age. By six weeks of age, male kittens are significantly heavier than female kittens and consume a proportionately larger quantity of food. As a rule, milk contains from 0.85 to 1.6 kcal/ml (3.6 to 6.7 kJ/ml) and milk replacers contain approximately 1 kcal/ml (4.2 kJ/ml) as fed. In general, kittens less than one week old will eat a volume equal to 10 to 15% of their body weight as milk or properly formulated milk replacer per day and a volume equal to 20 to 25% of their body weight per day between Weeks 1 to 4. This is also a reasonable target if the caloric content of the food is unknown. A very common mistake is to underestimate the energy requirements of neonates. In the beginning, however, it is better not to overfeed to avoid diarrhea. In most cases, it is best to follow label recommendations on commercial products or feed based on energy calculations.

Protein
The minimum protein requirement of nursing kittens has not been established. However, it is assumed to be comparable to that for weanling kittens, which is approximately 18 to 20% DM (Smalley et al, 1985). These requirements were established using purified diets and may not accurately reflect the needs of kittens fed commercial foods made from typical ingredients. The AAFCO recommendation of 30% DM appears adequate (2007); however, the protein content of queen's milk ranges from 33 to 44% DM (Adkins et al, 1997; Baines, 1981).

It is essential that commercial milk replacers and homemade replacer formulas have adequate protein and essential amino acid content. The arginine and histidine levels in the formula are particularly important. Deficiency of these amino acids can cause cataract development in neonates and contribute to anorexia and poor growth. The minimum recommended levels of these two amino acids for growth in kittens after weaning are 0.96 and 0.33% DM, respectively (NRC, 2006). These recommendations are based on a food with 22.5% DM crude protein. For foods with 30% crude protein, DM arginine should be increased to 0.975% (NRC, 2006).

Taurine
Taurine is important for normal growth and development of kittens. Fortunately, dietary taurine is more available to kittens than adult cats (Earle and Smith, 1994), presumably because of reduced bacterial degradation of taurine in the GI tract. Normal plasma taurine concentrations are maintained in 12- and 18-week-old kittens fed taurine at 150 to 197 mg/kg body weight/day (Earle and Smith, 1994). Queen's milk supplies about 300 mg taurine/liter (NRC, 1986; Adkins et al, 1997). Queens fed low-taurine foods have significantly lower milk taurine levels, which may impair normal growth and development.[a] Dietary taurine intake influences milk taurine concentrations, thus it is not surprising that cow's milk is a poor source of taurine (i.e., only 1.3 mg/l) (NRC, 1986). Therefore, homemade milk replacers based on cow's milk should be supplemented with taurine (30 mg taurine/100 ml milk replacer). Taurine is commercially available as crystalline taurine from veterinary pharmacies or health food stores.

Fat
Milk fat is an important source of energy and essential fatty

acids for nursing kittens. The composition of the queen's diet can significantly influence milk fat quantity and quality, which translates into fat composition of the offspring (Pawlosky and Salem, 1996). The fat content of queen's milk increases throughout lactation. Average fat concentrations of 28% DM or 86 g/l appear typical (Dobenecker et al, 1998; Adkins et al, 1997; Baines, 1981). Queen's milk provides the essential fatty acids linoleic and arachidonic acid at 5.8 and 0.5% DM, respectively (Dobenecker et al, 1998). Docosahexaenoic acid (DHA) is also essential for normal retinal development and function in kittens (Pawlosky et al, 1997). Milk DHA concentrations reflect the dietary intake of the queen. The recommended DM level of DHA plus eicosapentaenoic acid (EPA) for kittens after weaning is 0.01%. EPA should not exceed 60% of the total DHA plus EPA (NRC, 2006). These levels are probably also suitable for orphan formulas.

Carbohydrate
No carbohydrate requirements have been established for nursing and growing kittens. However, the lactose concentration of queen's milk ranges from 14 to 26% DM. Intestinal lactase activity declines to adult levels very soon after weaning (Kienzle, 1987). Overfeeding cow's milk causes diarrhea, bloating and abdominal discomfort in kittens due to bacterial metabolism of undigested lactose in the large intestine. Owners who wish to offer cow's milk should be advised to limit the quantities given and to discontinue feeding cow's milk if intolerance occurs.

Calcium and Phosphorus
Calcium concentrations are low in colostrum (0.22% DM) and increase significantly to approximately 1% DM by mid to late lactation (Adkins et al, 1997). Thus, requirements appear limited early on and increase with bone mineralization and growth. Milk phosphorus concentrations do not vary to the same extent. Therefore, calcium-phosphorus ratios increase from a low of 0.4:1 to 0.8:1 on Day 1 of lactation to approximately 1:1, or higher, between one to three weeks of lactation and remain at that level throughout lactation (Adkins et al, 1997; Dobenecker et al, 1998).

Trace Minerals
Queen's milk contains iron, copper and zinc concentrations markedly higher than those in human and bovine milk but similar to those in canine milk. Copper and iron levels gradually decline throughout lactation, whereas zinc concentrations remain constant. Consequently, mineral deficiencies are rarely reported to occur in nursing kittens fed queen's milk. However, milk replacers made from cow's milk should be supplemented to levels typically found in queen's milk to avoid deficiency (**Table 23-3**).

Commercial milk replacers are often fortified with iron at concentrations higher than those found in queen's milk. Orphaned kittens, especially low birth-weight neonates born with low iron reserves, may benefit from iron intakes higher than those normally found in milk. The additional iron supports hematopoiesis and helps avoid anemia sometimes observed in three- to four-week-old neonates.

Digestibility
DM digestibility of queen's milk is very high (>95%). Digestibility of milk replacer formulas should also be high (>90%) to allow for smaller quantities to be fed and avoid diarrhea.

Osmolality
High osmolality should be avoided in milk replacers because it may cause hyperosmolar diarrhea and potentiate dehydration. High osmolarity may delay gastric emptying and predispose to regurgitation, vomiting and aspiration during the next meal, if the stomach is not completely empty. The osmolarity of queen's milk is approximately 329 mOsm/kg.

FEEDING PLAN

The feeding plan includes determining the best food and feeding method, under the prevailing circumstances. **Tables 23-5** and **23-6**, respectively, provide feeding plan summaries for nursing and orphaned kittens.

Assess and Select the Food
Foods should be liquid until kittens are three to five weeks old, then semi-solid to solid foods may be introduced, which marks the beginning of the weaning process (**Box 23-2**). Foods may consist of queen's milk, commercial milk replacers or homemade milk replacers (including supplemented human enteral formulas). **Table 23-7** provides a list of commercial milk replacers and compares their nutrient profiles (key nutritional factors) with queen's milk. **Table 23-8** provides two homemade milk replacer recipes and **Table 23-9** compares these recipes' nutrient profiles with that of queen's milk.

Kittens should receive colostrum within the first 12 to 24 hours after parturition. Subsequently, immunoglobulins are no longer absorbed from the GI tract and passive transfer will not occur (Casal et al, 1996). If colostrum is unavailable, milk collected from queens at any stage of lactation may be substituted. Antibody levels in non-colostral milk appear to adequately transfer passive immunity to kittens (Casal et al, 1996).

Alternatively, sterile serum may be given to kittens subcutaneously if milk is unavailable (Pedersen and Wastlhuber, 1991). To collect serum, using sterile technique, blood should be obtained from healthy, well-vaccinated donors free of communicable diseases. After the blood has clotted and been centrifuged, the serum is removed and administered in a sterile manner. Ideally, serum donors should be blood-typed to avoid neonatal isoerythrolysis. A dosage of 150 ml/kg/day is divided into three doses and given over a 24-hour period. This dose provides passive antibody concentrations that are similar to antibody concentrations of kittens that receive colostrum until at least six weeks of age (Levy et al, 2001). After the first 24 hours, kittens should be fed queen's milk or a complete and bal-

Table 23-5. Feeding plan summary for nursing kittens.

1. Ensure good husbandry practices are understood and in place (**Box 23-1**).
2. Ensure colostrum intake by the kittens within the first 12 hours.
3. Provide queen's milk only until three to four weeks of age, then initiate the gradual weaning process by introducing small amounts of semisolid to solid food to augment the queen's milk (**Box 23-2**).
4. The weaning food should be a good quality growth/reproduction type commercial food (Chapters 22 and 24).
5. Assess nursing kittens daily. Body weights should be obtained at birth then once weekly, if no complications are present. Normal birth weights range from 85 to 120 g and healthy kittens should gain approximately 100 g/week; minimally they should gain 7 g/day. Poor weight gain or failure to thrive should prompt the breeder/owner to seek an immediate evaluation by a veterinarian.
6. Kittens not thriving on queens' milk should be fed via partial or total orphan feeding techniques; check the queen, including its food, to ensure there are no health or nutrition issues to affect lactation.
7. Wean at six to nine weeks (**Box 23-2**) and feed according to recommendations in Chapter 24 (growing kittens).

Table 23-6. Feeding plan summary for orphaned kittens.

1. Ensure good husbandry practices are understood and in place (**Box 23-1**); have owner attempt to provide as much total care as would be expected from the queen.
2. Ideally, kittens should have had colostrum within the first 12 hours; if not, and if available, queen's milk is the second best choice provided if given in the same time frame; alternatively, sterile serum can be given subcutaneously (50 ml serum/kg body weight every eight hours for a total of three doses).
3. Use foster queen if possible; partial orphan feeding is next best and bottle feeding is the best of the hand-feeding techniques (**Figure 23-4** and Chapter 16).
4. **Table 23-7** lists commercial milk replacers and compares them to queen's milk; **Table 23-8** provides two homemade formulas and **Table 23-9** compares them to queen's milk. Commercial milk replacers are best.
5. Use **Table 23-4** to estimate kittens' daily energy requirement; divide the daily energy requirement by the energy density of the milk replacer to determine the daily amount to feed. Most milk replacers will provide about 1 kcal/ml when properly diluted. Besides energy and other nutrients, on average, orphaned kittens should receive about 180 ml/kg body weight/day; if necessary, add additional water to the milk replacer if the recommended dilution doesn't provide for this total fluid intake.
6. Milk replacers should be heated to 38°C (100°F) and the daily amount divided and fed four or more times/day at equal intervals.
7. Good hygiene is critical and includes: Washing/boiling feeding utensils before each feeding. Preparing no more than 24 hours worth of milk replacer and refrigerating unused portions. Carefully washing kittens with a moist, soft cloth twice weekly.
8. Gradually initiate the weaning process by introducing small amounts of semisolid to solid food to augment the milk replacer (**Box 23-2**).
9. Ensure the weaning food is a good quality growth/reproduction type commercial food (Chapters 22 and 24).
10. Assess orphaned kittens daily. Body weights should be obtained at birth then once weekly, if no complications are present. Normal birth weights range from 85 to 120 g. Healthy kittens should gain approximately 100 g/week; minimally they should gain 7 g/day. Poor weight gain or failure to thrive should prompt the breeder/owner to seek an immediate evaluation by a veterinarian. Weekly veterinary checks should be recommended for the first month.
11. For kittens failing to thrive when receiving the milk replacer, review the milk replacer quality (**Tables 23-7** and **23-9**), dilution calculations and feeding amounts; switch to a different milk replacer if necessary.
12. Wean at six to nine weeks (**Box 23-2**) and feed according to recommendations in Chapter 24 (growing kittens).

anced feline milk replacer.

Queen's milk is considered an ideal food for nursing kittens because it provides all essential nutrients, antibodies, enzymes and hormones. Commercial milk replacers and homemade replacer recipes may mimic the essential nutrient content of queen's milk but lack its other beneficial properties. However, queen's milk is rarely available in sufficient quantities to hand raise orphans. The next best option is to attempt to foster kittens to a surrogate queen. If milk replacers are used, generally commercial products are preferred although several homemade formulas have proved sufficient.

Commercial and homemade milk replacers should closely mimic the profile of queen's milk. Unsupplemented ruminant milk may be used as a base for homemade formulas but does not meet the nutritional needs of kittens. Goat's milk provides no nutritional benefit over cow's milk. **Tables 23-7** and **23-9** are useful for assessing and selecting milk replacers.

The quality of queen's milk and milk replacers is difficult to assess without analysis. Measurement of kitten growth is indirect, but probably the most practical method of assessment. Additionally, the queen's food should be assessed if the queen is losing excessive amounts of weight. A thin queen (body condition score 1/5 to 2/5) may not produce enough milk or may produce poor-quality milk. If milk analysis is required, a sample can be collected by manually expressing milk from the queen after preventing the kittens from nursing for a short time. Parenteral oxytocin (5 IU/queen) facilitates milk collection. Small samples (1 to 3 ml) are easily collected during normal lactation and should be frozen until analysis. Commercial laboratories do not routinely analyze such small milk samples; therefore, an appropriate research facility should be contacted ahead of time for specific information about sample size, preservation and shipping instructions.

Assess and Determine the Feeding Method

Nursing kittens should be allowed free access to the queen as the preferred feeding method. Kittens should be observed to ensure they have received colostrum by 12 hours after partu-

Box 23-2. Weaning.

Weaning is usually a gradual process that begins with the queen avoiding the kittens and kittens eating increasing amounts of solid food. Typically, weaning begins when kittens are three to four weeks old and is complete at six to nine weeks of age. At three to four weeks of age, kittens begin to eat solid foods, although approximately 95% of their caloric intake is still provided by the queen's milk. By five to six weeks of age, kittens eat nearly 30% of their caloric requirement as solid food and the remainder as milk. A progressive intake of solid food continues until the kittens are completely independent of the queen. Most domestic shorthair kittens are weaned by six weeks of age, whereas purebred kittens are usually weaned around eight to nine weeks of age. Later weaning allows more time for kitten growth and immune system maturation, which may help reduce kitten mortality in the postweaning period.

The weaning process may be initiated by the gradual refusal of the queen to allow the kittens to nurse or by the breeder who separates the kittens from the queen. During weaning, many queens will reduce food intake and milk production gradually. Regardless, the queen's energy requirement will decrease from lactation to maintenance levels after weaning is complete.

A commonly used schedule for the final phase of the weaning process follows. On the first day: 1) the kittens and food are withheld from the queen, 2) the kittens are allowed free access to their weaning food and 3) the kittens are returned to the queen at the end of the day and allowed to nurse. The following day: 1) the kittens are removed and allowed free access to their weaning food and not returned to the queen (they are weaned) and 2) the queen is given one-fourth of its ration. Over the next three days, food amounts for the queen are gradually increased to pre-breeding (maintenance) levels. The kittens should continue to be housed and fed separately. To minimize mammary gland engorgement in queens that are abruptly removed from their kittens and/or those that are heavy milk producers, have owners restrict food intake a day or two before the final weaning process is begun.

Weaning can be a stressful event in the kitten's life. Transition to independent feeding, greater environmental exposure and waning maternal antibodies result in reduced immune defense. These factors contribute to increased morbidity and mortality in the postweaning period. Proper nutrition and careful husbandry can reduce these events markedly.

Recommended nutrient allowances for weanling kittens are similar to those for lactating queens and for growing kittens, postweaning (Chapters 22 and 24). Energy requirements for weanling kittens are between 200 to 250 kcal/kg body weight (837 to 1,046 kJ/kg body weight). The stomach volume of kittens is small; therefore, feeding energy-dense foods helps meet the higher energy needs of weanling kittens without exceeding gastric capacity. Kittens from queens with lower body weights reportedly have limited growth. Milk production may be compromised in underweight queens. After weaning, however, smaller kittens compensate by increasing food intake and growth rate until they attain their expected size.

At the onset of weaning (three to four weeks of age), kittens should be offered moist foods or dry foods moistened with water or milk replacer. The food should be moistened until it forms a soft but not liquid gruel. Kittens at this stage lap at but do not prehend food. By six to eight weeks of age, most kittens have learned to eat solid, unmoistened foods; therefore, gruels are no longer necessary. The food should be highly digestible and complete and balanced for growth and reproduction. Semi-moist foods that promote a highly acidic urinary pH should not be fed as the sole food source for growing kittens. High levels of dietary acid may lead to metabolic acidosis and impaired bone mineralization.

The weaning process will be less stressful if kittens are initially offered the same food that will be fed after weaning. Using the same food facilitates the transition away from the queen and helps avoid gastrointestinal upsets associated with a food change. After three weeks of age, kittens should have water and food available at all times in addition to free access to the queen. Food and water should be easily accessible and offered in broad shallow pans. Food should be replenished three to four times daily. High-moisture foods begin to spoil and harbor high levels of bacteria when left at room temperature for prolonged periods (Chapter 11). Thus, washing pans between feedings is recommended. Ideally, food should be warmed to about 38ºC (100ºF) or at least brought to room temperature. Kittens first eat by accident, as they step into food and then ingest it during grooming. This process can be hastened by smearing small quantities of food around a kitten's mouth.

Daily monitoring of physical appearance, activity, stool quality and food intake is recommended. Kittens should be weighed and their body condition assessed weekly; they should continue to grow at approximately 100 g/week. Gender differences in growth rate are now evident; female kittens are normally smaller than males (Chapter 24). Kittens should demonstrate increasing activity and social and exploratory behavior. After a meal, the kittens' abdomen should be well rounded but not overly distended. Crying in neonates and older kittens usually indicates discomfort (e.g., cold, hunger, pain, disease or isolation).

The queen still consumes the kittens' feces to keep the nest box clean early during this phase. At about four weeks, the kittens begin to defecate outside the nest box and stools can be readily monitored. Kittens eating solid foods should have soft-formed stools, whereas those eating predominantly milk will have pasty yellow to light-brown stools. It is vital during this phase to practice good cattery husbandry and monitor kittens closely for disease. Weaning is a stressful event and outbreaks of diarrhea and disease are very common. Growth rate is universally impaired in sick and malnourished kittens.

rition. Most neonatal kittens require feeding every two to four hours during the first week of life then every four to six hours until weaning. Weak kittens may need to be placed on the queen and held to facilitate nursing. Chilled kittens will not suckle and have reduced GI function. It is imperative to adequately warm weak kittens before they are fed. Hypoglycemia and hypothermia may occur simultaneously in neonates and have similar clinical signs. If kittens fail to respond to warm-

ing, a dilute glucose solution (2.5% glucose) may be given orally. This should be repeated until kittens are able to initiate a strong sucking reflex. Because nursing kittens depend completely on queen's milk, the feeding plan for the queen should be evaluated and modified if necessary (Chapter 22).

It may be necessary to alter the feeding method when managing orphaned kittens, especially if they are hand reared. Evaluation of the current feeding method with foreknowledge of growth demands will facilitate this part of feeding plan development. Orphaned kittens and those too weak to nurse are candidates for fostering, partial orphan rearing or hand feeding. These feeding methods are discussed below.

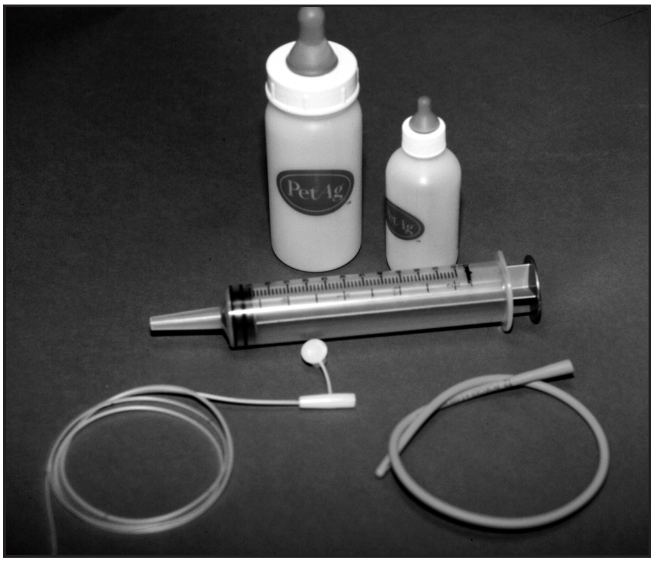

Figure 23-4. Various bottles and feeding tubes can be used for hand feeding orphaned kittens.

Fostering

The optimal means of feeding orphaned or rejected kittens is to foster them to another lactating queen. Fostering is the least labor intensive, provides optimal nutrition, reduces mortality, improves immune status, usually provides an optimal physical environment and promotes normal social development of kittens. Unlike large animals, queens readily accept additional kittens during lactation. If several foster mothers are available, it is best to place orphans in litters with fewer than 14 days age difference. Larger kittens often crowd out smaller individuals if the age discrepancy is too large. This situation can be managed by supervised feeding until the orphans can fend for themselves. Unfortunately, foster mothers are not normally available and alternative techniques must be used.

Partial Orphan Rearing

Kittens that cannot be successfully raised by the queen for reasons of health, poor lactation performance or too large of a litter, may be left with the mother but given supplemental feeding to support nutritional needs. Supplemental food may be given by hand feedings or timed feedings using a surrogate queen. Kittens may also be reared in a communal situation. Partial orphan rearing can be accomplished by dividing the litter into two groups of equal number and size. One group remains with the mother while the other is removed and fed milk replacer. The groups are exchanged three to four times daily. It is important to feed the separated group before it is returned to the mother. As a result, the group just placed with the dam will be less inclined to nurse immediately. It is better to supplement all the kittens in the litter rather than just a few. The advantages of partial orphan rearing are similar to those of fostering. In addition, continued access to the mother can help stimulate milk production and mothering behaviors. When using foster or surrogate mothers, it is important to monitor for signs of rejection and cannibalism. Partial orphan rearing may be necessary to assist the efforts of foster mothers. Unfortunately, foster and surrogate mothers are usually unavailable.

Hand Feeding

The most common method of raising orphaned kittens is hand feeding. Eyedroppers, syringes, bottles and stomach tubes are typically used to hand feed orphans. The method of choice largely depends on the age, vitality and adequacy of the sucking reflex of the kitten and the handler's expertise.

BOTTLE FEEDING

Bottle feeding is the preferred method for vigorous kittens with good nursing reflexes. Bottle feeding has the advantage that neonates will nurse until they are satiated and reject the milk or formula when full. However, bottle feeding can be time

Figure 23-5. Feeding tubes should be premeasured and marked at a spot approximately 75% of the distance from the nose to the last rib. This placement will ensure the tube tip is in the distal esophagus.

Figure 23-6. Kittens should be held horizontally in the palm of the hand for tube feeding.

Figure 23-7. A lubricated tube is gently advanced to the premeasured mark and warm formula is administered over several minutes. The tube should be withdrawn and repositioned if resistance or struggling is encountered.

consuming, especially with large litters.

Most kittens will readily nurse small pet nursing bottles available in pet stores (**Figure 23-4**). Feeding bottles for dolls or bottles with nipples for premature human infants are alternatives. The opening should only allow one drop at a time to fall from the nipple when the bottle is inverted. A horizontal slit made with a razor blade instead of a round hole may make it easier for neonates to obtain milk or formula. Milk should be sucked-never squeezed-from the bottle. A rapid flow rate may lead to aspiration of milk resulting in pneumonia and/or death.

Kittens should normally be held horizontally with the head in a natural position. This position reduces the risk of aspiration (Figure 16-1).

TUBE FEEDING

Kittens that are weak or suckle poorly may need to be tube fed. Tube feeding is faster than bottle feeding and is often used when several orphans must be cared for by the same person. Bottle feeding allows kittens to control the amount of food intake, whereas tube feeding bypasses this control mechanism. Infant feeding tubes (5 to 8 Fr.) or soft urethral or intravenous catheters may be used (**Figure 23-4**).

The tube should be lubricated and placed in the lower esophagus, which is approximately 75% of the distance from the nose to the last rib (**Figure 23-5**). It is best to measure and mark the tube with an indelible marker or a piece of tape before insertion. Recheck measurements every few days to account for growth of the kitten. The orphan should normally be placed horizontally in the palm of the hand with its head in a natural position (**Figure 23-6**).

The mouth can be opened using the same hand that steadies the head. Gently advance the tube to the premeasured mark. If resistance is encountered or the kitten suddenly struggles, the tube may be in the trachea. It should be removed and repositioned into the esophagus. Do not feed until proper placement is ensured. After the tube is placed, attach the feeding syringe and slowly administer the warmed formula over one to two minutes (**Figure 23-7**). The stomach may be palpated to determine the degree of distention. Administration of formula should be stopped if the stomach becomes taut or there is resistance to formula flow. Continuation of feeding may result in gastric overdistention and regurgitation. If regurgitation occurs, withdraw the tube and discontinue feeding until the next meal.

Success of orphan rearing depends on how well the caregiver fulfills the daily routine of hygienic measures, strict feeding schedules and all aspects of care normally provided by the queen. These measures are vital for survival of kittens early in life.

Hygiene

Strict hygiene is especially important with hand feeding. Hygienic measures must be more stringent for orphaned kittens because they may have received less colostrum and be more susceptible to infections than other neonates.

- Feeding materials (e.g., bottles and nipples) should be cleaned thoroughly and boiled in water between uses.
- Ingredients for homemade milk replacers should be fresh and refrigerated until used.
- Clients should never prepare more milk replacer than can be used in 24 hours and refrigerate.
- Formulas should be discarded after one hour at room tem-

perature.

- At least twice a week, orphans should be washed gently with a soft moistened cloth to simulate cleaning by the dam's tongue.

Feeding Amount, Schedule and Rate and Formula Temperature

To determine the amount to feed, first use **Table 23-4** to estimate the kittens' daily energy requirement (DER). Then, divide the DER by the energy density of the milk replacer to determine the amount to feed. Most milk replacers provide about 1 kcal/ml when properly diluted. Orphaned kittens should receive about 180 ml/kg body weight/day (18 ml/100 g body weight). If necessary, add additional water to the milk replacer if the recommended dilution doesn't provide for this amount of total fluid intake. During the first week of life the capacity of milk intake is limited to about 10 to 15 ml per feeding.

The energy density of the milk replacer should be adequate at the recommended dilution. If the energy density is too low, the neonate's intake capacity may be exceeded. If this occurs, the neonates might not gain weight, and could actually lose weight, despite apparently adequate volume intake. Affected neonates may start vocalizing and become restless.

Orphans should be fed at least four times daily. Very young neonates and weak kittens should preferably be fed every two to four hours. Older kittens should be fed every four to six hours. Normally, one- to two-week-old kittens will obtain more than 90% of their normal daily intake in four to five meals.

Milk replacer should be warmed to 38°C (100°F) and delivered slowly. Cold foods, rapid feeding rates and overfeeding may result in regurgitation, aspiration, bloating and diarrhea.

Review and have clients correct the feeding methods if untoward signs develop. If diarrhea is observed, food volume should be reduced or diluted with water, then gradually returned to levels to meet caloric requirements over successive feedings. It is better to underfeed than overfeed neonatal kittens.

REASSESSMENT

Nursing kittens should be reassessed daily. Body weights should be obtained at birth then once weekly, if no complications are present. Poor weight gain or failure to thrive should prompt the breeder/owner to seek an immediate evaluation by a veterinarian.

Adequacy of the queen's milk production can be assessed by the growth rate of the kittens, kittens' contentment and, to some extent, the degree of mammary gland distention. Expressing milk from a queen's nipples demonstrates the functionality of individual mammary glands, but does not indicate adequate milk production.

Orphaned kittens should be evaluated daily for the first two weeks of life. They should remain normally hydrated, sleep quietly between feedings and gain weight at a rate similar to queen-raised neonates. Alertness, eagerness to suckle, general behavior, body temperature (i.e., temperature of skin and lower limbs), body weight and stool character should be recorded daily or more often if neonates appear weak or listless.

Orphan rearing permits precise measurement of food intake. Nursing kittens should grow about 100 g/week. If kittens do not thrive when fed a commercial milk replacer or homemade replacer, the nutrient content should be compared with mother's milk (**Tables 23-7** and **23-9**). The dilution recommended by the manufacturer should also be checked. In some cases, it may be necessary to switch to another formula.

Kittens with rectal temperatures less than 35°C (95°F) should not be fed. At this temperature, the sucking reflex is usually absent and normal gut motility has ceased. Neonates should first be warmed slowly after receiving a warm solution of 2.5% glucose by subcutaneous injection (1 ml/30 g body weight).

Weaning is an important event and is integral to successful feeding of nursing and orphaned kittens (**Box 23-2**).

Feeding Growing Kittens: Postweaning to Adulthood

Kathy L. Gross

Iveta Becvarova

Jacques Debraekeleer

"Kittens are born with their eyes shut. They open them in about six days, take a look around, then close them again for the better part of their lives."
Stephen Baker

INTRODUCTION

The postweaning growth period includes kittens from weaning (about eight weeks of age) until adulthood (10 to 12 months). The nutritional needs of growing kittens include maintenance needs similar to those of adult cats and energy and substrates necessary for rapid tissue accretion (**Figure 24-1**). Growth rate slows if nutritional deficiencies exist. Thus, nutritional requirements are easiest to determine in growing animals using growth rates as a nutritional marker. The nutritional needs of postweaning, growing kittens are best understood by comparing their needs with those of other lifestages. Nevertheless, the optimal nutrient levels for growth may not represent the optimal levels for other physiologic functions. Further research may redefine nutrient requirements of growing kittens as physiologic parameters besides growth are studied. The ultimate goal of feeding kittens is to ensure they develop into healthy adults. The specific objectives, however, are to optimize growth, minimize risk factors for disease and achieve optimal health.

PATIENT ASSESSMENT

History and Physical Examination

The general health and risk factors should be determined for every kitten early in the growing phase. A thorough history and physical examination, including determination of body weight and body condition, are generally sufficient. Ideally, a veterinarian should assess the kitten at weaning and monthly thereafter until the kitten is four months old. This schedule coincides with typical vaccination protocols for young kittens. The veterinary health care team should educate the owner about nutrition, weight management, neutering and dental care during these examinations. The owner can then evaluate stool and appetite daily and body condition weekly or every two weeks.

Kittens should continue to grow at approximately 100 g/week until about 20 weeks of age. At 20 weeks, males typically gain 20 g/day whereas females gain 11 g/day (NRC, 1986). Growth rate slows as kittens approach 80% of adult size at 30 weeks and reach adult body weight at 40 weeks (10 months) (Figure 23-1). Most cats will achieve skeletal maturity at 10 months of age although some growth plates have yet to close. Additional weight gain may occur after 12 months of age and represents a phase of maturation and muscle development.

There is no evidence that the age at neutering alters growth rate. Investigators evaluating early neutering found kittens neutered at 12 weeks of age reached similar size as adults neutered at the more typical ages of six to nine months (Root, 1995). Unfortunately, energy requirements decline following

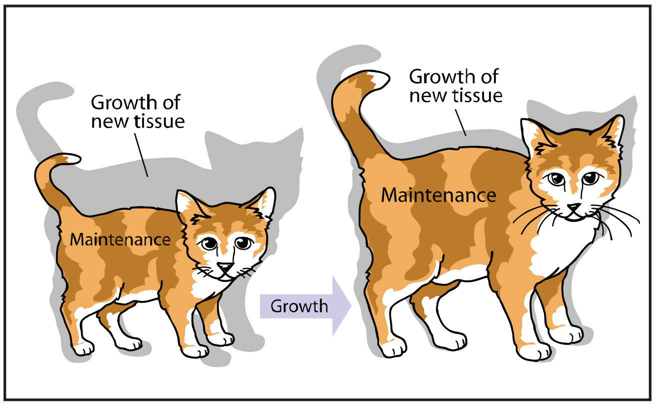

Figure 24-1. Representation of nutritional requirements of kittens. The nutritional needs of growing cats include maintenance requirements similar to those of adult cats (depicted here as the body of the cat) plus nutrients necessary for rapid tissue accretion (shaded area). The proportion of nutrient intake needed for maintenance vs. tissue accretion changes throughout growth as depicted here.

Table 24-1. Key nutritional factors for foods for growing kittens (postweaning to adult).*

Factors	Recommended food levels**

***As determined in growing kittens.

neutering; therefore, the risk for obesity increases (Root, 1995; Flynn et al, 1996; Scarlett et al, 1994). Neutering, however, is not the only risk factor for obesity. Practitioners have noted an alarming increase in the number of young cats with marked abdominal fat accumulation before neutering. An indoor lifestyle, high-fat foods, overfeeding and certain feeding practices (e.g., free-choice feeding) are additional risk factors for obesity (Scarlett et al, 1994). Obesity should be prevented at an early age because it significantly affects the health, longevity and quality of life of cats (Scarlett and Donoghue, 1997). Therefore, the risks for obesity should be determined as part of each cat's health evaluation at each veterinary visit.

Key Nutritional Factors

Key nutritional factors for postweaning, growing kittens are reviewed below and in **Table 24-1**.

Energy Density

Growing kittens have high energy requirements to meet the needs of a rapid growth rate, thermoregulation and maintenance. Kittens may grow at rates from 14 to 30 g/day during the rapid growth phase. Although ensuring optimal growth is desired, excessive energy intake may lead to obesity. Ten-week-old kittens have a daily energy requirement (DER) of approximately 200 kcal/kg body weight (837 kJ/kg body weight), which declines to adult levels (80 kcal/kg body weight [335 kJ/kg body weight]) at 10 months of age. Age-related changes in energy requirement have not been observed after 10 months in young cats (Root, 1995). Neutering reduces energy requirements by 24 to 33% regardless of the age at neutering (Root, 1995; Flynn et al, 1996). After neutering, limiting food intake and/or feeding a food with a lower energy density may be required to prevent excessive weight gain. The energy density of the food fed to rapidly growing kittens should be between 4.0 to 5.0 kcal metabolizable energy (ME)/g (16.7 to 20.9 kJ ME/g). A higher energy density allows smaller volumes of food intake to satisfy caloric needs. However, foods with energy densities at the lower end of this range should be fed to neutered kittens and those with a body condition score (BCS) of 4/5 or greater. The prevalence of obesity increases dramatically after one year of age. Over-nutrition is of greater concern than undernutrition in growing kittens.

Foods with an energy density of at least 4 kcal ME/g (16.7 kJ ME/g) dry matter (DM) or greater are likely to have above average digestibility. The mean apparent digestibility of several nutrients was found to be lower in younger kittens but increased with age. Fat digestibility increased until kittens were 24 weeks of age (Harper and Turner, 2000). Bile salt-activated lipase is a component of queen's milk suggesting that it plays a role in facilitating fat digestion in nursing kittens (NRC, 2006). Besides the inherent issues of apparent digestibility in younger kittens, their small stomach capacity relative to their body size limits food intake in the face of relatively high-energy demands. Providing highly digestible foods maximizes use of the nutrients consumed.

Protein

The protein requirements of kittens reflect their essential amino acid requirements and minimal nitrogen needs. Protein also provides sulfur-containing amino acids, which are required in greater amounts in kittens than in other species (MacDonald et al, 1984). Carrying over from the nursing period, protein requirements are high at weaning then decrease gradually to adult levels as growth slows. Kittens fed purified foods meeting all essential amino acids at or above the requirement have minimum protein needs of 20% DM (MacDonald et al, 1984; Smalley et al, 1985). Protein biologic value and amino acid digestibility in practical cat foods are typically lower than in purified foods (NRC, 1986). The minimum recommended allowance for crude protein for commercial foods for growth of kittens after weaning is 22.5% (NRC, 2006). The Association of American Feed Control Officials (AAFCO) recommends a minimum crude protein level of 30% DM (2007). This same

crude protein level resulted in growth rates of approximately 30 g body weight/day in kittens fed purified foods (Rogers et al, 1987). To provide sufficient sulfur-containing amino acids without additional supplementation, at least 19% of the food must come from animal protein (MacDonald et al, 1984). Thus, the recommended range of crude protein for practical foods for healthy kitten growth is 35 to 50% DM (**Table 24-1**). High-protein foods (56% DM) must contain the essential amino acid arginine at 1.5 times the requirement to maintain normal urea cycle function (Rogers et al, 1998).

In other species (swine and poultry), amino acid requirements as ratios to total energy intake are more important than protein content or protein calories. Eventually, protein and amino acid nutrition studies in cats and dogs will likely follow this approach.

Fat and Fatty Acids

Dietary fat serves three primary functions in growing kittens, it: 1) supplies essential fatty acids, 2) acts as a carrier for fat-soluble vitamins and 3) provides a concentrated source of energy in food. However, excessive fat and caloric intake may predispose young kittens to obesity. As kittens grow, body composition changes dramatically. In one study, fat comprised only 5.5% of body weight in eight-week-old kittens, increased to 14.6% of body weight by 18 weeks and was 24.3% by six months of age. This is the upper end of body fat for ideal body condition (Munday et al, 1994).

Kittens tolerate wide levels of dietary fat (NRC, 2006). When kittens are offered foods with differing levels of fat, they select foods with a fat content of 25% DM (Kane et al, 1981). True dietary fat requirements are much lower. The minimum recommended allowances for growth are 9% DM (AAFCO, 2007; NRC, 2006). However, optimal growth rates are achieved with higher fat intake. Unless excessive growth or weight gain is evident, feeding foods with 18 to 35% fat is preferred to enhance palatability, meet essential fatty acid needs and maintain the energy density of the food at or above 4.0 kcal ME/g (16.7 kJ ME/g). Overweight and neutered kittens may need foods with dietary fat levels well below this range to achieve ideal body condition (BCS 3/5) and/or they should be limit fed.

Kittens, like adult cats, require linoleic and arachidonic acid, and they also require fatty acids of the omega-3 (n-3) series (docosahexaenoic acid [DHA], 20:6n-3). Studies indicate DHA is essential for normal neural, retinal and auditory development in kittens (Pawlosky et al, 1997). Similar results have been found in other species (Pawlosky et al, 1997; Birch et al, 2002; Diau et al, 2003; Hoffman et al, 2003). The inclusion of fish oil as a source of DHA in foods for puppies improved trainability (Kelley et al, 2004). The need for DHA during growth in kittens may be even more important than in puppies considering the cat's reduced ability to convert shorter chain fatty acids to DHA. The minimum recommended allowance for DHA plus eicosapentaenoic acid (EPA) is 0.01% DM with EPA not exceeding 60% of the total (NRC, 2006). Thus, DHA needs to be at least 40% of the total DHA plus EPA, or 0.004% DM.

AAFCO recommendations for growth for linoleic acid and arachidonic acid are 0.5 and 0.02% DM, respectively (2007). The minimum recommended allowances are similar or the same: 0.55 and 0.02% DM, respectively (NRC, 2006). These levels will sustain adequate growth. The minimum recommended allowance for α-linolenic acid is 0.02% DM (NRC, 2006). Commercial cat foods that carry an "AAFCO approved" label statement should provide adequate amounts of these fatty acids.

Calcium and Phosphorus

Weaned kittens appear to be fairly insensitive to inverse calcium-phosphorus ratios (e.g., kittens have been fed foods with ratios as low as 0.38:1 with no deleterious effects) (Morris and Earle, 1996). The minimum requirement for dietary calcium in growing kittens is approximately 5 g/kg food (0.5% DM) (Morris and Earle, 1996). Thus, AAFCO minimum allowances for calcium (0.8% DM) and phosphorus (0.6% DM) (2007) and NRC minimum recommended allowances (0.8 and 0.72% [DM], respectively) are appropriate for postweaning kittens (2006). Unlike the situation with puppies, calcium excess in kittens is not associated with developmental orthopedic disease. However, very high concentrations of calcium significantly reduce magnesium availability (Howard et al, 1998). Dietary calcium concentrations of 2% resulted in a nearly twofold increase in the magnesium requirement of growing kittens. Providing calcium in amounts sufficient to meet the needs of growing kittens without impairing the availability of other nutrients is the basis for recommending ranges of 0.8 to 1.6% and 0.6 to 1.4% DM for calcium and phosphorus, respectively (**Table 24-1**). The calcium-phosphorus ratio should be between 1.1:1 to 1.5:1.

Calcium deficiency coupled with phosphorus excess occurs most commonly in kittens fed unsupplemented all-meat diets. Nutritional secondary hyperparathyroidism results in osteitis fibrosa and is manifested by limping, pain and reluctance to move. Kittens fed such foods should immediately be fed a commercial food that meets the recommended minimum requirements with a calcium-phosphorus ratio of 1.2:1 to 2:1. Additional supplementation of calcium is not recommended and may lead to hypercalcemia as a result of serum parathyroid hormone excess.

Potassium

The potassium requirement of kittens is highly dependent on the protein content of the food and the effect of the food on acid-base balance (Hills et al, 1982). Urinary potassium loss is markedly increased when kittens are fed high-protein, acidified foods. To avoid syndromes associated with hypokalemia, postweaning kittens should not be fed highly acidifying foods and potassium allowances should be between 0.6 to 1.2% of the DM intake. The minimum recommended allowance is 0.4% DM (NRC, 2006). Chloride levels of 0.1% DM also cause hypokalemia despite adequate potassium levels (Yu and Morris, 1998). Some foods intended for lifestage feeding target urinary pH levels more appropriate for adult cats. These foods

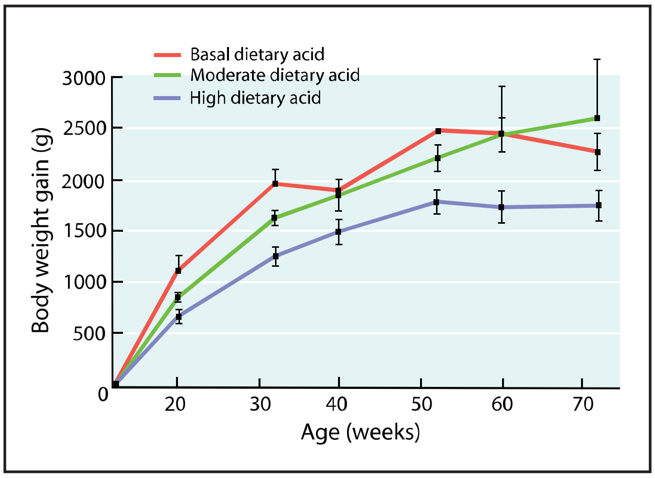

Figure 24-2. Effect of dietary acid load on body weight gain in kittens. Kittens fed highly acidifying foods grow more slowly and plateau at lower body weights than kittens fed more basic foods. (Adapted from Buffington CA, Rogers QR, Morris JG. Effects of age and food deprivation on urine pH of cats. Veterinary Clinical Nutrition 1994; 1: 12-17.)

Table 24-2. Feeding plan summary for growing kittens.

1. Using **Table 24-3** (or manufacturer's information), select a food with key nutritional factors closest to the target levels; remember urinary pH values are lower in kittens compared to those of adult cats; therefore, highly acidified foods should be avoided.
2. The selected food should also have been approved for kitten growth by a credible regulatory agency (e.g., AAFCO).
3. Determine the preferred feeding method. Generally, free-choice feeding is easiest but is best considered for kittens less than five months of age; free-choice feeding may predispose to overweight/obesity.
4. For food-restricted meal feeding, age, body condition and other assessment criteria will determine the DER. DER is calculated by multiplying resting energy requirement by a factor of 2.5 for kittens less than six months and by 2 for kittens between six months to adulthood. DER calculations should be used as guidelines, starting points and estimates for individual animals and not as absolute requirements. See **Table 24-4** for details about calculating DER for growing kittens.
5. If using food-restricted meal feeding, determine the quantity of food based on DER calculation (DER ÷ food energy density); divide between three to four feedings/day for younger kittens.
6. Regularly monitor body condition, weight gain and general health.

Key: DER = daily energy requirement, AAFCO = Association of American Feed Control Officials.

should be carefully assessed to ensure potassium is provided at appropriate levels.

Urinary pH

The urinary pH of growing kittens is lower than that of adult cats fed similar foods. Presumably, the lower pH is caused by hydrogen ions released during bone formation, which are excreted into urine. This increased response to dietary acidification continues until kittens are about 12 months old (**Figure 24-2**) (Buffington et al, 1994). Kittens fed highly acidifying foods (e.g., free-choice fed, urinary pH at or below 6.0) grow more slowly and plateau at lower body weights than kittens fed more basic foods. In addition to contributing to slow growth rates, feeding highly acidified foods results in poor bone mineralization in growing kittens (Buffington, 1988). To reduce the risk of acidification on bone mineralization and growth, kittens should not be fed foods that produce urinary pH values less than 6.2 when fed free choice. Because growing kittens have a reduced risk for developing struvite-mediated lower urinary tract disease (Bartges, 1996), an upper maximum for urinary pH is poorly defined. A urinary pH of 6.5 will reduce the risk of struvite precipitates in cats at risk for lower urinary tract disease and avoid over-acidification.

Other Nutritional Factor

Tyrosine is not an essential amino acid but is made from phenylalanine. Also, tyrosine spares about half of the needed phenylalanine. Therefore, it is appropriate to consider the amount of phenylalanine required as the sum of phenylalanine plus tyrosine. Although phenylalanine and tyrosine have not been shown to be the most limiting amino acids for growth in commercial foods, at least twice as much phenylalanine, or phenylalanine plus tyrosine, are required for maximal black hair color as for growth (Yu et al, 2001; Anderson et al, 2002). Phenylalanine and tyrosine are necessary for protein, thyroid hormone and catecholamine synthesis (NRC, 2006). The minimal recommended allowance for phenylalanine plus tyrosine in foods for kitten growth after weaning is 1.91% (DM) with 50% or more supplied by phenylalanine (NRC, 2006).

FEEDING PLAN

The feeding plan includes use of the best food and feeding method to ensure the goal of achieving a healthy adult. **Table 24-2** summarizes the feeding plan.

Assess and Select the Food

The two steps in assessing and selecting a food for healthy kitten growth include ensuring the nutrient profile is approved by a credible regulatory agency such as AAFCO and that the food's key nutritional factor profile closely fits the recommended levels for foods for healthy kitten growth (**Table 24-1**).

Proof that a food has AAFCO approval, or that of a similar regulatory agency, can be found on the label of commercial products. The label statement should note that the food is complete and balanced for kitten growth (Chapter 9). Such foods are often the same foods marketed for feeding reproducing queens and are sometimes referred to as growth/reproduction-type foods. Foods labeled for all lifestages should also have a nutrient profile to adequately support growth. But for optimal growth and long-term health, layering on the requirement of meeting the key nutritional factor profiles is an important part of the selection process.

The profile of key nutritional factors for the food being fed,

Key: ME = metabolizable energy, DHA = docosahexaenoic acid, Ca = calcium, P = phosphorus, K = potassium, na = not available from manufacturer.

*From manufacturers' published information or calculated from manufacturers' published as fed values; all values are on a dry matter basis unless otherwise stated.

**Energy density values are listed on an as fed basis and are useful for determining the amount to feed; cup = 8-oz. measuring cup. Energy density also reflects digestibility; foods with higher energy density are likely to have better digestibility than foods with lower energy density. To convert kcal to kJ, multiply kcal by 4.184.

or considered, should be compared to the recommended levels. **Table 24-3** provides this comparison for several commercial foods marketed for kitten growth. For foods not in this table, contact the manufacturer to obtain the food's key nutritional factor levels. This approach is usually necessary to obtain information about homemade foods. A more appropriate food should be selected if the current food does not adequately compare to the key nutritional factors listed in **Table 24-1**. It is better to change to a food formulated specifically for kittens than to try balancing an inappropriate food.

Both dry and moist foods are appropriate for weaned kittens. Dry foods are more energy dense per volume of food, which benefits small kittens with increased caloric needs. Moist foods tend to be more palatable and thus encourage food intake. Semi-moist foods that excessively acidify the urine (i.e., <6.0 pH units) should be avoided until skeletal growth is complete. Identification of health risks such as obesity and over-acidification necessitates a scrupulous review of foods provided for growth.

Treats are unnecessary but may be fed in small quantities (i.e., <10% of the daily caloric intake). Milk is commonly offered to kittens as a treat. Amounts offered should be limited because intestinal lactase levels decline shortly after weaning (**Box 24-1**) (Pawlosky et al, 1997). Fresh water should be provided daily and be available at all times.

Assess and Determine the Feeding Method

Feeding methods include the amount to feed and how the food is offered. Several feeding methods are appropriate for growing kittens. However, the overall feeding method should be tailored to the individual kitten's needs, the type of food being offered and the owner's preference.

Table 24-4. Daily energy requirements of growing kittens.

Age (months)	kcal/kg BW/day	kJ/kg BW/day
Birth	250	1,045
1	240	1,005
2	210	880
3	200	840
4*	175	730
5	145	610
6**	135	565
7	120	500
8	110	460
9***	100	420
10	95	400
11	90	375
12	85	355

Key: RER = resting energy requirement = $70(BW_{kg})^{0.75}$, BW = body weight.
*Up to 50% of adult BW (at about four months of age) or 3.0 x RER.
**Between 50 and 70% of adult BW (around six months of age) or 2.5 x RER.
***Between 70 and 100% of adult BW (around nine to 12 months of age) or 2 x RER.

Box 24-1. Feeding Cow's Milk to Growing Kittens.

Carbohydrates are not required in the food of growing kittens as long as an adequate supply of glucogenic amino acids is available. Nevertheless, cats can readily digest starch in cereal grains (i.e., >95% digestible). However, excessive feeding of poorly digestible carbohydrates may result in bloating, gas and diarrhea. These signs are often observed in kittens offered large quantities of cow's milk after weaning. The combination of high lactose levels with waning intestinal lactase levels results in carbohydrate overload.

To determine an amount to feed, the kitten's DER may be calculated based on the age-associated energy requirements listed in **Table 24-4**, divided by the caloric content of the food. The caloric content of many foods is not readily available; therefore, feeding guides on package labels and the manufacturers' literature are useful starting places. After an initial food amount is chosen, weight gain and body condition need to be regularly evaluated to provide a basis for tailoring the feeding amounts to individual cats. Young postweaning kittens should be evaluated weekly. Evaluations every two weeks are appropriate after kittens are about four months old. Owners can easily evaluate body weight and can be taught to determine body condition; however, a member of the veterinary health care team should confirm/reinforce the owner's findings during vaccination and wellness visits.

Free-choice feeding is often preferred because it reduces the risk of underfeeding and the marked gastric distention that sometimes accompanies rapid food consumption when food-restricted meal feeding regimens are used. The feeding frequency should be three to four times daily for meal-fed kittens less than six months of age. This frequency ensures sufficient food intake to meet the high nutritional demands of kittens without encouraging engorgement. By six months of age, most kittens will tolerate twice daily feeding. Free-choice feeding is preferred for kittens younger than five months.

If kittens are thriving on their current regimen, alterations in the feeding method are unnecessary. A more appropriate feeding method should be considered for kittens with poor growth rates and those with excess weight gain and obesity. Free-choice feeding methods should be used for underweight and slow-growing kittens. Providing unlimited food for free-choice intake is inappropriate for overweight and obese kittens. A defined food quantity should be measured then offered as meals or fed free choice until consumed. Neutering increases the risk for obesity; therefore, use caution when recommending free-choice feeding of high-fat foods to neutered kittens.

Young kittens should be fed in shallow pans to facilitate access to food. Food should be offered at room temperature; however, moist foods should not be left out for prolonged periods at room temperature because they may spoil (Chapter 11).

REASSESSMENT

After weaning, kittens should be weighed monthly until they are four to five months old. Weighing is usually performed at the time of vaccinations or veterinary examinations. The growth rate varies from ideal by gender, breed and nutritional status; however, it can be evaluated using Figure 23-1 as a guide. Owners should continue to monitor daily food and water consumption. Determination of total intake is necessary only if inappetence, illness or poor growth rate is evident. Body condition scoring every one to two weeks is a better means to assess growth and adequacy of food intake. Results of body condition assessment allow owners to monitor kitten growth and adjust food offerings as needed to maintain ideal body condition (BCS 2.5/5 to 3.5/5). Kittens provided proper nutrition are healthy and alert and have ideal body condition, steady weight gain and a clean, glossy coat. Normal stools are firm, well formed and medium to dark brown. The veterinarian should conduct a nutritional assessment at each visit, or approximately monthly from six to 16 weeks of age, and then annually. Instructions for nutritional modifications and dental care can be given at that time.

CASE 24-1

Lumbar Pain in a Young Cat

M. Anne Hickman, DVM, PhD, Dipl. ACVN
Pfizer, Inc.
Groton, Connecticut, USA

Claudia A. Kirk, DVM, PhD, Dipl. ACVN and ACVIM (Internal Medicine)
College of Veterinary Medicine
University of Tennessee
Knoxville, Tennessee, USA

Patient Assessment

An eight-month-old castrated male domestic shorthair cat was examined for hind-limb stiffness, lethargy and a soft tissue mass in the lumbar region. The cat suffered a twisting fall one month earlier. It was subsequently stiff and lethargic and had some lumbar pain. An examination at that time revealed no significant findings. Treatment included exercise restriction, antibiotics (cefadroxil) and oral glucocorticoids (dexamethasone). No improvement occurred over the next month; therefore, the cat was presented for a second opinion.

Physical examination revealed a 3.2-kg cat with good body condition (body condition score [BCS] 3/5). The cat was stiff in the rear legs, had an arched back and a soft tissue swelling in the thoracolumbar region that was very sensitive to palpation. Neurologic evaluation was unremarkable. No other abnormalities were noted.

Results of a complete blood count were normal except for moderate Heinz body formation on red blood cells. Serum biochemistry analyses were within normal limits. Urinalysis results were normal. Radiographs of the spine revealed diffuse osteopenia, increased opacity over the caudal aspect of L_1 and a mild subluxation between L_1 and L_2. Ultrasonographic examination of the lumbar region and abdomen was unremarkable.

Assess the Food and Feeding Method

The cat was fed ground sirloin and beef and veal baby foods. These foods were offered in several meals throughout the day. No commercial foods were offered.

Questions

1. What is the approximate calcium-phosphorus ratio of this diet?
2. What is the tentative diagnosis for this patient?
3. What caused the Heinz body formation in this cat?
4. Outline a feeding plan, including an appropriate food and feeding method.

Answers and Discussion

1. This cat's diet consists of all-meat ingredients (beef and veal). In general, meat is relatively high in phosphorus and low in calcium, which gives an inverse calcium-phosphorus ratio, approximately 1:20.
2. A diagnosis of secondary nutritional hyperparathyroidism is likely based on the dietary history and generalized skeletal osteopenia. The clinical signs of thoracolumbar swelling and pain are probably related to a compression fracture of L_1 and L_1-L_2 subluxation that occurred during the fall. The osteopenia probably contributed to the injury.
3. Heinz body formation is caused by oxidative denaturation of hemoglobin in erythrocytes. In cats, the unusual metabolism and unique hemoglobin structure of erythrocytes increase their sensitivity to oxidant injury. Heinz bodies usually appear within 24 hours of exposure of erythrocytes to an intoxicant. Affected erythrocytes undergo hemolysis or are removed within several days. Mild to severe anemia may result. Causes of Heinz body formation include ingestion of onions, acetaminophen, phenacetin, phenazopyridine, methylene blue, D,L-methionine, propylene glycol, benzocaine, zinc toxicosis, excessive vitamin K_3, diabetes mellitus and other systemic diseases. Onion powder used in human baby foods has been implicated in excessive Heinz body formation in cats. This is the most likely cause in this patient because it was regularly fed two different baby foods.
4. The diet should be changed to a balanced commercial or homemade cat food. Homemade food recipes should have an obvious source of calcium such as dicalcium phosphate, bone meal or calcium carbonate. Changing the cat's food from an all-meat diet to a balanced food may be difficult. The new food should be introduced gradually over several weeks. If necessary, a nutritionist can be contacted to formulate a homemade food to include the cooked sirloin the cat is currently eating. If food refusal becomes a major problem, hand feeding or assisted feeding with a feeding tube may be necessary. Caloric requirements should be calculated to reflect a young cat that will probably be confined with limited opportunities for exercise.

Progress Notes

Cerebrospinal fluid was collected and analyzed to rule out central nervous system infection as a cause of back pain. Results were normal. Blood samples were collected to measure parathyroid hormone (PTH) concentrations. PTH concentrations were elevated, confirming a diagnosis of hyperparathyroidism.

A balanced commercial moist cat food formulated for growing cats was chosen (Science Diet Feline Growth[a]). The cat's daily energy requirement (DER) was estimated to be 1.4 x resting energy requirement because the cat was still maturing and would be strictly confined. DER for a 3.2-kg cat = 166 kcal (695 kJ) x 1.4 = 232 kcal (971 kJ) or one-half of a 5.5-oz. can twice daily. Increasing amounts of food were mixed with cooked ground sirloin for several weeks. Within three weeks, the cat was eating only the commercial moist food. The food was warmed to body temperature in a microwave oven and offered in several meals throughout the day to encourage acceptance.

Exercise was severely restricted. The owners were instructed to confine the cat to a small kennel or room to prevent jumping. The owners were also advised that the cat should be reassessed monthly. The reassessment should include a dietary history, physical examination and radiographs to monitor bone density. By 12 months of age, the cat's bone density should return to normal and the cat can then be fed a commercial or homemade food that meets adult maintenance requirements. At that time, the DER also could be increased to reflect normal activity levels.

Endnote

a. Hill's Pet Nutrition, Inc., Topeka, KS, USA. This food is currently available as Science Diet Kitten Original.

Critical Care Nutrition and Enteral-Assisted Feeding

Korinn E. Saker

Rebecca L. Remillard

"Let food be your medicine and medicine be your food."
Hippocrates

CLINICAL IMPORTANCE

Patients of any age may become malnourished from inadequate nutrient intake. Malnutrition is any disorder with inadequate or unbalanced nutrition associated with either nutritional deficiencies or excesses. By most estimates, many hospitalized people and companion animals do not receive adequate nutrition. Hospitalized veterinary patients are more commonly malnourished due to decreased total food intake. The major consequences of malnutrition in all patients, but more prominently in sick or injured patients, are decreased immunocompetence, decreased tissue synthesis and repair and altered drug metabolism.

Immunocompetence

The reciprocal relationship between nutrition and immunity has been recognized for centuries. A malnourished patient is more susceptible to infections and a septic patient is more likely to be anorectic, which results in malnutrition. Nutrient imbalances suppress immune function, which increases the risk of disease; conversely, certain diseases alter some nutrient requirements (Semba et al, 1997; Burkholder and Swecker, 1990). Decreased protein-calorie intake is the most common cause of secondary immunodeficiency in people and can cause progressively poorer responses in several components of the immune system including significantly impaired cell-mediated responses, secretory IgA production, phagocytosis, complement function, antibody affinity and cytokine production (Shikora et al, 1994; Chandra, 1992; Redmond et al, 1991). Although fewer studies are available for review, similar alterations in the immune system are seen in pets with insufficient caloric intake (Freitag et al, 2000; Simon et al, 2000). Studies have shown that protein deficiencies that limit amino acid and nucleotide substrates for cell proliferation result in reduced numbers of circulating T-lymphocytes, helper cells and suppressor cells (Chandra and Kumari, 1994). Malnutrition also decreases immune function of existing cells through reduced complement secretions, less effective macrophage function and decreased killer cell activity (Saxena et al, 1984). Cytokine production and release are independently impaired in protein-calorie malnutrition and in several micronutrient (zinc, iron, pyridoxine, vitamin A, copper and selenium) deficiencies (Meydani, 1990; Chandra, 1992a).

Numbers of T_4 helper cells and T_8 cytotoxic suppressor cells in malnourished people return to normal quickly with refeeding (Chandra, 1983). Immunoglobulins and circulating antibodies are maintained at relatively low levels during malnutrition, but are highly responsive to appropriate refeeding stimuli. For example, investigators measured serum globulin concentrations in 12 healthy beagles before and 24 hours after small bowel resection. All dogs were fed via gastrostomy tube immediately after surgery. Six dogs received a monomeric food whereas the other six were fed an electrolyte solution. Twenty-four hours postoperatively, the dogs fed the monomeric food

Box 25-1. Regulation of Food Intake.

For many years it has been known that the hypothalamus is the center of appetite control. Although voluntary food intake can vary in amount and composition from day to day, over time, energy intake is matched to energy expenditure. Body weight is tightly conserved; therefore, food intake, meal frequency and size are highly regulated. The role of peripheral and central pathways involved in appetite control is being studied as obesity increases in human and pet populations.

Appetite is the desire for food and is often used synonymously with hunger. Satiety is the opposite of hunger and means that hunger has been satisfied. The body is normally in a state of hunger, which is intermittently relieved by eating. Hunger and satiety centers are found in the brain. The lateral hypothalamus contains the hunger center; stimulation of this area causes an animal to eat voraciously. The ventromedial hypothalamus contains the satiety center. Stimulation of this area causes complete satiety. Many neuroendocrine and metabolic factors affect these centers and therefore contribute to appetite control.

Short- and long-term input from the periphery including nutrients, gut vagal nerves, sensory spinal nerves, gut peptides and gut hormones act on the arcuate nucleus of the hypothalamus. The peptide, ghrelin, released from the stomach, is the "hormone of hunger." Ghrelin is released in response to gut nutrients rather than gastric distention. Peptide YY (PYY) is an appetite depressant. It affects gut motility centrally, acting as an "ileal brake." Neural control of PYY is demonstrated by its release shortly after food intake before nutrients reach the small intestine and colon, the site of highest PYY concentrations. Glucagon like peptide-1 (GLP-1) acts on the pancreas to cause release of insulin and inhibit food intake. Its rapid enzymatic breakdown has limited its potential use in Type II diabetics. Other gut peptides, pancreatic peptide (PP) and oxyntomodulin (oxm) play roles in decreasing food intake and homeostatic regulation of body weight. The peripheral appetite depressant, cholecystokinin (CCK) is secreted in the duodenum in response to fat and protein ingestion. CCK, gut vagal nerves and sensory spinal nerves travel to the nucleus tractus solitarius (NTS) satiety center in the brainstem.

Insulin, released peripherally in proportion to body fat mass and blood glucose levels, acts directly on hypothalamic appetite centers. Another gut hormone, leptin, is released from adipocytes in direct relationship to body fat. Leptin decreases appetite and increases thermogenesis. Obese patients appear to be leptin resistant, which may impede their ability to regulate body weight.

Gut peptides (ghrelin, PYY, GLP-1, PP, oxm) and hormones (insulin and leptin) act directly on the arcuate nucleus of the hypothalamus. The arcuate nucleus has two populations of neurons. The orexigenic neurons release two neuropeptides, neuropeptide Y (NPY) and agouti-related peptide (AgRP), which stimulate feeding and promote obesity. The anorexigenic neuron center acts as an appetite inhibitor with the neuropeptides alpha-MSH and cocaine and amphetamine-regulated transcript (CART).

These neuron centers of the arcuate nucleus project to the paraventricular nucleus of the hypothalamus. The paraventricular nucleus receives direct input from other peripheral signals. Peripheral CCK, nutrients, vagal and sensory spinal signals travel to the NTS, which then acts directly on the paraventricular nucleus.

Central signals to the paraventricular nucleus include the appetite stimulator, melanin-concentrating hormone (MCH) of the lateral hypothalamus. The cortex and limbic system integrate appetite signals with the paraventricular nucleus. The paraventricular nucleus then coordinates both central and peripheral signaling for feeding, energy metabolism, sympathetic nervous system activity and the endocrine axis.

In addition, the special senses of taste and smell are involved in the regulation of food intake. Taste is mediated through taste buds and free nerve endings. Taste bud cells are constantly renewed by dividing epithelial cells surrounding the taste buds. Taste buds are located on the tongue, soft palate, pharynx, larynx, epiglottis, cranial esophagus and even on the lips and cheeks of some species. Gustatory information received from taste buds is projected by cranial nerves to several areas of the brain including the lateral hypothalamus. Olfaction occurs via axons of bipolar neurons that course through the small holes of the cribriform plate of the ethmoid bone and form connections in the olfactory bulb. As with taste, there are olfactory projections to the hypothalamus.

synthesized more than twice the amount of globulin (12 g) than those dogs fed the electrolyte solution (5.3 g) (Moss, 1978). Other cell populations and specific cell functions are likewise quickly responsive to daily nutrient intake. Cats fed 25% of their resting energy requirement (RER) for seven days had significantly decreased total white blood cell (WBC) count, lymphocytes and monocytes; major histocompatibility complex (MHC) class II expression; phagocytic activity; lymphocyte proliferative capacity and delayed-type hypersensitivity response by Day 4. These alterations were reversed by Day 4 of refeeding to meet RER (Freitag et al, 2000; Simon et al, 2000). The immune system depends on and is responsive to adequate nutrition.

Tissue Synthesis and Repair

Tissue synthesis and wound healing are a function of local and whole body nutritional status (Crane, 1989). On the cellular level, amino acids and carbohydrates are needed for collagen and ground substance synthesis. Fibroblasts require energy to synthesize the RNA, DNA and ATP necessary for protein anabolism. Migration of fibroblasts and epithelial and endothelial cells also requires energy. On the organ level, the liver has energy and protein needs specifically for synthesis of fibronectin, complement and glucose. The bone marrow requires nutrients for production of platelets, red blood cells (RBC) and leukocytes. Transportation of these necessary

components and oxygen to wound sites requires the muscular activities of respiration and cardiac work. Tissue trauma and healing alter the normal cycle of protein turnover (synthesis and degradation) in the body. In rats, the rates of protein synthesis and degradation increased after trauma (Stein et al, 1976). Studies in perioperatively fed people indicate a 91% increase in protein synthesis with only a 10% increase in protein degradation (net synthesis) (Kien et al, 1978). Conversely, perioperatively fasted people had only a 50% increase in protein synthesis with a 79% increase in protein degradation (net loss) (Birkham et al, 1980). Therefore, proper nutrition on the cellular level depends on whole body nutrition for net tissue synthesis and wound healing.

Drug Metabolism

Cellular activities depend on and are regulated by the coordinated actions of peptides, lipids, vitamins and minerals as substrates, enzymes, coenzymes and cofactors of intermediary metabolism. Therefore, all nutrients are essential for the maintenance of normal cellular structure and function (Parke, 1991). Nutrient deprivation alters the normal metabolic synergy responsible for ion gradients, membrane potentials, production of high-energy phosphate compounds and antioxidant defenses. Enteral and parenteral nutritional support with products containing little or no lipid decreases hepatic cytochrome P-450 concentration and activity, which significantly decreases specific drug clearances (Knodell, 1990; Raftogianis et al, 1995). Protein-calorie deficiencies may result in decreased: 1) hepatic biotransformation of certain antibiotics, 2) concentrations of serum proteins that bind and transport drugs throughout the body and 3) renal blood flow, which decreases the rate of drug elimination and increases the possibility of drug overdose (Walter-Sack and Klotz, 1996). Therefore, protein-calorie malnutrition may alter the expected metabolism of certain drugs, which may increase or decrease their therapeutic effect even when given at recommended dosages (Pelissier et al, 1993; Krishnaswamy, 1989) (Chapter 69). Patients receiving sufficient calories and protein are expected to have better, or near normal, drug distribution, metabolism and elimination than patients with protein-calorie malnutrition.

Inadequate nutritional support can suppress the immune response, cause organ dysfunction, impair wound healing, result in muscle wasting and weakness, increase the incidence of acquired infections and increase mortality. As an example, a 50% decrease in jejunal mucosal mass and thickness normally occurs after burn injuries when no enteral feedings are given for 24 hours. Early feeding prevents this mucosal atrophy. Malnutrition in people, even imprecisely defined, is associated with prolonged ventilatory dependence and increased complication rates with longer hospital stays and higher costs (Remillard and Martin, 1990). Similarly in veterinary patients, malnutrition is thought to increase morbidity and mortality. Diseased and debilitated patients require nutrients daily to maintain optimal immune function, tissue synthesis and repair and proper drug metabolism.

ANOREXIA, CACHEXIA AND ACCOMMODATION

Normally, satiety occurs after a patient's caloric needs have been met. Conversely, anorexia is the loss of desire for food before caloric needs have been satisfied (**Box 25-1**). Anorexia may be partial or complete. The anorexia is complete if a patient consumes no food for a period beyond that considered normal. The anorexia is partial if the patient consumes some food but less than that considered a normal daily intake.

The flavor of food results from chemical stimulation of taste buds and free nerve endings in the nose, mouth and throat. "Taste" disorders often result from abnormalities in olfaction. Disorders of taste or smell can impair appetite and occur because of:

- Old age. The number of taste buds declines with age. Olfaction is usually the first sensory system to show an aging effect.
- Damage to neural connections due to surgery or traumatic head injury. Accidental blows to the head can shear the fine olfactory nerves that pass through the cribriform plate and are a common cause of anosmia (inability to smell) in people.
- Impaired renewal of taste buds and olfactory epithelium. Decreased chemosensory cell turnover is consistent with the decreased cell renewal reported to occur in the small intestinal epithelium as a result of food deprivation, radiation therapy, uremia, vitamin B_{12} deficiency and therapy with methotrexate. Many endocrine factors also depress cell proliferation. These factors and many conditions and drugs (**Table 25-1**) probably impair regeneration and function of taste buds and olfactory cells in the same manner that they impair regeneration of intestinal epithelium. The turnover time of taste buds and olfactory cells is about 10 days. Therefore, a return to normal taste function after mitosis is interrupted requires at least 10 days and usually longer.
- Modification of receptor cells as a result of a chronic change in local environment (e.g., an alteration in saliva or the fluids bathing the olfactory mucosa) due to drugs or metabolic agents such as urea.

Numerous medical problems including organic disease, inflammation, trauma and neoplasia can cause anorexia. In addition, pain, fear and other components of emotional stress inhibit the desire for food (Schiffman, 1983). If anorexia persists, depletion of body nutrient stores occurs. Nutritional depletion may also result from facial or oral injuries, or obstruction or dysfunction of the gastrointestinal (GI) tract, liver or pancreas so that the patient is incapable of ingesting, chewing, swallowing, digesting or absorbing food. In general, patients not eating for more than 48 hours or those consuming less than 50% of normal intake for more than three days should be of concern and noted as having a form of anorexia. Cats and dogs with a history of complete anorexia for three or more days or those with a history of partial anorexia for several weeks warrant further nutritional assessment.

Cachexia is a state of general illness, malnutrition and profound disability. For nearly 50 years, investigators and nutri-

Table 25-1. Disorders and drugs that affect taste and smell in people.*

Disorders		
Adrenocortical insufficiency	Cushing's syndrome	Nasal polyposis
Allergic rhinitis	Diabetes mellitus	Niacin deficiency

tionists have recognized that cachexia and a resultant low body condition score (BCS) are associated with increased risk of complications in people (Windsor, 1993). Loss of skeletal and visceral proteins can have adverse anatomic and functional consequences in food-deprived patients. These adverse effects include anemia, reduced heart muscle mass and function, decreased pulmonary mechanical function and diminished respiratory drive, altered intestinal morphology and mildly impaired absorptive abilities (Biden and Taylor, 1983). Cachexia may affect dogs and cats with long-standing cancer, cardiac disease or renal disease (Chapters 30, 36 and 37, respectively). A state of metabolic "accommodation" that prolongs survival has been recognized in people with chronic diseases. A similar state of metabolic accommodation probably occurs in chronically ill dogs and cats.

Accommodation occurs when the energy equilibrium is reestablished at a constant but lower food intake and lean-tissue wasting is arrested before protein deficiency becomes fatal. Accommodation in people is successful when: 1) total lean-tissue depletion is less than that considered critical, 2) weight is low but stable and 3) albumin levels and total peripheral WBC counts are normal with an intact delayed cutaneous hypersensitivity response (Hoffer, 1994).

Accommodation with the exception of an intact delayed cutaneous hypersensitivity response accurately describes the condition of some chronically ill patients (i.e., those with chronic renal, hepatic or cardiac insufficiency). Some chronically ill, cachectic cats and dogs may be maintained at a less than optimal body weight and condition for some time, even though important organ function deficits are apparent. In these cases, metabolic rate has been down regulated and protein turnover has been altered to establish a fragile homeostasis. This homeostasis can be maintained until a new stress supervenes. Affected patients very often do not survive additional stresses such as trauma, surgery, infection or tumors, as might a previously healthy dog or cat.

Metabolic Changes Through Days of Food Deprivation

Simple Starvation

Simple starvation includes metabolic changes that occur in mammals, in the absence of disease, as days of food deprivation continue. The time course of metabolic changes and associated alterations in nutrient usage should guide how these hospitalized patients are fed. An understanding of the metabolic changes that take place (particularly in the liver) during starvation is essential to understanding metabolic alterations present during anorexia and disease states.

In the postprandial period of well-fed patients, exogenous dietary nutrients are used to meet immediate metabolic needs, thus sparing endogenous fuels stored as glycogen, adipose and muscle protein. After these needs are met, replenishment of glycogen reserves (in the liver, fat and muscle) as well as proteins catabolized since the last meal, takes place. Any excess energy in the form of carbohydrate, fat or protein is then converted to triglycerides for storage as fat in adipose, muscle and liver tissue. In the fed state when serum glucose is high, the liver becomes a net importer of glucose, trapping it in hepatocytes by phosphorylation via glucokinase. Glucokinase is an inducible hepatic enzyme whose maximal enzymatic activity (Km = 180 mg/dl) for glucose is reached with the help of insulin, at high blood glucose concentrations (Engelking and Anwer, 1992).

Patients undergoing food deprivation display almost complete reversal of the metabolic processes described for the well-fed patient. Due to the lack of exogenous dietary sources, endogenous sources become the primary fuel for meeting immediate metabolic needs. Glycogen stores, instead of being replenished, become exhausted as the initial energy source. Then in order to preserve vital functions as long as possible, patients use different proportions of stored body fat and protein to maintain blood glucose concentrations. Which fuel or mixture of fuels the patient uses depends on the length of time the patient was food deprived and the quantity of each of the fuel stores available to the patient (**Figure 25-1**). The adaptation from fed to starved state is one in which fuel use by the patient shifts from primarily a mixture of fuels to one in which the primary fuel is fatty acids.

Carbohydrate metabolism is profoundly altered during the first week of starvation. During the first few days, omnivores (i.e., dogs) maintain blood glucose levels through glycogenolysis and gluconeogenesis. In simple, uncomplicated starvation of mammals, a decrease in blood glucose below 120 mg/dl decreases activity of hepatic glucokinase. This triggers hepatic glycogenolysis during which the liver becomes a net exporter of glucose to preserve serum glucose levels (**Figure 25-2**). This is observed after four to five hours of fasting and will only maintain blood glucose levels for another 12 to 28 hours (Cahill and Owen, 1968). Thereafter, gluconeogenesis must maintain blood glucose concentrations because hepatic glycogen stores will have been depleted. In contrast, carnivores (i.e., cats) must rely solely on gluconeogenesis, beginning intraprandially for maintenance of blood glucose levels because of their decreased hepatic glycogen reserves. This decreased reserve is due in part to lower glycogen synthase and glucokinase concentrations (**Table 25-2**).

Gluconeogenesis is initiated by glucagon and later glucocorticoids as serum glucose levels decrease (**Figure 25-3**). This process is carried out predominately in the liver and kidneys using substrates (glycerol, lactate and glucogenic amino acids) resulting from the catabolism of adipose and muscle tissue. Adipose tissue supplies glycerol for glucose production and fatty acids for oxidation to supply energy. Muscle catabolism releases glucogenic amino acids, lactic acid and pyruvate for glucose production by the liver (Welborn and Moldawar, 1997). Once available in the circulation, extrahepatic tissues are able to trap glucose intracellulary due to the presence of hexokinase, the enzyme present in all mammalian cells. Hexokinase has a low Km (1 mg/dl) for glucose compared to glucokinase and it does not require insulin to be effective. Therefore, intracellular trapping of glucose via hexokinase activity can happen at very low blood glucose levels (Engelking and Anwer, 1992).

In an effort to conserve circulating glucose for glucose-dependent tissues, the liver releases ketone bodies as an alternate fuel for non-glucose dependent tissues. Ketones are oxidation products of long-chain fatty acids, which originate from triglycerides in adipose stores. Unlike fatty acids, which are water insoluble and must be carried in the blood by albumin, ketones are water soluble and thus have a very wide distribution within the body and are able to diffuse across cell membranes. In this way they act to serve as a direct source of energy for vital organs such as the brain. Additionally the insoluble nature of fatty acids and their dependence on albumin limits their serum concentration. Thus the advantages of converting fatty acids to ketones are threefold: ketones are water soluble, not dependent on albumin for transport and can provide lipid fuel to cells at a much higher blood and interstitial fluid concentration. In

mammals, serum ketones can reach 2 to 3 mM within a few days of starvation, with levels increasing to between 7 and 8 mM after one week. This is greater than the normal glucose concentration of 5 mM (Engelking and Anwer, 1992).

Increased serum ketones contribute to the adaptive response of the patient towards conservation of endogenous protein and glucose sparing for the non-adaptive, glucose-dependent tissues (erythrocytes and renal medullary cells). Enzymatic changes in peripheral tissues and brain caused by increased serum ketone concentrations promote ketone use and decrease the demand for glucose. Ketosis in food deprivation is an appropriate physiologic response and may not lead to severe ketoacidosis except in diabetic dogs and cats. Thus, ketone bodies serve as a readily diffusible lipid-source fuel for muscles, kidney cortex, peripheral nerves and the brain during periods of starvation. Ketone body production is usually maintained until adipose tissue is depleted.

In addition to adaptation from mixed fuels to fatty acids as a primary fuel source, as food deprivation continues metabolism begins to decrease. By the third day of food deprivation in all mammals, the basal metabolic rate decreases to promote conservation of resources for long-term survival. Decreases in blood glucose levels result in a decrease in serum insulin release. The conversion of thyroxine (T_4) to triiodothyronine (T_3) is insulin responsive and thus declines in the face of decreased insulin (Gavin and Moeller, 1983). T_3 levels begin to decrease within 24 hours of fasting and may be 40 to 50% lower as compared to values in fed animals by Day 3 of food deprivation (Vagenakis et al, 1975). Thus the net effect is a hypometabolic state, which becomes a beneficial adaptation allowing conservation of body functions until appropriate caloric intake resumes.

By Day 5 of food deprivation in all mammals, endocrine changes have mandated a metabolic shift from exogenous fuel usage in the fed state to endogenous fuel usage in the forms of fatty acids and ketone bodies. Decreased insulin levels trigger lipolysis in an effort to conserve protein stores and maintain blood glucose levels for glucose-dependent tissues. By undergoing fatty acid oxidation, amino acids are partially spared, which helps maintain muscle protein stores throughout starvation until the end stages. Body proteins are only partially spared because muscles will catabolize branched chain amino acids. Nitrogen is exported with pyruvate as alanine and to a lesser extent glutamine, which may be deaminated and transaminated for hepatic protein synthesis. Additionally, their ketoanalogs are used for hepatic and renal glucose synthesis (Felig et al, 1969).

The respiratory quotient (RQ) can provide an indication of which substrate(s) are undergoing catabolism. An RQ of 0.7 indicates fat catabolism, 0.8 indicates protein catabolism and 1.0 indicates that carbohydrates are being used as the primary fuel. Studies involving well-fed dogs measured an RQ of 0.94 at rest, indicating high carbohydrate use. The RQ of the same dogs after five to 15 days of starvation was 0.8 indicating a shift from primarily carbohydrate use to that of lipid and/or protein catabolism (Himwich and Rose, 1927). This is a testament to the importance of fat as a primary fuel source after three to five days of food deprivation.

Refeeding management of the food-deprived patient is aimed at matching the number of "no food" days with the pattern of fuel use (i.e., adaptation from using a mixture of fuels to primarily using fat). This is often in the patient's dietary history. As described, the different proportions of stored carbohydrate, fat and protein that is/are used to maintain blood glucose and provide an energy source mainly depends on the duration of food deprivation. To minimize the metabolic complications of refeeding, the refeeding formula should contain a complete balance of nutrients and should have a carbohydrate, fat and protein source similar to that which the liver has become adapted or is estimated to be using from body stores. Oftentimes this requires a feeding formula that is lower in carbohydrate and higher in fat and protein sources as compared to a maintenance-type food. As described, patients deprived of food are in a state of catabolism, which can often be reversed by refeeding if body protein losses have not exceeded 25 to 30%.

Disease State

In contrast to patients undergoing simple starvation, patients in disease states are often inappetent or anorectic due to their disease process. Although similar in their decreased dependence on glucose for fuel and increased propensity for lipolysis, patients in disease states have increased energy requirements

and are more dependent on proteolysis than are patients that are simply food deprived. The hypermetabolic state that results from illness and anorexia is generated by general neuroendocrine responses and local mediators common to stressful stimuli. The specific hormonal and subsequent physiologic changes that occur in a stressed patient are unique to that disease condition, the time course of the disease process and other complicating diseases or conditions. The metabolic responses have best been characterized in conditions with a known acute onset such as trauma or infection (sepsis) (Cuthbertson, 1979). The response has been described as having an acute (ebb) phase followed by an adaptive (flow) phase (Popp and Brennan, 1983). These phases can vary in duration and intensity depending on the severity of the condition. Duration is usually shorter with trauma as compared to infection during which the acute phase remains until the infection has been eliminated.

The acute phase is characterized by catabolism and generally occurs within the first 24 to 72 hours. As mentioned, the hypermetabolic state that occurs results from a milieu of neuroendocrine and locally activated mediators stimulated by the sympathetic nervous system as part of the stress response. As in simple starvation, glucose use is somewhat reserved; however, part of this reservation is by consequence of increased cortisol levels perpetuating insulin resistance and hyperglycemia. Simultaneous sympathetic nervous system stimulation and release of catecholamines, cortisol, adrenocorticoids, glucagon, growth hormone and antidiuretic hormone induce metabolic and physiologic responses including:

- Insulin antagonism leading to insulin resistance.
- Hyperglycemia from glycogenolysis and gluconeogenesis, which provides an energy source for the "fight or flight" phenomenon.
- Increased lipolysis to provide fatty acids and glycerol for glucose and energy production.
- Increased proteolysis and net protein catabolism from albumin and skeletal muscle sources to supply gluconeogenic amino acids for glucose production and hepatic and immune cell proteins.
- Increased rate and depth of respiration and increased cardiac work to maintain perfusion to muscles and wound sites.

These responses are amplified in infection in which a toxic response results from invasive organisms and resorption of necrotic tissue. The amplification is caused by release of chemical mediators and lysosomal enzymes including histamine, kinins, prostaglandins, cytokines and serotonin. Interleukin-1 induces fever, which increases energy expenditure 10 to 13% per degree Celsius increase in body temperature. Endotoxins released from dying gram-negative bacteria trigger coagulation cascades that profoundly affect carbohydrate metabolism and cytokines stimulate production of hepatic acute-phase proteins. The net result is a hypermetabolic state with increased energy requirements that if not met, result in catabolism of endogenous fat and protein stores.

In the *acute phase*, glucose is the preferred fuel; however, muscles are insulin resistant and hyperglycemia is maintained for net immune and hepatic tissue anabolism. This is beneficial to the patient because it ensures an energy source in the face of hypoperfusion or poorly perfused organs (Daley and Bistrian, 1994). General feelings of malaise and anorexia signal the patient to reduce activity of skeletal muscle and signal the GI tract to conserve energy for essential tissue maintenance and repair. Although in the short-term, hyperglycemia appears to benefit the patient, maintaining this state is not conducive to recovery. Thus, the acute phase is characterized by decreased exogenous nutrients in the face of increased energy demands (hypermetabolic state) and a net negative energy balance. Breakdown or catabolism of protein and fat stores is necessary to address this imbalance between expenditure and intake.

This catabolic phase will continue until the neuroendocrine stimuli and cytokine mediators are removed. During severe head trauma, burns, multiple trauma and sepsis, lean tissue loss and overall body weight loss are rapid and unremitting in the absence of feeding. It is difficult to reverse the ongoing catabolism and achieve nitrogen balance in patients with these injuries and conditions. The goal in providing nutrition to these patients is to feed the catabolism with exogenous sources of protein and fat while sparing endogenous sources. The latter is critical because loss of 25 to 30% of body protein stores has been associated with reduced heart muscle mass and function, decreased pulmonary function, diminished respiratory drive, compromised immune function and therefore mortality (Matthews and Fong, 1993).

There is a definite turning point in which clinicians note a subjective improvement in their patients. This noted improvement is associated with the adaptive phase in which net anabolism occurs. The adaptive phase is characterized by increased metabolic rate, nitrogen gain and normal body temperature and may last for several days, weeks or years (Daley and Bistrian, 1994). The convalescent anabolic phase rebuilds damaged and catabolized lean tissue and therefore requires exogenous energy and protein sources. RQ values determined in resting postoperative and severely traumatized dogs were 0.76, indicating that fat was the preferred energy fuel, while dietary protein is used for anabolic processes (Walton et al, 1996).

In the catabolic and adaptive phases, fat and protein will more effectively address nutrient needs of the patient. Therefore, provision of dietary carbohydrates should be minimized, whereas fat and protein calories are maximized in refeeding formulas (provided there is no contraindication). Increased food carbohydrate fractions may lead to electrolyte disturbances and hyperglycemia, though the latter happens rarely in dogs. Cats, however, have very low glucokinase activity and cannot effectively transport glucose into hepatic cells given high intravenous and occasionally high enteral concentrations (**Table 25-2**). Subsequently, hyperglycemia is a commonly observed phenomenon during refeeding of cats. Additionally, specific disease states will affect the type and/or degree of metabolic and hormonal alterations in the patient, which subsequently influence substrate usage. In consideration of these factors, the recovery phase is patient dependent, which underscores the need for continual and consistent reassessment

Table 25-3. Examples of hospital feeding orders.

1. Offer 2 cans of product XX every 6 hr PO.
2. Give 100 ml of product YY gruel every 6 hr via PEG (percutaneous gastrostomy) tube.
3. Administer 300 ml of parenteral solution IV every 8 hr.
   Sometimes the feeding orders should contain special conditions:
4. Begin feeding liquid product ZZ at 10 ml/hr via NG (nasogastric) tube. D/C (discontinue) all feeding if vomiting begins.
5. Administer 300 ml of parenteral solution IV every 8 hr. Check urine glucose and decrease rate to 150 ml every 8 hr if urine is positive. Recheck serum potassium daily and increase to 40 mEq/l if below normal.
6. Give 30 ml of product YY gruel every 6 hr by PEG. Increase meal volume fed by 10 ml every 24 hr. decrease volume by 50% if vomiting begins.

of the patient to optimize the nutrition support plan.

PATIENT ASSESSMENT

Malnutrition can be recognized in patients through use of a nutritional assessment protocol. Nutritional assessment helps identify those patients that require assisted feeding to avoid or reduce nutrient deficiencies and the associated complications. Although inadequate nutrient intake may complicate many disorders, anorexia has been traditionally viewed as a secondary problem that will improve when the primary disease problem has resolved, i.e., "They'll eat when they feel better." However, it is better to be proactive and recognize the value of administering nutrients to veterinary patients and realize that, "They'll feel better sooner when they eat."

Diseased and debilitated patients (hospitalized or not) need to be assessed frequently, regardless of their age or lifestage. Assessment uses a number of parameters taken together to give an overall impression of whether a patient is experiencing malnutrition and requires specific nutritional intervention. Useful parameters to be assessed have been identified in large populations of people; however, no such parameters have been specifically formulated for dogs and cats. A veterinary nutritional assessment protocol should include history, physical examination (with special attention given to certain risk factors), body condition assessment (BCS) and laboratory tests (Buffington, 1994). Weight and dietary history, physical examination and body condition are relatively easy parameters to obtain. However, specific laboratory and immunologic tests that correlate well with nutritional status have not been identified. To date, very few clinical studies have been performed in veterinary patient populations to determine which parameters are applicable and their accuracy in determining nutritional status and predicting outcome (Michel, 1993).

History and Physical Examination

All patients should receive a physical examination including an accurate determination of body weight and an estimate of body condition. Weight changes must be viewed as a proportion or percentage of "normal, usual or optimal" weight within a certain time period as opposed to absolute changes in units (e.g., g or kg lost). Weight loss of more than 10% within a week is clinically significant and warrants further assessment. As a point of reference, a weight change of 10 to 15% within several days is most likely a hydration problem and should be corrected first with medical or fluid management. Pets on a designated weight-loss program can safely lose 1 to 4%, more typically 1 to 2%, of their body weight per week (Laflamme, 1993) (Chapter 27). A 10% (5 kg) weight loss within a week for a 50-kg dog is easily recognized as significant, but a similar percent weight loss over seven days for a 5-kg cat (i.e., 0.5 kg) is not easily recognized. This weight loss should be considered as serious as the same percentage weight loss in the dog. It is more difficult to accurately determine a 0.5-kg weight change than a 5-kg change; therefore, cats should be weighed on a scale that is accurate between 0 and 15 kg.

Body weight is an objective measurement, whereas body condition is a more subjective evaluation of the patient's tissue composition relative to its weight (i.e., fat, muscle and bone) (Chapter 1). Body condition scoring adds valuable information to body weight data. Decreasing fat stores indicate low energy intake and vice versa. Muscle wasting implies protein intake has been insufficient because skeletal muscle mass supports hepatic protein synthesis when dietary intake is inadequate. In one human study, using three independent clinicians' nutritional assessment of the same 64 patients, there was a 77% agreement among clinicians, and their clinical judgment of nutritional risk correlated well with

objective data such as albumin, transferrin and cholesterol concentrations and weight loss history (Lupo et al, 1993).

Survival rates of people have been directly correlated with available muscle mass. Loss of more than 25 to 30% of body protein compromises the immune system and muscle strength, and death results from infection, pulmonary failure or both (Matthews and Fong, 1993). Decreased muscle mass may occur before serum protein levels drop below normal in chronic states because overall muscle wasting is less life threatening than decreased serum protein concentrations. Muscle atrophy due to protein malnutrition occurs bilaterally and should involve several muscle groups. Bedridden patients can develop muscle atrophy due to decreased use just as astronauts develop muscle atrophy of anti-gravity muscles because muscle size depends on exercise and gravity (Lane et al, 1993). Selected muscle groups may be atrophied in animals that have limited use of a limb. Therefore, lack of activity should be considered when evaluating the muscles of a patient, particularly one that is partially paralyzed or has a long-term illness.

Recording the food intake of hospitalized patients helps determine whether or not assisted feeding is necessary. In addition to having complete feeding orders, the medical record should also contain the time of day and amount of food actually consumed by the patient. Consumption can be simply recorded as some percentage of the food offered (e.g., 0%, 50%, 100%). If feeding orders are properly written and food consumption is recorded, it will be apparent after 24 hours of hospitalization whether or not the patient is consuming sufficient food to meet its RER, and whether assisted feeding is necessary. In a study of 276 hospitalized dogs, a positive-energy balance (>95% RER) was achieved in only 27% of 821 dog days recorded, whereas a negative-energy balance (<95% RER) was observed on the majority (73%) of the dog days. The primary reasons for the 601 negative-energy balance dog days were: 1) dogs refused to eat any or all of the food offered (43%) and 2) the attending veterinarian ordered nil per os (NPO) (34%) (Remillard et al, 1998). Currently, many hospitalized dogs do not consume their RER primarily because they refuse to eat the food offered to them. Also, feeding orders for hospitalized patients should be clear and complete. Properly written hospital feeding orders identify a specific food product with the amount, frequency and the route of intake specified, if not per os (**Table 25-3**). In the same study, fewer than 20% of approximately 1,000 written feeding orders were complete and accurate.

Assisted feeding should be considered for any patient with a suspected or documented food intake below the calculated daily RER for more than three days. Nutritional support should initially deliver sufficient amounts of a nutritionally balanced food to meet the RER of the patient at its current weight when the BCS is 3/5 or less. RER is primarily determined by total weight of metabolically active tissues such as skeletal and smooth muscle and visceral organs. BCS is primarily a measure of body fat stores. RER and BCS taken together are used to initially estimate the patient's daily caloric requirement. Animals with a BCS of 4/5 or 5/5 generally have the same muscle and organ mass as those with a BCS of 3/5; however, these animals have increased fat stores, which do not increase RER. It may be prudent, therefore, to calculate RER on an estimate of optimal weight in overweight patients to prevent overfeeding (Chapter 27). After several days, the food intake may be increased if warranted.

Figure 25-4. This dog experienced four months of starvation because its owner was unable to care for it due to a chronic terminal illness. **Table 25-4** presents laboratory data from this animal.

Laboratory Data and Other Clinical Information

The changes in most laboratory data due to malnutrition are indistinguishable from those occurring in some disease processes; however, malnutrition should be considered when examining the patient and reviewing the data (**Figure 25-4** and **Table 25-4**). RBC number, hemoglobin content, urea nitrogen, potassium, albumin and total protein concentrations, total WBC and lymphocyte count are useful in nutritional assessment of adequately hydrated patients. RBCs, hemoglobin, albumin and total protein have moderately long half-lives of one to eight weeks and are an indication of the energy and protein status of the patient over the preceding weeks to months. In one study, dogs fed a protein-deficient food (4% dry matter

Box 25-2. Future Laboratory Tests for Nutritional Assessment.

DELAYED-TYPE HYPERSENSITIVITY TESTING

The delayed-type hypersensitivity (DTH) skin test has been promoted as an inexpensive and simple bedside preoperative test for people with sepsis-related mortality risk, again relating the close tie between immunocompetence and patient outcome. Patients who did not have an appropriate skin reaction to a multi-antigen intradermal injection had a sepsis rate of 34% and a mortality rate of 38% vs. a 7% sepsis rate and 3% mortality rate for patients who reacted to the test injection. Several diseases and drugs, however, may alter the specificity of this test as an indicator of malnutrition.

Delayed-type intradermal hypersensitivity testing is not currently used in dogs and cats; however, some preliminary work in cats has shown promise. Cats infected with feline leukemia and feline immunodeficiency viruses had a DTH response less than that of normal cats. In another study, healthy cats receiving no food had a significantly reduced response to an intradermal injection of feline rhinotracheitis-calicivirus-panleukopenia antigens on Day 4 vs. when they received food daily.[a]

LYMPHOCYTE FUNCTION TESTING

Other promising indicators of nutritional status in the development stage for dogs and cats are specific immune function tests. A battery of immune function tests has been developed for use in cats, including: 1) immunophenotyping to identify relationships between immunosuppressor and helper cells, 2) measuring membrane calcium flux to evaluate membrane function, 3) immunophenotyping to identify cells expressing major histocompatibility class II surface antigen, 4) measuring phagocytic capabilities of monocytes and 5) assessing neutrophil activation. Preliminary data indicate differences in these lymphocyte function tests among normal-fed, normal-fasted and ill anorectic cats.[b]

ACUTE-PHASE PROTEIN TESTING

Laboratory tests available in other species, but not yet fully investigated as parameters of nutritional assessment in dogs and cats include serum prealbumin, transferrin, retinol-binding protein, fibronectin and cholesterol concentrations and total iron-binding capacity. A group of down-regulated proteins (prealbumin, transferrin, fibronectin and retinol-binding protein) and up-regulated proteins (ceruloplasmin, α-1-antitrypsin, α-1-acid glycoprotein and C-reactive protein) may prove useful in nutritional assessment. These proteins have relatively short half-lives (two hours to 10 days) in people, and have been suggested as indicators of the patient's energy and protein status. The half-lives of these proteins are unknown in cats and dogs but are assumed to be relatively short and related to the nutritional status of the patient.

GENE EXPRESSION TESTING

Gene expression of metabolic enzymes and hormones in the fed vs. fasted state can be differentiated. The means by which food affects genetic activity probably differs among responding organs but also depends on the duration of the fast and the composition of the refeeding food. Many nutritional studies using animals have demonstrated the expression of enzymatic genes using a three-day fast followed by refeeding specific dietary formulations. For example, this starvation-refeeding paradigm has demonstrated that fasting causes adaptive increases in the concentrations of many hepatic and renal enzymes that convert amino acids to precursors of glucose and fatty acids. Conversely, feeding a carbohydrate diet decreases the activity of those enzymes involved in gluconeogenesis and amino acid catabolism. Fasting and refeeding alter the structure of chromatin in regions near the structural genes involved in metabolic regulation. The alterations in chromatin also depend on the amount of carbohydrate, protein and fat in the refeeding food. The method of refeeding affects transcriptional regulation of certain genes. In the future, it should be possible to more accurately assess the metabolic state (i.e., nutritional status) of animal patients by measuring the activities of specific enzymes, cell receptors and gene signaling pathways and then to administer an appropriate refeeding formulation.

[DM] protein) with adequate caloric intake (19% DM fat) had below normal serum albumin and total protein levels but normal globulin concentrations after four weeks (Davenport et al, 1994). As an indicator of morbidity and mortality, serum albumin concentration is a reliable tool (Mendez et al, 2005). Numerous studies in people have demonstrated that a low serum albumin value correlates with complications during recovery. It is not recommended, however, to use serum albumin levels alone to determine nutritional status in critical care patients, because multiple factors can lead to hypoalbuminemia without malnutrition (Makhija and Baker, 2008). Establishment of an accurate and sensitive nutritional assessment protocol for veterinary patients, such as the Subjective Global Assessment used in people, would provide a valuable tool for veterinary practitioners.

Decreased serum protein levels may occur in more acute states of inadequate protein intake relative to a large protein loss (e.g., protein-losing enteropathies, open abdomen). In starving animals, loss of muscle mass decreases the body's protein reserves and, together with a slower rate of protein turnover in the remaining muscle, decreases the body's ability to synthesize proteins in response to metabolic needs (Tomkins et al, 1983). Such patients are poor surgical candidates because the body's protein reserves (muscle mass) have

been catabolized to maintain the higher priority protein pools. If surgery can be safely postponed, several days of preoperative nutritional support in such patients is advisable. Only one to three days of adequate energy and protein intake may be required to up-regulate hepatic and muscle anabolic enzymes (Zeiderman et al, 1989).

Serum potassium and urea nitrogen concentrations may also be lower in anorectic patients because these variables are largely affected by food intake on a day-to-day basis. Urea nitrogen, however, tends to increase in endstage starvation because muscle is catabolized for energy when fat stores are depleted. Serum creatine kinase levels have also been evaluated as a possible marker in feline malnutrition and refeeding (Fascetti et al, 1997). Creatine kinase concentrations, however, will also increase and decrease in many disease states (Kitagawa et al, 1991). Several different types of tests that may lead to better nutritional assessment are currently under investigation (**Box 25-2**).

Risk Factors

Physiologic State

The physiologic status of the patient should be noted. This is relatively simple but rarely noted in the medical record. Knowing the gender, reproductive status, age and activity level of a patient aids in the nutritional evaluation. For example, a neutered bitch at less than optimal weight and body condition (BCS 2/5) is clearly very different from one currently lactating for eight puppies. Dietary recommendations should reflect the obvious difference in energy requirement. Neuter status can alter metabolic rate and energy needs (Root et al, 1996; Flynn et al, 1996). The metabolic processes of growth, gestation and lactation do not necessarily cease when a dog or cat becomes acutely ill. Several days of inadequate energy intake may be necessary before the hormonal milieu for growth, gestation or lactation is down regulated. Environmental temperature is usually a minor risk factor because most hospitalized dogs and cats are kept indoors.

History of Malnutrition

Patients fed homemade foods, table foods, vegetarian or single item foods are at greater risk for developing subclinical nutritional imbalances and warrant further nutritional assessment. Foods designed, formulated or prepared by owners may not be nutritionally complete, balanced or consistent (Chapter 10). These patients may not only have protein-calorie malnutrition, but are more likely to have several vitamin and mineral imbalances concurrently (e.g., calcium and certain micromineral deficiencies and/or subclinical vitamin A and D toxicoses).

Patients with a history of nausea, vomiting and diarrhea are at increased risk of malnutrition because nutritional intake probably has been less than optimal before admission. Nutrient intake may be voluntarily decreased with nausea, whereas vomiting and diarrhea can compromise nutrient digestion and absorption. Such clinical signs are also associated with additional losses of body protein.

Key Nutritional Factors

The primary focus of the key nutritional factor discussion is on enteral foods. However, some information regarding parenteral nutrition (Chapter 26) is included here and in the "Other Nutritional Factors" section that follows.

The Association of American Feed Control Officials (AAFCO) allowances (2008), and the "recommended allowances" listed in the National Research Council (NRC) Nutrient Requirements of Dogs and Cats (2006) are based on healthy animals, but are often referenced when estimating average nutrient requirements of critically ill dogs and cats to be fed enterally. This approach has been considered appropriate because most foods used in assisted feeding have nutrient digestibilities greater than those of typical pet foods (AAFCO, 2008) and, therefore, the actual available nutrient level provided by these foods would be greater than the referenced estimate. Assessment of the critical care patient may reveal nutritional factors that are not accounted for by AAFCO or the NRC; therefore, the practice of using these references for critically ill patients should be approached with caution. When estimating nutrient intakes for patients receiving parenteral nutrition, the NRC "minimal requirement" recommendations are probably better estimates than AAFCO allowances, because NRC minimum requirement recommendations were typically determined using synthetic foods, which better approximate 100% availability (2006). In addition to assuring that enteral foods intended for critically ill patients meet AAFCO (or some other credible regulatory agency) allowances, special emphasis is placed on the key nutritional factors and their recommended levels discussed below and summarized in **Table 25-5**.

Unlike the key nutritional factor recommendations for normal and clinical conditions described in the rest of this book, in critical care nutrition, nutrient requirements are conventionally expressed on an energy rather than on a DM basis (Chapter 1). This designation is primarily an extension of the units used in actual clinical metabolic trials. In addition, nutrient profiles of oral liquid products and parenteral solutions used in nutritional support/recovery are more commonly expressed on an energy rather than on a DM basis.

Fluid and Electrolyte Therapy

Initial support often involves management of fluid, electrolyte and acid-base disorders. The water requirements in ml for normal healthy animals approximate their daily energy requirement (DER) in kcal (i.e., 1 kcal [4.184 kJ] DER = 1 ml of water). Fresh, clean water should be available to patients at all times, unless the patient requires a period of nothing per os. Most patients in an intensive care unit (ICU) have venous catheters in place and receive crystalloid fluid therapy. These patients may have fluid restrictions or, conversely, may require diuresis. In these cases, the water or fluid administered will not be equal to the patient's DER. Daily maintenance fluid requirements are approximately 60 ml/kg body weight/day.

The patient's fluid and electrolyte (sodium, potassium, calcium, magnesium and phosphorus) balance should be near normal limits before assisted feeding is begun. Nutritional support

Table 25-5. Key nutritional factors for commercial liquid or blended foods for canine and feline patients requiring enteral nutrition (EN) support.

Factors	Recommended food levels
Water	Correct dehydration with parenteral fluid therapy before starting assisted feeding. Supply at 1 ml/kcal DER unless patient requires fluid restriction or diuresis. Typical daily maintenance fluid requirement is 60 ml/kg body weight.
Electrolytes	Major electrolyte disorders, acid-base abnormalities and blood glucose levels should be corrected before instituting EN support.
Osmolarity	250 (optimal) to 400 mOsm/liter.
Energy density	Supply 1 kcal/ml (as standard minimum). If the patient is not eating at least RER per os, provide nutritional support by assisted-feeding techniques to meet this requirement. By the fifth day of food deprivation or longer, patients should receive the majority (60 to 90%) of their calculated RER as lipid. If using a liquid or blended food, select a product that provides 1.0 to 2.0 kcal/ml (1.0 to 2.0 kcal/g), as fed.
Digestible carbohydrate	Dogs and cats: 2 to 4 g/100 kcal is a safe starting point for refeeding. Increase to 6 to 10 g/100 kcal 3 to 4 days into the refeeding process.
Protein	Dogs: Use a food that provides 5.0 to 12.0 g protein/100 kcal. Cats: Use a food that provides 7.5 to 12.0 g protein/100 kcal.
Arginine	≥146 mg arginine/100 kcal for dogs. ≥250 mg arginine/100 kcal for cats.
Glutamine	≥500 mg/100 kcal.
Fat	Provide a calorically dense food (5 to 7.5 g fat/100 kcal), except in cases in which high fat content is not tolerated. Provide a low-fat content food (2.0 to 3.5 g fat/100 kcal) if fat restriction required*

Key: DER = daily energy requirement, RER = resting energy requirement, to convert kcal to kJ, multiply kcal by 4.184.
*For example, patients with pancreatitis.

should not be initiated until the patient is hemodynamically stable because administering enteral or parenteral nutrition may further compromise the patient. Nutritional support should not be initiated as a "last ditch" effort in unstable patients. Major electrolyte disorders, acid-base abnormalities and blood glucose levels should be corrected before instituting enteral or parenteral nutritional support. It is also desirable to correct severe tachycardia, hypotension, colloid and volume deficits before starting assisted feeding (Minard and Kudsk, 1994). A practical goal is to begin nutritional assessment and support within 24 hours of hospitalization for the injury or illness (Burkholder, 1995).

Osmolarity

Osmolarity refers to or represents the number of solute particles per liter of solution. Serum concentrations greater than 310 mOsm/l in dogs and greater than 330 mOsm/l in cats are usually considered hyperosmolar (Tilley and Smith, 2004). During enteral nutritional support, the osmolarity of a food appears to have the most significant clinical impact on GI function and stool character (i.e., presence of diarrhea) (Pasulka and Crockett, 1994). In general, osmolarity of commercial pet foods is not reported. Instead digestibility of typical dry or moist foods is evaluated and, among other things, reflects the potential of a food to be tolerated by the GI tract. As digestibility increases, the osmolarity decreases, allowing for greater absorption of ingesta/digesta and minimizing the draw of excess water into the GI tract. Conversely, the osmolarity of liquid foods is reported for veterinary and human products. To optimize GI function, transit time and stool character, liquid foods of 250 to 400 mOsm/l are recommended.

Along with GI tolerance, another clinical concern affects critical care patients fed hyperosmolar foods. As described previously, these patients often exhibit insulin resistance associated with the stress response to illness and/or trauma. Liquid foods providing increased digestible (soluble) carbohydrate-derived calories are hyperosmolar (>400 mOsm/l). This promotes and perpetuates a hyperglycemic state, thus increasing the risk of the hyperglycemic hyperosmolar syndrome (Schaer, 2005). Specific concerns for delivery of hyperosmolar nutrient solutions intravenously are discussed in Chapter 26.

Energy and Energy Density

Knowing a patient's approximate caloric requirement is important because feeding more of any food than is necessary may cause metabolic complications. Overfeeding patients is possible through a feeding tube or with parenteral nutritional support. In people and several animal models, excessive carbohydrate intake was associated with hyperglycemia, hypercarbia, fatty liver, increased ventilatory drive and failure to wean from a ventilator (Deitel et al, 1983). Excessive fat administration has been associated with hyperlipidemia, hypoxia, increased rate of infection and higher postoperative mortality (Lowry and Brennan, 1979).

The proportion of fat and carbohydrate supplying calories to hospitalized patients should be similar to that which the liver is estimated to be using from body stores (**Figure 25-2**). Caloric density is important in both enteral and parenteral feedings when volume is limited. Enterally fed patients can be volume restricted by gastric or intestinal sensitivities. Parenterally fed patients can be fluid restricted due to cardiorespiratory diseases and functional disabilities. In general, most dogs and cats tolerate the volume of food or solutions that meet the patients' RER within easily tolerated volumes when the caloric density is approximately 1 kcal/ml.

In malnutrition, without disease or injury, decreased T_3 concentrations decrease the metabolic rate in an effort to conserve functional protein and energy stores. However, with an ongoing disease process or traumatic injury, the neuroendocrine responses to stress increase the metabolic rate above that found in simple starvation. Respiration calorimetry measurements of more than 3,000 people with a wide variety of diseases, specifically excluding hyperthyroidism, showed that 90% of the patients had energy requirements from 15% above to 15% below RER (Boothby and Sandiford, 1924). The energy expenditure in people with trauma peaks in three to four days

and then subsides by Days 7 to 10 unless complicated by sepsis (Moore and Moore, 1994). Energy expenditure of people with other disease conditions probably follows a similar pattern with varying requirements above RER that may occur over time.

Hospitalized veterinary patients are assumed to be similar to ill people and their DER is very near their RER. Results of a few preliminary respiration calorimetry measurements in dogs with specific disease conditions suggested that most had requirements near RER (Walton et al, 1996; Ogilvie et al, 1996). Estimating the RER of hospitalized patients should be calculated by the equation RER = $70(BW_{kg})^{0.75}$ (Chapter 5). Most hospitalized veterinary patients should be fed at their calculated RER, realizing their actual energy requirement is likely to change over the course of the disease process and recovery. In human surgical patients, there was relatively little additional benefit to increasing intake after half of the caloric requirement of patients had been achieved (Elwyn et al, 1981). Therefore, initially feeding patients at RER, or at least 60% of RER, if 100% RER is not possible, is a rational and safe recommendation that decreases the probability of metabolic complications. Regular nutritional assessment of the patient is strongly recommended to adjust initial feeding rates.

There are exceptions when the caloric requirement will be greater than RER. Particular cases have energy requirements 1.3 to 2.1 x RER as determined by bedside respiration calorimetry in people (Moore and Moore, 1994). For example, according to indirect respiration calorimetry, people with severe closed-head and brain injury have energy requirements 40 to 60% above their calculated RER (Ott et al, 1990). Brain injury apparently increases oxygen consumption and acute-phase protein synthesis, which subsequently increase patients' caloric and protein requirements significantly above RER. Energy requirements of twice RER appear to be the upper limit in the most severe head injuries. Energy expenditure may be 30 to 50% above RER in patients with multisystem trauma. Severely burned patients also have energy and protein requirements 80 to 100% above RER, relative to the extent of skin damage and surface area exposed (Moore and Moore, 1994). The body loses heat, moisture and protein through wounds that have little or no epithelial covering. The patient's actual metabolic rate and resultant energy requirement are related to the degree of trauma, disease and/or complications and can only be approximated in a clinical setting.

The energy density of foods intended for patients requiring assisted feeding is often reported relative to the water or fluid content of the food. This is because an animal's energy requirement in kcal is approximately equal to its water requirement in ml and most critical care feeding is done in a liquid form. Thus, when patients are fed a sufficient amount of food to meet their energy requirements, they also meet their requirements for water. The recommended energy density of a food intended for assisted feeding (enteral or parenteral nutrition) is 1 to 2 kcal/ml.

Adjusting for Protein Calories

Calculating and adjusting for protein calories is of minor consequence when feeding at RER. If one assumes that part of the caloric intake is to be supplied by protein, then that fraction of protein intake that is used for energy vs. that which is used for protein synthesis must be estimated because the same amino acid cannot do both. Theoretically, if protein were supplied at 4 g/100 kcal to the patient but all of it was oxidized for energy with none going to synthesis, the protein could only account for 14% (4 g x 3.5 kcal/g) of the total caloric intake at best.

The most conservative and simplest method is to first provide the entire caloric need with fat and carbohydrate, and then meet the protein requirement entirely with amino acids, and not estimate the fraction of the protein that may be catabolized vs. anabolized. This method will not shortchange either the caloric or protein requirement because the fraction of amino acids actually used for energy will provide only a small amount (<15%) of additional calories. Essential amino acids provided by food are most efficiently used in protein synthesis and should not be used for energy, if at all possible. In summary, protein calories may be taken into account, however, the contribution is small and not significant.

Carbohydrate

Carbohydrate usage during the healthy fed state results in energy storage (glycogen) or energy production (ATP) in a very efficient manner. Conversely, use of this nutrient in refeeding scenarios during the unfed state is less efficient and can result in adverse metabolic and physiologic states, particularly in diseased or injured patients. Insulin resistance, presence of bacteria with infection, diminished production of digestive enzymes, altered GI absorptive capacity and alteration of gut microbiota complicate the recovery process and influence dietary carbohydrate tolerance. The two major clinical manifestations currently associated with carbohydrate intake include altered glucose control and diarrhea. Consequently, most foods formulated for recovery are low in carbohydrate content.

Tight glucose control in ICU patients has been regarded as beneficial because both hyperglycemia and hypoglycemia have detrimental effects on tissue function and clinical outcome, but recently this goal has been challenged (Elia and De Silva, 2008). Adverse effects of hyperglycemia that can predispose the patient to infection and delay recovery from illness include osmotic shifts, glucosuria, altered immune and endothelial cell function and promotion of free radicals. Conversely, hyperglycemia is a normal response to injury or stress. Glucose is needed for wound healing and inflammatory/immune cells that are involved in the metabolic response to injury, as well as other physiologic functions. A review of several human ICU-based studies indicated that narrowly controlled glucose did not significantly reduce hospital mortality (Elia and DeSilva, 2008). Circulating glucose is the major energy source for the brain. Although in most ICU patients, during the unfed state and during diabetic ketoacidosis, the brain can use ketones as an energy source. Once re-fed, the circulating insulin acts to suppress ketone body concentrations, which once again leaves glucose as the major energy source for the brain. Reducing the blood glucose concentration in some patients (lower than seen with stress/injury response) could have detrimental effects such

as neuronal dysfunction, neuronal death or cerebral infarction (Gandhi et al, 2007). In contrast, partial or complete cessation of nutrition has been identified to be one of the major risk factors for developing hypoglycemia (Elia and De Silva, 2008). A low-carbohydrate food can amplify the onset of the hypoglycemic state, particularly in small-breed dogs.

Diarrhea appears to be a common problem in critically ill patients during refeeding. Malabsorption of dietary carbohydrate or fat, hyperosmolar formulas (generally high carbohydrate content), and feeding high volumes of enteral fluid have all been reported as causal factors (Mutlu et al, 2001). Complications of diarrhea include effects on hydration, acid/base status, mineral balance, contamination of wounds, decreased colonic fermentation and reduced butyric acid production (Thaklar et al, 2005; Kien et al, 1999). Traditional attempts to minimize the osmotic diarrhea, believed due to carbohydrate malabsorption, have focused on limiting the dietary carbohydrate intake (Kein et al, 2004). Small intestinal carbohydrate malabsorption (breath H_2) and colonic fermentation, stool volume and total enteral fluid volume were measured in burn patients receiving a high carbohydrate (Vivonex TEN) enteral food over a four-week period. Although all patients had diarrhea over several weeks, the lack of correlation of either carbohydrate intake or breath H_2 with stool volume suggested diarrhea was due to factors other than carbohydrate malabsorption (Thaklar et al, 2005). Notwithstanding, prevention and possibly treatment of osmotic diarrhea has been addressed by delivery of lower osmolarity nutrient solutions.

The value of dietary carbohydrate in maintaining an adequate and healthy population of gut microbiota cannot be overlooked. The intestinal microflora has been proposed as an environmental factor responsible for control of body weight and energy metabolism. Fermentation of non-digestible dietary fiber (insoluble carbohydrate) and resistant starches (oligosaccharides) along with numerous other mechanisms are linked to the health of gut microflora and energy metabolism. The major part of the microbiota is present in the colon where food products have escaped digestion, so the biologic functions controlled by this microflora seem to relate to effectiveness of bacteria to harvest energy that has been ingested, but not digested, by the patient. Human and rodent studies similarly conclude that microbiota can extract energy from non-digestible carbohydrate based on species (Turnbaugh et al, 2006; Ley et al, 2006), suggesting a benefit of providing adequate insoluble carbohydrate in the diet of critically ill patients. Additionally, fructooligosaccharides taken in the diet (5 to 20 g/day) improved mucosal barrier function, improved glucose tolerance and insulin homeostasis in human patients and rodents (Cani and Delzenne, 2007). Another study further highlights the value of resistant starches and dietary fiber as sources of short-chain fatty acids in critically ill/injured patients. Increased short-chain fatty acids, in particular butyrate, significantly enhanced colonic anastomosis healing and increased intestinal bursting pressure postoperatively in rats (Campos et al, 2008).

Perioperative carbohydrates minimize postoperative complications. Intracellular tight junctions maintain the intestinal epithelial barrier. Formation of dysfunctional tight junctions after stressful events such as surgery, contribute to postsurgical complications and delayed recovery (Bouritius et al, 2008). Adequate intestinal blood flow along with the mononuclear phagocytic system, located predominately in the liver, work in tandem to protect against bacterial translocation. Studies have indicated that glucose supplementation increases intestinal blood flow and that hepatic glycogen content contributes to increased survival rate by maintaining the liver system. Clinically these findings were substantiated when rats receiving a carbohydrate drink consisting of glucose, maltose and polysaccharides (12 g carbohydrate/100 ml) for six days before major abdominal surgery retained intestinal barrier function and were protected from translocation of bacteria to distant organs compared to cohorts not fed carbohydrates (Bouritius et al, 2008). Based on these studies, dietary carbohydrates maintain the mucosal barrier, hasten tissue healing, minimize complications and shorten hospital stays.

The dietary carbohydrate level in the initial refeeding of critically ill patients should be based on patient assessment and timing. Dampening the body's natural response of hyperglycemia to illness/stress may not be as beneficial as previously thought; carbohydrates in various forms have metabolic and physiologic value to patients. Conversely, promotion of a severe hyperglycemic state in these patients is contraindicated to recovery. On average, "recovery" type foods provide 2 to 4 g carbohydrate/100 kcal, with increased fat and/or protein content; this appears to be a safe starting point for refeeding. Then, consider transitioning to a higher carbohydrate food (6 to 10 g/100 kcal) and evaluating the insoluble carbohydrate (fiber) source three to four days into the refeeding process, based on patient reassessment.

Protein

Protein in the body is always in flux between synthesis and breakdown. Protein synthesis requires that amino acids be present within cells at the correct time and ratio so that a protein may be constructed successfully. Protein degradation involves the release of amino acids, and if the amino acid is deaminated, the ketoacid analog is converted to glucose or fat and the amino group enters the hepatic urea cycle and is ultimately excreted in the urine. Under most circumstances, about 15% of the RER comes from the oxidation of amino acids (Kinney, 1988). Providing a dietary protein source to patients in catabolic states spares endogenous skeletal muscle protein and supplies essential amino acids and amino groups for acute-phase proteins and the immune response. Excessive dietary protein should be avoided in patients with kidney or liver disease (Chapters 37 and 68). However, high dietary protein intakes are handled well by most canine and feline critical care patients to replace dietary carbohydrate when carbohydrates are not well tolerated.

Protein administration should complement nonprotein calories because amino acids will be oxidized for energy when a patient's total energy need has not been met first. Sufficient calories must be available from fat and/or glucose before ingest-

ed amino acids will be used for tissue synthesis and repair (Mallet, 1984). Excessive protein feeding requires energy expenditure to rid the body of excess nitrogen, which, in certain patients, may or may not be handled well by the liver (urea cycle) and kidneys and can result in hyperammonemia with accompanying clinical signs of encephalopathy. Conversely, insufficient protein has been linked to low albumin concentrations, poor immune response, impaired healing and increased risk of wound dehiscence and muscle wasting. The most efficient use of protein in people occurs when 2 to 6 g protein/100 kcal are administered (Stein, 1986).

Commercial products intended for enteral support of canine and feline critical care patients provide between 5.5 and 14.3 g protein/100 kcal. Due to a lack of evidence to the contrary and because these products appear to work well in critical care patients, a range of 5.0 to 12.0 g protein/100 kcal is recommended for canine patients and 7.5 to 12.0 g protein/100 kcal is recommended for feline patients. Because of the overlap of these recommendations, several commercial products intended for enteral support are designated for use in both canine and feline critical care patients.

When formulating parenteral nutritional support, it is prudent to first provide for total caloric needs with carbohydrate and fat, and then meet the protein requirement. If sufficient calories are supplied to patients as either fat or carbohydrate, then most of the essential amino acids will be used for protein synthesis and not burned for energy. A starting point of 2 to 3 g protein/100 kcal parenterally (Remillard and Thatcher, 1989) can be used for most dogs that can excrete protein waste products and do not have an extraordinary protein loss. A lower range (1 to 2 g/100 kcal parenterally) is a more reasonable estimate for patients with kidney or liver diseases. A higher range (3 to 4 g/100 kcal parenterally) is a more reasonable estimate for cats because of their constant state of gluconeogenesis from amino acids. Protein intake can then be adjusted based on the patient's needs and ability to handle the initial protein recommendation (e.g., decreasing serum albumin concentration or encephalopathic signs).

In addition, specific nutrients affect immunocompetence. Some nutrients act directly on the lymphoid system and immune cell function, thereby altering host immune response to pathogens. As an example, arginine, glutamine and dietary nucleotide-enriched foods are associated with significant reduction in wound infection and length of hospital stay in human burn patients.

Arginine

Arginine is essential to traumatized patients. It has a marked immunopreserving effect in the face of immunosuppression induced by protein malnutrition and cancer. In postsurgical patients, arginine supplementation enhances T-lymphocyte response and augments T-helper cell numbers, with a rapid return to normal T-cell function postoperatively, compared with findings in control patients (Bower et al, 1995). These data taken together suggest that arginine supplementation may increase or preserve function in high-risk surgical patients and theoretically enhance the host's capacity to resist infection. Arginine enrichment stimulates the immune system, improves wound healing and decreases morbidity and mortality in burn patients. A feeding regimen with arginine as 9% of the protein source has been suggested and tested in burn patients. Those receiving the arginine-enriched food had a significant reduction in the incidence of wound infection and shorter hospital stays. As a nutrient substrate, arginine appears nontoxic and may benefit surgical patients at increased risk of infection (Goffschlich et al, 1990). The optimal arginine intake for people is unknown, so selection of enteral foods based solely on arginine content is not recommended for human patients.

Numerous studies in a variety of animal models demonstrated the efficacy of arginine-supplemented foods in reducing the catabolic response to major trauma, sepsis and injury and in improving the immune response after a variety of adverse stimuli. For example, a food containing arginine as 2% of the total nonprotein calories significantly increased survival after 30% surface burns (Irenton-Jones and Baxter, 1990). Furthermore, in animal studies, exogenous arginine supplementation consistently improved nitrogen retention, protein turnover and wound healing. Arginine augments cellular immunity, as evidenced by enhanced skin allograft rejection in normal mice, and improves delayed hypersensitivity responses.

Arginine is an essential amino acid in dogs, cats and people. Therefore, most pet foods meeting AAFCO nutrient concentrations should contain at least 146 mg arginine/100 kcal for adult dogs and 250 mg arginine/100 kcal for adult cats (providing approximately 80 to 200 mg/kg body weight). Arginine content of human enteral products is variable but usually stated on the label. Human enteral products and parenteral nutrition solutions must contain at least adequate amounts of arginine if used for more than a few days in dogs or cats.

Glutamine

Glutamine is an amino acid that plays an important role in many cellular processes. Human studies suggest that glutamine concentrations in whole blood and skeletal muscle decrease markedly following injury and other catabolic states, thus making it "conditionally" essential during serious injury or illness (Lacey and Wilmore, 1990). Numerous clinical trials suggest that intervention with glutamine reduces rates of infectious complications in postsurgical patients and complications and mortality rates in critically ill patients (Novak et al, 2002). Replicating cells such as fibroblasts, lymphocytes and intestinal epithelial cells have high glutaminase activity and consume glutamine, but the intracellular level of glutamine remains low. The mechanism linking the beneficial effect of glutamine on attenuating cellular metabolic dysfunction and enhancing cell survival depends on glutamine-induced enhancement of specific heat shock proteins (Peng et al, 2006). These findings may be important for patients with large wounds or inflammation associated with infection.

The controversy persists as to which route of glutamine administration (enteral or parenteral) is most effective at

improving clinical outcomes in critically ill patients. At least 80% of the published data in laboratory animals demonstrate a positive effect with glutamine-enriched feedings. Positive effects include enhanced protein metabolism, intestinal and pancreatic repair and regeneration, nutrient absorption, gut-barrier function, systemic and intestinal immune function and animal survival. The mechanism(s) for these effects are not well clarified, but studies suggest several possibilities. First is the inter-organ conversion of glutamine-derived citrulline to renal arginine synthesis (Ligthart-Melis et al, 2007). A second mechanism is through glutamine attenuation of the gut-derived inflammatory response (Wischmeyer, 2006).

Numerous animal studies have demonstrated the value of enteral glutamine during stress. For example, rats undergoing abdominal radiation and fed glutamine orally for eight days following the stress had significantly increased jejunal villous number and height and an increased number of mitoses per crypt, whereas non-irradiated control rats fed the same food without glutamine supplementation had no significant increase in mucosal cell activity (Klimberg et al, 1990). Similarly, dogs had an increased intestinal requirement for glutamine during the immediate postoperative phase (less than seven days), but uptake rates returned to normal later during the recovery phase (after 10 days) (Souba et al, 1987). Oral glutamine supplementation influences GI function, along with cell morphology. For example, rats undergoing ischemia-reperfusion injury maintained small intestinal barrier function when provided with enteral glutamine (Kozar et al, 2004).

Provision of exogenous glutamine to stressed patients might better support the metabolic requirements of the small intestine and possibly decrease the rate of systemic protein catabolism (Wischmeyer, 2006), therefore, supplementation is warranted. The optimal concentration of glutamine for different disease states is still under study. It is presently unclear whether glutamine must be in the free form to be beneficial or if the protein-bound form is also beneficial in maintaining gut integrity. Most enteral foods contain some protein-bound glutamine but the glutamine concentration of these products must be estimated. Some enteral products have added free glutamine. The glutamine content of these products is often stated on the label. Glutamine levels in commercial enteral foods intended for critical care canine and feline patients should be at least 500 mg/100 kcal.

Although based on human studies indicating the gut preferably takes up enterally administered glutamine compared with intravenously provided glutamine (Ligthart-Melis et al, 2007), evidence suggests intravenous glutamine can provide benefits as well. In protein-depleted rats, intravenous glutamine supplementation resulted in increased villous height, increased small-bowel mucosal weight, enhanced DNA activity (O'Dwyer et al, 1989) and improved DNA content and sucrase and lactase activities. Parenteral admixture supplemented with 2% glutamine and administered for 48 hours before and 72 hours postintestinal abdominal surgery in undernourished dogs improved ileal morphology, increased CD4:CD8 cells, select immunoglobulins and mononuclear cell function and resulted in fewer postsurgical diarrhea days compared to dogs administered non-glutamine supplemented parenteral admixture (Saker et al, 2001). In short-term studies in rats and pigs, adding glutamine to nutritional intravenous solutions reduced some aspects of disuse intestinal atrophy and enhanced intestinal immune function (Remillard et al, 1998). Intravenous glutamine supplementation immediately following hemorrhagic shock partially restored the depletion of hepatic ATP, reduced cellular apoptosis and oxidative stress-associated cell damage in rat and feline models (Yang et al, 2007; Krizova et al, 2004), suggesting additional benefit from intravenous-glutamine supplementation during critical illness. Intravenous glutamine should probably be limited to short-term use (one week or less) just before oral refeeding. Inclusion of 2% L-glutamine via the intravenous route has been safely used in human and veterinary patients. However, it should be noted that inclusion of glutamine in parenteral nutrition solutions can be difficult to achieve due to solubility constraints.

Fat

Supplying the majority of calories as fat to critically ill patients has several benefits. Fat contains 8.5 kcal metabolizable energy/g and is therefore calorically dense compared to carbohydrate and protein. Therefore, more calories may be provided in a smaller volume to patients. After three to five days of not eating, the liver has shifted from glucose to fat metabolism, therefore providing more fat and less dextrose at this time reduces metabolic complications of nutritional support. Additionally, providing calories as fat rather than dextrose reduces CO_2 production, which noticeably reduces respiratory work in patients requiring oxygen therapy. On average, "recovery" type foods provide 5 to 7.5 g fat/100 kcal; this appears to be a safe starting point for refeeding. The exceptions include patients with pancreatitis or other conditions in which enteral intake of a high-fat food is not tolerated.

Other Nutritional Factors

Other nutritional factors can be important considerations for enteral foods or parenteral fluids for critical care patients. Factors such as vitamins and minerals are typically included in adequate amounts in commercial veterinary therapeutic enteral foods formulated for dogs and cats. However, these nutrients are important to consider in parenteral nutrition support. Other factors (nucleotides, essential fatty acids and antioxidants) may benefit veterinary patients based on the human critical care literature and case reports. The optimal daily dose and duration of provision have yet to be standardized for dogs and cats. Typical ingredients used in many enteral foods contain nucleotides, essential fatty acids and antioxidants. Some critical care foods have been specifically enriched, whereas others have not been and would need exogenous supplementation if they were deemed valuable. Provision enterally is more efficient and practical than through parenteral fluids.

B Vitamins

Folic acid, thiamin, riboflavin, niacin, pantothenic acid, pyri-

doxine and B_{12} are essential for hepatic metabolism of glucose, fat and protein. These are coenzymes for the tricarboxylic acid (TCA) cycle, ATP production and RBC metabolism. B vitamins are required in small amounts relative to other nutrients, but they are required daily and are necessary for efficient energy metabolism. Most commercial pet foods contain adequate amounts of these nutrients, so deficiency should not be of concern if the patient is eating or being fed enough food to meet its RER. B vitamins should be added to the fluids (1 to 2 ml of vitamin-B complex/1,000 ml of crystalloid fluid) of all patients that are not eating but receiving fluid therapy or parenteral nutrition support.

Microminerals

Zinc, copper, manganese, chromium and selenium are vital cofactors for optimal hepatic and peripheral metabolism of energy substrates. Microminerals (i.e., trace minerals or trace elements) are important cofactors (metalloenzymes) and participate in tissue repair and albumin synthesis; therefore, zinc, copper and manganese should be included in all food forms used for assisted feeding. Most pet foods contain adequate amounts of these nutrients, thus deficiency should not be of concern if the patient is eating enough food to meet its RER. Specialized solutions containing essential trace (zinc, copper and manganese) minerals can easily be added to parenteral nutrition solutions at approximately 1 ml per 100 kcal of solution.

Fat-Soluble Vitamins and Macrominerals

Hospitalized patients rarely need fat-soluble vitamins and macrominerals. Most patients have fat and hepatic stores of the fat-soluble vitamins sufficient to meet metabolic needs for months to years. However, administering fat-soluble vitamins should be considered in cases of prolonged malnutrition in which the patient is severely underweight with little to no fat stores (i.e., BCS 1/5). Most pet foods contain adequate amounts of these nutrients, thus deficiency should not be of concern if the patient is eating enough food to meet its RER. Fat-soluble vitamins are not added to parenteral nutrition solutions due to insolubility problems. It is easiest to administer a single dose of vitamins A, D and E by deep intramuscular injection to patients needing these vitamins. Such an injection supplies approximately one to two months of daily requirements.

Macrominerals (i.e., calcium, phosphorus, magnesium, sodium and potassium) are rarely needed by patients above that required to maintain serum electrolyte levels. Whole body stores of these minerals can be depleted but are usually easily corrected by intravenous administration. The distribution between the intracellular and extracellular fluid space can be a problem and imbalances should be corrected before assisted feeding is begun (**Box 25-3**). Sodium, potassium and magnesium levels may

Box 25-3. Refeeding Syndrome.

Refeeding syndrome in people is characterized by generalized muscle weakness, tetany, myocardial dysfunction, dysrhythmias, seizures, excessive sodium and water retention, hemolytic anemia and death due to cardiac or respiratory failure. A similar syndrome occurs less commonly in veterinary patients. When it does occur, it is most often seen in patients receiving parenteral nutrition or during inappropriate assisted enteral feeding and most commonly presents as hypokalemia or hypophosphatemia. Significant electrolyte shifts occur from extracellular to intracellular compartments as energy and amino acids are reintroduced. This electrolyte shift will occur regardless of the route of administration (i.e., enteral or parenteral). Often serum ion levels are deceptively normal in anorectic patients before refeeding begins (**Table 25-4**). However, when calories are reintroduced, particularly from carbohydrate, potassium and phosphate shift intracellularly with glucose resulting in hypokalemia and hypophosphatemia.

Potassium moves into cells with refeeding because glucose stimulates insulin release, which in turn stimulates the Na-K ATPase pump and glycogen synthesis, which requires 0.33 mEq potassium/g of glycogen. Phosphate moves into cells with refeeding to support the increased production of phosphorylated intermediary compounds of energy metabolism. Severe hypophosphatemia, hemolytic anemia and death have occurred in cats within 12 to 72 hours of refeeding with either an apparently normal or phosphorus-deficient diet. The refeeding formula should contain at least the Association of American Feed Control Officials recommended minimum allowance of 0.5% dry matter phosphorus.

In people, hypomagnesemia is another common electrolyte complication that must be corrected. Hypomagnesemia increases urinary excretion of potassium, exacerbates hypokalemia and causes hypocalcemia, which is refractory to supplementation until the hypomagnesemia is corrected. Little information is available about magnesium status in hospitalized dogs and cats; however, serum magnesium levels should probably be monitored in veterinary patients with abnormal serum electrolytes.

RECOMMENDATIONS FOR AVOIDING COMPLICATIONS OF THE REFEEDING SYNDROME

1. Anticipate the potential for the problem and re-feed with formulations known to contain adequate potassium, phosphate and magnesium levels and lowered digestible (soluble) carbohydrate content.
2. Use initial nutritional refeeding rates that do not exceed the patient's resting energy requirement (RER) and 2 to 6 g protein/100 kcal (parenterally) or 5.5 to 7.5 g protein/100 kcal (enterally). These rates can be increased as needed over subsequent days. Consider refeeding a high-fat, low-carbohydrate formula to patients that have not eaten for four to five days or more.
3. Monitor serum potassium, phosphate and magnesium levels as needed. Once a day is sufficient for most cases.
4. Supply water-soluble vitamins free choice, particularly thiamin, to facilitate energy metabolism.
5. Monitor patients daily for signs of fluid overload and congestive heart failure.

The Bibliography for **Box 25-3** can be found at www.markmorris.org.

become a concern in patients experiencing excessive urinary loss of those minerals due to intensive diuretic therapy. Most pet foods contain adequate amounts of these nutrients, thus deficiency should not be of concern if the repleted patient continues eating enough food to meet its RER. Calcium and magnesium are not added to parenteral nutrition solutions due to insolubility problems; however, phosphorus, sodium and potassium can be added to parenteral nutrition solutions at maintenance concentrations or for repletion if needed.

Nucleotides

Nucleotides are precursors of DNA and RNA, but they also participate in a number of metabolic reactions fundamental to cellular activity. Dietary nucleotides appear to be important for maintenance of normal cellular immunity and are vital to maintain host defenses against bacterial and fungal pathogens. Dietary nucleotides appear essential to the normal maturation of lymphocytes (Hall et al, 1998). In vitro mixed lymphocyte culture response and mitogen stimulation are suppressed in patients supported on a casein-based laboratory food. Such foods are nucleotide free. Mice maintained on nucleotide-free foods are much more susceptible to lethal infections caused by *Candida albicans* and *Staphylococcus aureus* and exhibit depressed macrophage bactericidal activity compared to nucleotide-fed counterparts. Similarly, animals fed a nucleotide-free food for six weeks had significant immunosuppression as demonstrated by enhanced cardiac allografts and diminished ability to survive a fungal challenge. These findings are significant because all commercially available parenteral and nearly all enteral human products are devoid of nucleotides.

The clinical value of nucleotides was evaluated in two separate studies that investigated the effects of a human enteral product enriched with arginine, nucleotides and omega-3 fatty acids (Impact[a]). In one study, researchers investigated the effects of this enriched enteral product on immune parameters of patients undergoing major abdominal surgery. In general, patients receiving the enriched product had enhanced immunocompetence and fewer infectious complications than patients in other groups. In the other study, a subset of patients with sepsis who were fed the enriched enteral product (Impact) had shorter hospital stays and a major reduction in the frequency of acquired infections vs. other groups (Bower et al, 1995). Though clinical gain was evident from the nucleotide-enriched food, it is not clear if the benefit was from nucleotides alone or from the combination of special nutrients provided in the food. There are no reported studies evaluating the clinical value of nucleotide-enriched foods for critical care veterinary patients, likely because pet foods that use meats and cereal grains as ingredients should provide adequate levels of dietary nucleotides. Despite the limiting data substantiating their clinical value in veterinary patients, dietary nucleotides are a vital component of regimens to maintain or restore immune function and host defense and, therefore, should be considered when choosing a critical-care food.

Omega-3 Fatty Acids

The effect of dietary fatty acids on the immune system depends on which fatty acid is fed and what specific aspects of the immune system are evaluated. Dietary fatty acids are thought to affect the immune system by three mechanisms: 1) altered eicosanoid synthesis, 2) changes in cell membranes that affect membrane-associated protein and receptor function and 3) changes in intracellular nonesterified fatty acid pools that affect cytokine production. Generally, omega-3 (n-3) fatty acids produce fewer inflammatory cytokines, whereas omega-6 (n-6) fatty acids produce more proinflammatory cytokines (Lands, 1992).

The capacity of tissues and WBC to produce pro- or antiinflammatory prostaglandins and lipoxygenase products is largely determined by the amount and type of fatty acids present, which is mostly determined by concentration of dietary fatty acids. Omega-3 fatty acids, once incorporated into the plasma membrane, affect immune cell function by altering membrane fluidity and second messenger function, and by increasing production of dienoic prostaglandins, the 3-series prostaglandins and 5-series leukotrienes. These changes may be responsible for alterations in such cell functions as phagocytosis, production of interleukins and production of superoxides. A significant reduction in dietary omega-6 polyunsaturated fatty acids will lower production of proinflammatory eicosanoids and appears to be a prudent approach in nutritional support of immunocompromised, traumatized, postoperative or infected patients. Conversely, the inclusion of omega-3 fatty acids in such foods would seem to be beneficial in increasing antiinflammatory eicosanoid production. Findings suggest that marked improvement can be made in foods by adjusting the omega-6 and omega-3 components to ensure optimal immune function.

Clinical evidence suggests that dietary omega-3 fatty acids may benefit the management of severe inflammatory and autoimmune disorders in rodents and people. These less inflammatory metabolites alter immune function and may improve survival in patients in which the inflammatory process threatens to cause irreversible damage, as in septic shock or endotoxemia. Omega-3 fatty acids shift the response away from intense inflammation. In other studies, fish oil protected guinea pigs from endotoxic shock and lactic acidosis, providing them with a survival advantage (Fritsche and McGuire, 1996).

Timing of dietary omega-6 and omega-3 fatty acid manipulation is critical to influencing patient inflammatory response. The literature varies when reporting dosing route, concentration and species. Nonesterified fatty acids in tissues have been effectively altered within hours of oral dosing with omega-3 fatty acids. In cats, concentrations of specific fatty acids were altered in immune cell membranes within 28 days of enteral feeding (Saker, 2002); whereas in pigs, plasma phospholipid profiles differed significantly within eight days (Murray et al, 1991). Intestinal mucosa and plasma had an altered fatty acid profile within four weeks, whereas an alteration in the fatty acid profile of skin

generally occurred after six to 12 weeks of supplementation. In dogs, however, investigators found plasma fatty acid profile changes within two weeks after the onset of omega-3 dietary supplementation (Campbell and Dorn, 1992). Thus, there may not be enough time for dietary omega-3 fatty acid therapy to affect an acute inflammatory process, depending on the affected tissue unless the fatty acids were incorporated into the patient's dietary regimen before the onset of disease. The dietary dose that favors a less inflammatory cascade during a disease process is still not standardized across veterinary patients, but is suggested as an omega-6:omega-3 fatty acid ratio ranging between 5:1 to 1:1, depending on patient assessment.

On the other hand, chronic suppression of the inflammatory and/or immune response by feeding high levels of omega-3 fatty acids should be done cautiously and is not warranted in disease states in which a fully competent immune system is essential for survival and recovery. Studies in which mice were pre-fed (two to four weeks) extremely high levels of omega-3 fatty acids (40% of calories as fish oil) compromised their resistance in an infectious disease state (Chang et al, 1992). Platelet function was significantly diminished in healthy cats fed an enriched omega-3 fatty acid food (omega-6:omega-3 ratio of 1.3:1) for eight weeks (Saker et al, 1998). As with many other nutrients, excessive levels of omega-3 fatty acids can be detrimental.

FEEDING PLAN

The feeding plan discussion assumes that the health care team has determined that the patient is a candidate for nutritional support (see History and Physical Examination section, above).

Nutrients can be supplied enterally or parenterally (**Figure 25-5**). Enteral feeding provides adequate nutrition simply and cost effectively whether done orally or by feeding tube. Enteral feeding is usually preferred to parenteral feeding because it is less expensive, stimulates the systemic and GI immune systems, helps to maintain GI mucosal integrity and avoids most metabolic complications. However, nutrients must be administered parenterally when the GI tract is inaccessible or not functioning adequately enough to meet the patient's nutrient requirements enterally. Chapter 26 covers parenteral-assisted feeding.

Enteral-assisted feeding is providing nutrients to the patient using some portion of the GI tract. Patients that cannot or will not eat but who can digest and absorb nutrients from the small intestine should receive enteral-assisted feeding. Feeding via the GI tract is often the simplest, fastest, easiest, safest, least expensive and most physiologic method of feeding patients. Prior knowledge that a patient requires other medical and surgical procedures should also be considered when formulating an enteral assisted-feeding plan. For example, feeding tubes can easily be placed at the end of a procedure requiring anesthesia or tranquilization. Feeding tube placement must consider the treatment plan and owners' expectations. Some feeding tubes can only be used when the patient is in the hospital whereas other tubes may also be used for at-home feeding.

The two methods, enteral and parenteral, are not mutually exclusive; supplementing what the patient consumes voluntarily with parenteral calories and protein infusion is possible in many veterinary practices. Therefore, overall patient assessment, including evaluating a patient's ability to eat and assimilate food, is the first step in developing a feeding plan because it dictates the route, enteral, parenteral or both, for providing assisted feeding.

The food choice should be made based on a food's key nutritional factor profile and form of the food (i.e., liquid, moist) that best accommodates the specific nutritional support feeding method. For example, if a small nasogastric feeding tube were to be used, a liquid food of appropriate viscosity and key nutrient make-up would be selected. This is an added consideration compared to developing feeding plans for patients that do not require assistance.

Select the Feeding Method

Enteral Feeding Routes

ORAL FEEDING

Several routes exist for enteral feeding, but the first attempt usually should be oral feeding. Placing a bolus of food in the proximal portion of the mouth may stimulate the swallowing reflex and, if the patient offers no resistance, is a good method as long as the patient receives enough food to meet its RER. Simple syringe feeding of a liquid product is also a good method, if tolerated. For dogs, the syringe tip is placed between the molar teeth and cheek with the head held in a normal or lowered position; for cats, the syringe tip is placed between the four canine teeth (**Box 25-4**). The patient may choose to swallow the liquid or allow it to flow from the mouth down the esophagus by gravity. Some patients refuse to swallow boluses of food; therefore, forced feeding may increase the risk of food aspiration. Oral feeding should be discontinued if the patient does not swallow food voluntarily. Appetite stimulants may be used to induce food consumption in some patients; however, voluntary food intake rarely continues and their RER is often not met (**Table 25-6**).

Orogastric tubes require placement at each feeding but may provide a useful option for one or two days of feeding. They can be used as long as there is no nasal, pharyngeal or esophageal trauma or disease. Anesthesia is not required; therefore, this route can be used in patients that are an anesthetic risk. Neonates appear to tolerate multiple daily oral tube feedings better than adults. A red rubber or polyvinyl chloride tube (8 to 24 Fr.)[b] may be used with the tip placed in either the caudal esophagus or stomach. An indwelling feeding tube is the method of choice if enteral-assisted feeding is necessary for more than two days.

Feeding through an indwelling tube is easier and less stressful on the patient than forced feeding or repeated placement of an orogastric tube. Nasoesophageal, pharyngostomy, esophagostomy, gastrostomy and enterostomy are potential placement sites. Tubes should be placed in the most proximal functioning portion of the GI tract possible by the least invasive method. The stomach should be used whenever possible.

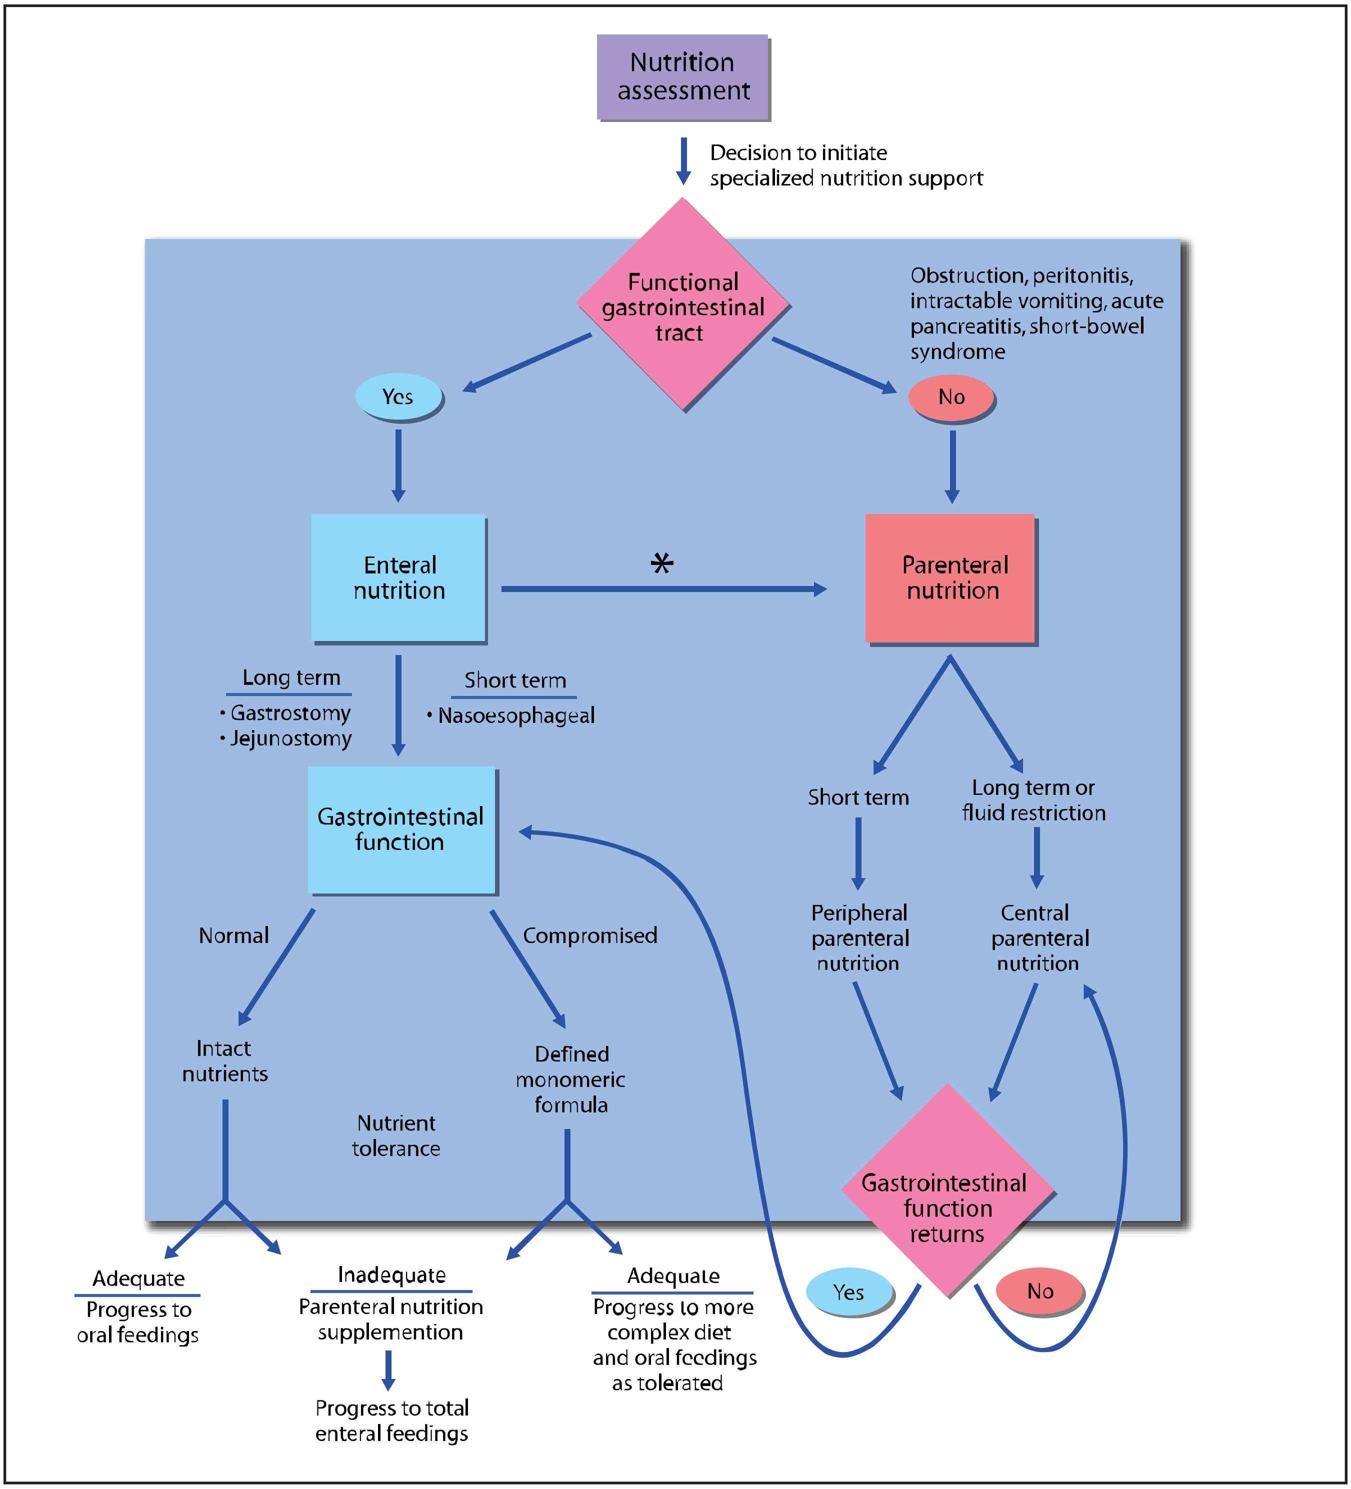

Figure 25-5. Clinical decision making algorithm for selecting the route of nutritional support. (Adapted from Hudak CM, Gallo BM, Gonce-Morton P, eds. Patient management: Gastrointestinal system. Critical Care Nursing, 7th ed. Philadelphia, PA: Lippincott, 1998; 771.)
*Nasoesophageal tube not tolerated or anesthesia not possible.

NASOESOPHAGEAL TUBES

Nasoesophageal tubes are generally used for three to seven days but are occasionally used longer (weeks, if moved to the opposite side every seven days). Polyurethane tubes (6 to 8 Fr., 90 to 100 cm) with or without a tungsten-weighted tip[c] and silicone[d] feeding tubes (3.5 to 10 Fr., 20 to 105 cm) may be placed in the caudal esophagus or stomach. The preferred placement of all tubes originating cranial to the stomach is in the caudal esophagus to minimize gastric reflux and subsequent esophagitis. An 8-Fr. tube will pass through the nasal cavity of most dogs. A 5-Fr. nasoesophageal tube is more comfortable for cats. Nasoesophageal feedings may be used in anorectic

Box 25-4. Syringe Feeding.

Patients are often fed a liquid or moist homogenized product by syringe on a short-term basis. For dogs, the syringe tip is placed between the molar teeth and cheek with the head held in a normal or lowered position (**Figure 1**). For cats, the syringe tip is placed between the four canine teeth (**Figure 2**). The patient may choose to swallow the liquid or allow it to flow down the mouth into the esophagus by gravity. Some patients refuse to swallow the liquid or food; therefore, force feeding may increase the risk of aspiration. Syringe feeding should be discontinued if the patient does not swallow food voluntarily.

Figure 1. Syringe-feeding technique for administering liquid or moist homogenized foods to dogs.

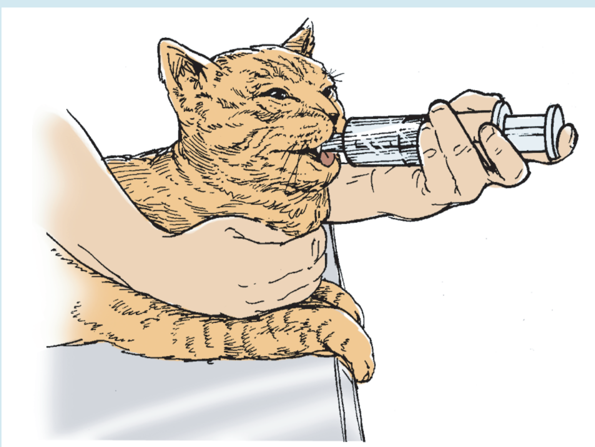

Figure 2. Syringe-feeding technique for administering liquid or moist homogenized foods to cats.

patients that do not have nasal, oral or pharyngeal disease or trauma. Anesthesia or tranquilization is not necessary to place a nasoesophageal tube, so this route provides enteral access to patients considered anesthetic risks. These tubes are most often used in the hospital, although conscientious owners can use nasoesophageal tubes at home (**Box 25-5**).

Table 25-6. Pharmacologic appetite stimulants.*

Cyproheptadine	Antihistamine and anti-serotonin effects. Dose cats at: a) 2 to 4 mg per cat per os once or twice daily, b) 2 mg per cat every 12 hours. May take up to 24 hours for a response. Give at this dosage for one week and then taper.
Diazepam	Short-lived appetite stimulant with sedative properties. Dose in cats varies: a) 0.05 to 0.15 mg/kg IV once daily to every other day or 1 mg per os once daily, b) 0.05 to 0.4 mg/kg IV, IM or per os. Eating may begin within a few seconds after IV administration. Food should be readily available.
Mirtazapine	Increases central nervous system serotonin while antagonizing serotonin activity in the GI tract. Dose cats at: 3.5 mg per cat per os every three days. May take up to 36 hours for a response.
Oxazepam	Short-lived appetite stimulant with sedative properties. Dose cats at 2 mg per cat (total dose) every 12 hours.
Prednisolone	Dose glucocorticoids at 0.25 to 0.5 mg/kg per os every day, every other day or intermittently as needed in dogs.

*Adapted from Plumb DC. Veterinary Drug Handbook, 3rd ed. White Bear, MN: Pharma Veterinary Publishing, 1999.

PHARYNGOSTOMY/ ESOPHAGOSTOMY/ GASTROSTOMY TUBES

Pharyngostomy and esophagostomy tubes (8 to 19 Fr.) may be placed in patients with disease or trauma to the nasal or oral cavity. The tip of the tube is placed in the caudal esophagus and the tube can be used for long-term (weeks to months) in-hospital or home feedings. **Boxes 25-6** and **25-7** describe pharyngostomy and esophagostomy tube placement, respectively.

For patients in which the pharynx and esophagus must be bypassed, gastrostomy tubes (mushroom-tipped, 16 to 28 Fr.)[e] can be placed either intraoperatively or percutaneously using an endoscope or a gastrostomy tube introduction device (Clary et al, 1996).[f] Gastrostomy tubes are also recommended for long-term feeding (weeks to months) if needed and have generally replaced pharyngostomy tubes, even when the esophagus is normal. Gastrostomy tubes are convenient and safe for in-hospital and at-home feedings.

There are two basic techniques for percutaneous placement of gastrostomy tubes. One technique uses an endoscope, whereas the other involves a "blind," nonendoscopic approach using a gastrostomy tube placement device or applicator. The advantages of percutaneous vs. surgical gastrostomy tube placement are ease and speed of placement, lower cost and less tissue trauma. **Boxes 25-8** through **25-10** describe these three methods of gastrostomy tube placement.

Any tube that has been placed into the esophagus or stomach allows for bolus or meal-type feeding schedules because the stomach acts as a food reservoir. Some patients, however, cannot tolerate bolus feeding into the stomach without vomiting. Such patients may benefit from a slow, continuous drip admin-

istration (by pump or gravity flow) of food into the stomach. Most veterinary patients tolerate bolus feedings of enteral nutritional support via nasoesophageal, esophagostomy or gastrostomy feeding tubes.

JEJUNOSTOMY TUBES

Jejunostomy tubes (J-tubes, 5 to 8 Fr.) are placed within the small intestine, ideally at the time of exploratory celiotomy, to bypass the proximal GI tract (Orton, 1986). J-tubes may also be placed by mini-laparotomy, or by threading a small feeding tube through a larger esophagostomy, pharyngostomy or gastrostomy feeding tube and placing the tip of the smaller tube in the jejunum (Crowe, 1986; Jergens et al, 2007). There is risk, however, that even a weighted-tip tube will be returned to the stomach by reverse peristalsis. Ideally, food should be administered through J-tubes at a slow, continuous drip delivered by a pump. Some patients, however, will tolerate frequent small-bolus feedings.

Amount to Feed and Feeding Schedule

Feeding plans require an understanding of the patient's metabolic state relative to changes in metabolism resulting from ongoing food deprivation. Estimating a patient's approximate caloric requirement is important because feeding more of any food than is necessary may cause metabolic complications. Overfeeding patients is possible through a feeding tube and should be avoided because it results in metabolic and mechanical complications. **Table 25-7** provides an example of using feeding guidelines to determine how much to feed and the feeding schedule.

The feeding schedule is often determined by the patient's ability to tolerate food and the logistics of feeding. Feeding an amount equal to the patient's RER during the first 24 hours of food reintroduction, if physically tolerated, is recommended. Feeding one-third of RER the first 24 hours and then increasing the amount by one-third every 24 hours until at RER is a more cautious approach to initial feeding, but is not always necessary. Foods should be warmed to room temperature, but not higher than body temperature, before feeding.

Food boluses must be infused slowly (over approximately one minute per 5 ml of food) to allow gastric expansion. Daily food dosage should be divided into several meals according to the expected stomach capacity. Gastric capacities for cats and dogs are typically 5 to 10 ml/kg body weight during initial food reintroduction. Maximum capacities as high as 45 to 90 ml/kg body weight have been measured in cats and dogs when fully re-alimented. Most often, the patient's RER can be met in volumes far less than these maximum gastric capacities. Salivating, gulping, retching and vomiting may occur when too much food has been infused or when the infusion rate is too fast.

Research in people has demonstrated that the stomach does not "shrink" during a prolonged fast, but rather the stretch receptors are more sensitive and stimulated by a smaller volume when refeeding occurs. Feeding should be stopped at the first sign of retching or salivating; then the meal size reduced by 50% for 24 hours and then increased by 25% gradually. Foods

Box 25-5. Nasoesophageal Tube Placement.

Nasoesophageal tubes are generally used for three to seven days, but are occasionally used longer (weeks if moved to the opposite side every seven days). Polyurethane tubes (6 to 8 Fr., 90 to 100 cm) with or without a weighted tip and silicone feeding tubes (3.5 to 10 Fr., 20 to 105 cm) may be placed in the caudal esophagus or stomach. The preferred placement of all tubes originating cranial to the stomach is in the caudal esophagus to minimize gastric reflux and subsequent esophagitis. An 8-Fr. tube will pass through the nasal cavity of most dogs; a 5- Fr. tube is more comfortable for cats.

The length of tube to be inserted is determined by measuring from the nasal planum along the side of the animal to the caudal margin of the last rib (**Figure 1**) and marking the tube at a point that is approximately three-fourths of the total measured length with a piece of adhesive tape or an indelible marker. This mark is how far the tube should be inserted. Tape will also provide a tab to secure the tube. The animal's nose is desensitized by placing a few drops of topical anesthetic (2% lidocaine or 0.5% proparacaine) into a nostril and tilting the head upward for a few seconds. The tip of the tube is lubricated with a water-soluble lubricant or 2 to 5% lidocaine ointment/jelly before passage.

To pass the tube, direct the tip in a caudoventral, medial direction into the ventrolateral aspect of the external nares. The head is generally held in a normal static position. As soon as the tip of the catheter reaches the medial septum at the floor of the nasal cavity in dogs, the external nares are pushed dorsally, which opens the ventral meatus, ensuring passage of the tube into the oropharynx (**Figure 2**). To aid passage, the proximal end of the tube is lifted as the nose is pushed upward (**Figure 2**). In cats, because of the lack of a well-developed alar fold, the tube can be inserted initially in a ventromedial direction and continued directly into the oropharynx. The tube is inserted until the adhesive tape tab or indelible mark is reached (**Figure 3**).

To evaluate proper tube placement, 3 to 15 ml of sterile water or saline solution may be injected through the tube and the animal evaluated for coughing (**Figure 4**). A lateral radiograph may be taken of the neck to confirm the tube is placed in the caudal esophagus (i.e., over the larynx). After confirmation of position, the tube is secured with either sutures or glue. The first tape tab is secured to the skin just lateral to the external nares. A second tape tab is secured to the skin on the dorsal nasal midline, just rostral to the level of the eyes. An Elizabethan collar is used in most animals to prevent inadvertent removal of the tube (**Figure 5**).

Complications of nasoesophageal intubation include epistaxis, lack of tolerance of the procedure and inadvertent removal of the tube by the animal. Incidence of tube removal by the animal has been reported to be as high as 50% even with use of collars. Nasoesophageal tubes should not be used in vomiting patients or those with respiratory disease.

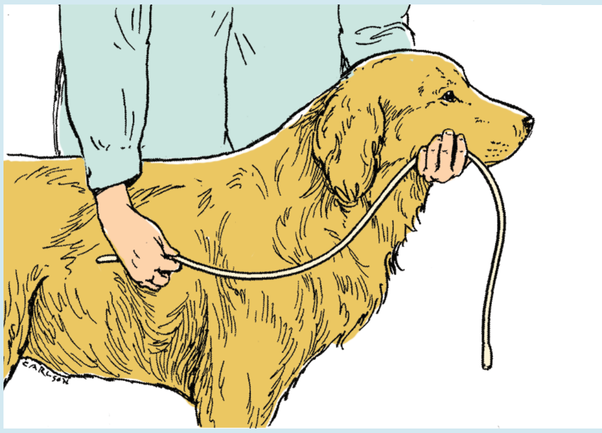

Figure 1. The length of tube to insert is determined by measuring from the nose to the last rib. Marking the tube at three-quarters of the distance between the last rib and the nose will place the end of the tube in the caudal esophagus. This location is marked with an indelible marker or a piece of adhesive tape. Tape can also serve as a suture tab to secure the tube.

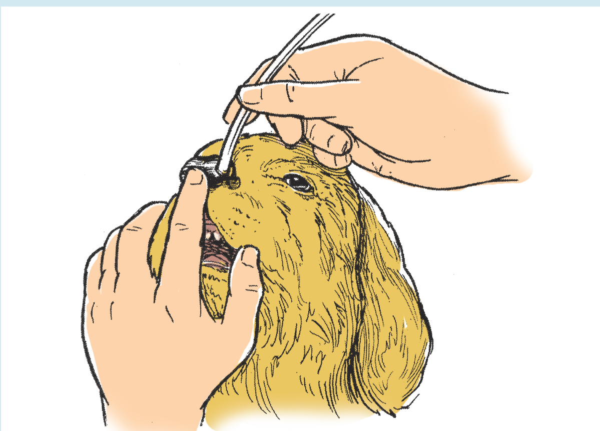

Figure 2. The external nares are pushed dorsally and the proximal end of the tube is lifted to facilitate passage of the tube into the ventral nasal meatus.

Figure 3. The tube is inserted until the indelible mark or adhesive tape tab is reached. Sutures or glue are used to secure the tape tab to the skin.

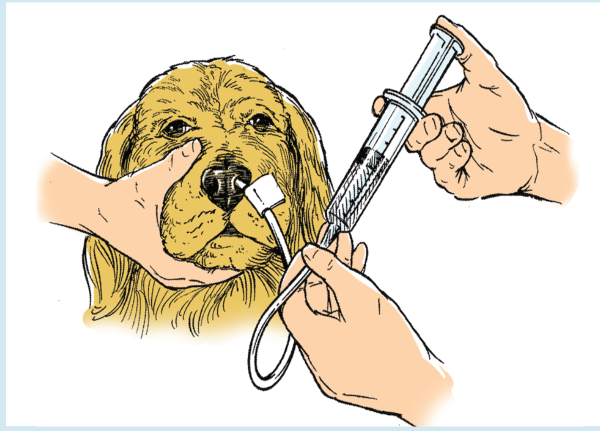

Figure 4. A test injection of sterile water or saline solution is made to ensure proper tube placement.

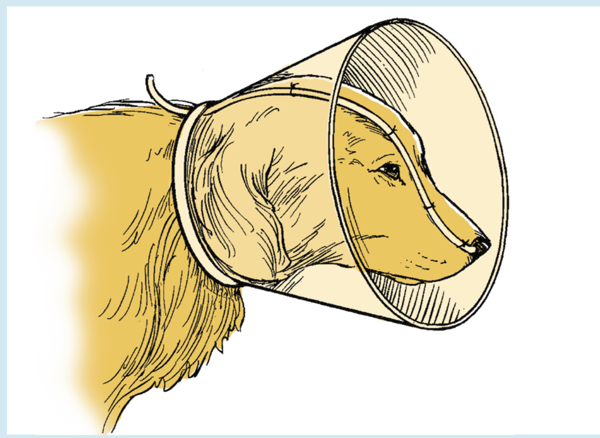

Figure 5. Securing the tube at several locations by suturing or gluing tape tabs to the skin and applying collars will help decrease inadvertent removal of the tube by the animal.

Box 25-6. Pharyngostomy Tube Placement.

In some instances, a pharyngostomy tube is used to bypass the nose and mouth of an animal requiring nutritional support (e.g., in cases of facial trauma) or when nasoesophageal tubes are not tolerated. Pharyngostomy tubes have been largely replaced by esophagostomy tubes or gastrostomy tubes placed percutaneously.

The patient is anesthetized, intubated and positioned in lateral recumbency. The area caudal to the mandible on either side is prepared for aseptic surgery. A 14- to 18-Fr. polyvinylchloride tube is premeasured as described in **Box 25-5, Figure 1**, except that the tube exit site will be caudal to the mandible.

With the mouth held open with a speculum, palpate the hyoid apparatus with one finger. The tube exit site must be carefully planned to avoid interfering with laryngeal opening and epiglottic movement. The tube should exit as far caudally and dorsally along the lateral pharyngeal wall as possible. The finger inside the mouth locates the hyoid apparatus and protrudes from the pharyngeal wall laterally at the selected exit site (**Figure 1**). Alternatively, forceps can be used to bulge the pharyngeal wall laterally. The finger locates the pulsating carotid artery, ensuring that it will be avoided, while providing a target for the tunneling forceps. A 1-cm skin incision is made over the bulging pharyngeal wall. Long, curved forceps are used to bluntly tunnel caudally through the tissues from outside to inside. Blunt dissection prevents injury to nearby nerves, carotid artery and jugular vein. Forceps are used to grasp one end of the feeding tube so it exits through the dissection site while the other end is advanced down the esophagus (**Figure 2**). The tube is then secured to the skin with tape and sutures.

Complications include airway obstruction, tube displacement, damage to cervical nerves and blood vessels and infection at the exit site. Placing the tube exit site caudal to the hyoid apparatus or use of very large diameter tubes is much more likely to result in airway obstruction or aspiration (**Figure 3**). The animal should be observed frequently for signs of respiratory embarrassment as it recovers from anesthesia. Frequent inspection and cleansing of the tube entrance/exit site help prevent skin infection. These tubes should not be used in vomiting patients or those with respiratory disease.

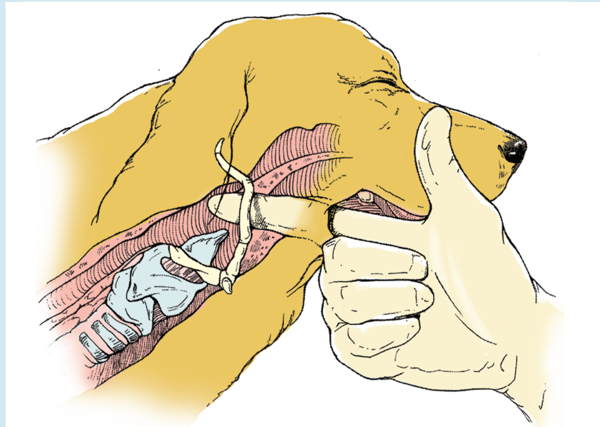

Figure 1. A finger is used to find the optimal exit site for the pharyngostomy tube. The tube should exit the pharyngeal wall as far caudally and dorsally as possible.

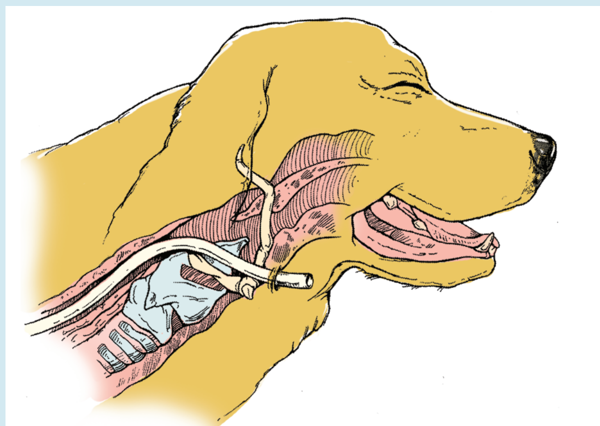

Figure 2. Proper placement of a pharyngostomy tube with the tube exiting dorsal and caudal to the larynx.

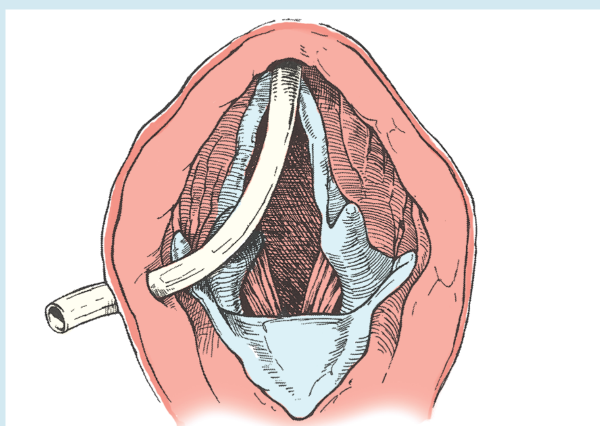

Figure 3. Inappropriate positioning of a pharyngostomy tube, as depicted here, causes the tube to course over the laryngeal opening and to interfere with movement of the epiglottis. This placement can lead to serious airway obstruction. The tube should exit the pharyngeal wall as far caudally and dorsally as possible.

Box 25-7. Esophagostomy Tube Placement.

Several techniques have been described for mid-cervical placement of esophagostomy tubes in dogs and cats. The animal receives light general anesthesia for esophagostomy tube placement. The entire lateral cervical region from the ventral midline to near the dorsal midline is clipped and aseptically prepared for surgery.

In one technique, appropriately sized, curved Kelly, Carmalt or similar forceps are inserted into the pharynx and then into the proximal cervical esophagus. The tip of the forceps is turned laterally and pressure is applied in an outward direction, thereby tenting up the cervical tissue so that the instrument tip can be seen and palpated externally. A small skin incision, just large enough to accommodate the feeding tube, is made over the tip of the forceps. In small dogs and cats, the tip of the forceps is forced bluntly through the esophagus. In larger dogs, a deeper incision is made to allow passage of the tip of the forceps through the esophagus. Tube sizes 12- to 19-Fr. are generally used. The tube is premeasured as described in **Box 25-5, Figure 1** so that the distal tip resides in the mid to caudal esophagus. The distal tip of the tube is grasped with forceps, pulled into the esophagus and out through the mouth, turned around and redirected into the esophagus. The tube is then secured with tape and sutures. A light circumferential bandage containing antibiotic-impregnated gauze is then placed at the exit site.

Another technique uses a percutaneous feeding tube applicator (ELD Gastrostomy Tube Applicator) (**Figure 1**).

Reported complications of tube esophagostomy for nutritional support include tube displacement due to vomiting or scratching by the animal and skin infection around the exit site.

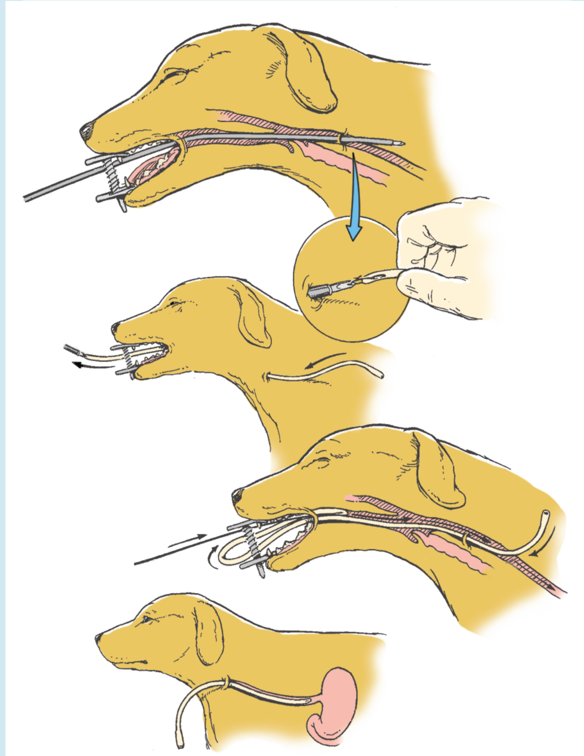

Figure 1. Insertion of a percutaneous feeding tube applicator into the mid-cervical esophagus. The distal tip is palpated and an incision is made through the skin and subcutaneous tissue over the tip of the applicator. The trocar is advanced through the esophageal wall and directed through the incision. The distal end of the feeding tube is secured to the eyelet of the trocar with suture material. The applicator and attached feeding tube are retracted into the esophagus and out the mouth. The feeding tube is redirected into the esophagus for final placement. A wire stylet can be inserted into the feeding tube if necessary to ease placement in the esophagus.

provided by J-tubes must be infused slowly and often in either very small quantities or preferably by a slow gravity drip or enteral pump with an hourly rate equal to RER/24 hours because the jejunum is volume sensitive.

Each bolus-fed meal must be followed by a water flush to clear the feeding tube of food residue. When the patient is volume sensitive, it is important to know the minimum volume required to effectively flush the tube. The patient's daily fluid requirement must also be met and additional water may be administered through the feeding tube to meet that requirement. Liquid oral medications may also be administered easily through feeding tubes. Plugged feeding tubes can be cleared by filling the tube with water or a nonalcoholic carbonated beverage and allowing time for the food plug to dissolve. End-port tubes are usually easier to maintain because food tends to become trapped in the blind end of side-port tubes. All tubes except orogastric and nasoesophageal tubes require standard every-other-day bandage care.

Assess and Select the Food

Selecting a food for hospitalized patients requires complete knowledge of the case, and often the food needs to be individually tailored because of each patient's unique circumstances. Refeeding patients in the early phase vs. refeeding in the later phases of food deprivation dictates the proportion of fat and carbohydrate in the refeeding formula. For example, the refeeding formula for a patient that has not eaten in seven days or more should contain predominantly fat as the energy fuel, as opposed to higher levels of carbohydrate (e.g., glucose). Pancreatitis patients, in which high-fat foods are contraindicated for dogs and presumably for cats, would be exceptions. In these cases, consider foods providing lower fat, low to moderate carbohydrate and increased protein calories. The food selection process should include a comparison of the key nutritional factor content of the food to the recommended levels. **Tables 25-8** and **25-9** list selected foods for assisted feeding and compares them to the recommended levels of key nutritional factors for dogs and cats, respectively.

Pre-existing conditions requiring specific nutritional modifications (e.g., renal insufficiency) or dietary modifications (e.g., adverse reactions to foods) must be understood and incorporated into selecting a food for the patient. For example, a cat diag-

Box 25-8. Surgical Gastrostomy Tube Placement.

A limited left flank celiotomy for gastrostomy tube placement provides an alternative when endoscopic or blind gastrostomy techniques are not performed. A gastrostomy tube may also be inserted when a celiotomy is performed for other reasons. General anesthesia is administered and the left flank is aseptically prepared for surgery. The prepared left paracostal area is draped and a 2- to 3-cm incision is made through the skin and subcutaneous tissue. The incision is made just caudal and parallel to the last rib, with its dorsal limit just below the ventral edge of the paravertebral epaxial musculature. The incision should be extended ventrally so that the intraperitoneal rather than the retroperitoneal space is accessed. The incision should be long enough to permit insertion of one or two fingers and a tissue forceps.

The greater curvature of the stomach is located and an Allis or Babcock tissue forceps is used to grasp and exteriorize the stomach through the incision. A stomach tube may be passed by an assistant and the stomach dilated with 10 to 15 ml of air/kg body weight if difficulty is encountered locating the stomach. Exteriorizing the stomach through a small flank incision can be difficult, especially in larger, deep-chested canine breeds. The left lateral aspect of the gastric body or the caudal aspect of the fundus is selected for the ostomy site. Two pursestring sutures are placed around the selected ostomy site (**Figure 1**). A stab incision is made through the ostomy site, the tube is inserted into the stomach and the pursestring sutures are tied snugly. Tube sizes 14 to 28 Fr. can be inserted.

The tube may exit the body wall through a separate stab wound or the original incision. The stomach is then fixed to the abdominal wall where the tube enters the peritoneum using a continuous suture pattern circling the gastrostomy tube placement (**Figure 2**). After the gastropexy sutures are placed, gentle traction is applied to the external end of the tube to ensure the stomach is adjacent to the abdominal wall (**Figure 3**). A rubber flange, which is slid down the tube to rest lightly against the skin, is sutured to the skin to secure the tube in place.

Potential risks with this procedure are the same as with any celiotomy and include wound infection, peritonitis and dehiscence. Pressure necrosis of the stomach may also occur if excessive tension is placed on the pursestring sutures. Wrapping the intraperitoneal tube with the omentum should contain leakage to a localized site. A layer of greater omentum can also be placed over the ostomy site before the stab incision is made into the stomach.

Percutaneous gastrostomy tube placement with gastropexy using a large-bore stiff plastic stomach tube has also been described. This technique is less invasive than the technique described here and may be more convenient for some veterinary practitioners.

Figure 1. Two full-thickness pursestring sutures are placed concentrically around the selected gastrostomy site to help invert the stomach around the tube. A stab incision is made in the center of the suture pattern for tube placement.

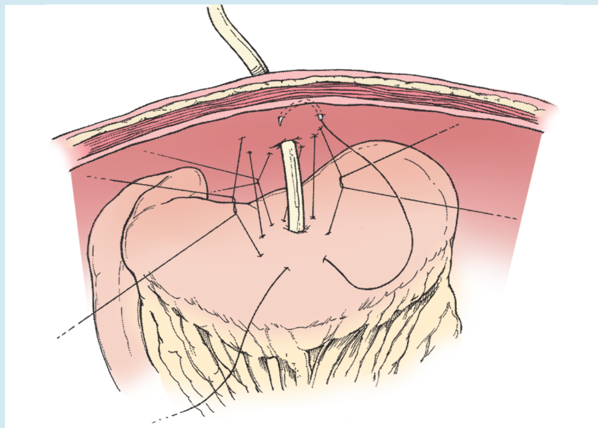

Figure 2. The stomach is sutured to the abdominal wall with four preplaced mattress sutures (or a simple continuous pattern). These sutures should include the strong abdominal fascia and the gastric submucosa. Tightening the loops brings the gastric serosa and omentum snugly in contact with the peritoneum.

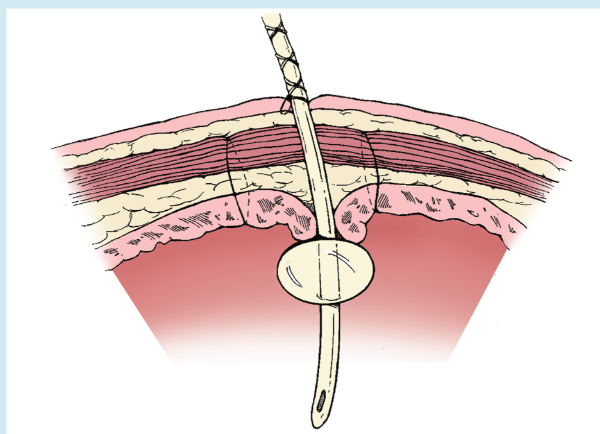

Figure 3. A mushroom-tip Pezzer catheter or one with an inflatable bulb is placed in the stomach. After the gastropexy sutures are placed, gentle traction is applied on the external end of the tube to ensure this area of the stomach is adjacent to the abdominal wall.

nosed with colitis that has a history of chronic renal insufficiency will require a feeding plan compatible with both diseases. Alternatively, the patient may be fed the food it was accustomed to eating before the injury or illness. The latter approach reduces the number of food changes that ultimately will need to be made.

Food selection will also depend on tube size and location within the GI tract, the availability and cost of products and the experience of the clinician. Commercial foods available for enteral use in veterinary patients can be divided into two major types: 1) liquid or modular products and 2) blended pet foods. Nasal and jejunostomy tubes usually have a small diameter (<8 Fr.), which requires use of liquid foods. Orogastric, pharyngostomy, esophagostomy and gastrostomy tubes have large diameters (>8 Fr.) and are suitable for blended pet foods.

Liquid Foods and Modules

Liquid foods consist of two basic types: 1) elemental or monomeric and 2) polymeric. Commercially available foods defined as "elemental" are not truly elemental, but contain nutrients in small hydrolyzed absorbable forms and are best described as monomeric. Protein requirements are usually met by free amino acids, dipeptides or tripeptides or larger hydrolyzed protein fractions. The fat source is often an oil of mixed (medium- and long-chain) fatty acids and the carbohydrate sources are mono-, di- and trisaccharides. Several liquid enteral feeding products on the human medical market are positioned as monomeric or hydrolyzed foods. They range between 270 to 550 mOsm/l and vary in protein and fat content based on the disease-specific formulation. These monomeric products are homogenized liquids that can be fed through any feeding tube including a J-tube. Monomeric foods are indicated in disease conditions such as inflammatory bowel disease, lymphangiectasia, refeeding parvoviral enteritis and pancreatitis cases and any other condition in which a patient's digestive capabilities are impaired. Most human liquid foods are adequate for adult dogs but are too low in protein for cats, puppies and adult dogs with increased protein losses (e.g., protein-losing enteropathies, drains). Most human liquid enteral products do not contain adequate concentrations of protein, taurine, arginine and arachidonic acid for long-term feeding of cats.

Polymeric products contain mixtures of more complex (less refined) nutrients. Protein is supplied in the form of large peptides (e.g., casein or whey). Carbohydrates are usually supplied as cornstarch or syrup, and fats are provided by medium-chain triglycerides (MCT) or vegetable oil. These foods require normal digestive function and are appropriate for most veterinary clinical situations, especially when a small tube (<8 Fr.) has been placed. In comparison to the rather vast selection of human polymeric diets, diets formulated for small animal veterinary patients are limited. Currently there are two liquid polymeric veterinary foods[g,h] that meet the current AAFCO nutrient allowances for adult dogs and cats. They are homogenized liquids providing between 1 to 1.25 kcal/ml, and one of these products[g] contains supplemental glutamine and carnitine.

Table 25-7. Example using enteral-assisted feeding guidelines.

Patient data needed	**Canine patient example**
1. Current body weight	12 kg
2. Calculate resting energy requirement (RER) as kcal/day	451 kcal/day
3. Expected daily fluid volume in ml/kg/day	60 ml/kg
4. Size (Fr.) and volume capacity of feeding tube	18-Fr., E-tube (10-ml volume)
Food information needed:	
Determine the caloric density of the food or food blend. Liquid foods have a set caloric density (kcal/ml) provided on the product information sheet. Moist foods need to be blended with a liquid (water or liquid food) to make a gruel (food blend) that can be delivered through a feeding tube or syringe.	
1. Determine gruel caloric density:	
Identify kcal per can of food	569 kcal/12.7 oz. can
Calculate ml/can (XX oz. in can x 30 ml/oz.); assumes 30 ml/weight/oz.	12.7 oz. x 30 = 383 ml
Determine ml of fluid needed to blend with canned food	100 ml warm water
Determine caloric density of fluid if not water*	–
Calculate caloric density of food blend. kcal/ml = (total kcal ÷ total ml)	569 ÷ (383 + 100) = 1.2 kcal/ml
2. Determine water provided in food or food blend:	
Calculate water in canned food (ml x % moisture); 75% moisture in canned food obtained from product information sheet	383 x 75% = 287 ml
Calculate water in liquid if not water**	–
Calculate % water in blend (ml total water ÷ total ml)	(287 + 100) ÷ 483 = 79%
3. Provide a feeding protocol:	
Method of food delivery (bolus feeding or constant rate infusion)	bolus
Beginning feeding rate (x % of RER)	25% RER
Daily caloric intake goal (kcal/day)***	113 kcal/day
Daily feeding rate	–
Calculate amount (kcal/day ÷ kcal/ml of food blend)	113 kcal ÷ 1.2 kcal/ml = 94 ml food blend/day
Determine meals/day (per 24 hr)	4
Determine feeding dosage (ml/meal/day)	94 ml ÷ 4 meals = 24 ml/meal; therefore, 24 ml q6hr
Water provided by food or food blend/day (ml)	94 ml x 79% = 74 ml water
Flush required after food delivery (ml)	4 x 10 ml flush = 40 ml water
Additional water needed to meet daily fluid volume (daily requirement = 60 ml/kg)	720 ml/day – (74 + 40) = 606 ml
Provide guidelines for residuals (see text)	–
Provide monitoring guidelines (see text)	–
Tube maintenance and removal guidelines (see text)	–

*If blending the canned food with a commercial liquid food, these foods provide a caloric density greater than 0. Determine the liquid food's caloric density and plug it into the top half of the equation. The caloric density can range between 0.8 to 1.9 kcal/ml depending on the commercial product.

**Every liquid food is part solids and part water, find this information about the product and calculate the absolute water contribution to the food blend, or assume the liquid food to be 100% water, if moisture content is 90% or greater.

***Increase this rate as tolerated by the patient or with a feeding goal to meet the patient's RER by Day 2 or 3.

Box 25-9. Percutaneous Endoscopic Gastrostomy Tubes.

Percutaneous endoscopic gastrostomy (PEG) tubes are inserted with the aid of general anesthesia. The patient is placed in right lateral recumbency and an area of the left flank extending 4 to 6 inches caudal to the last rib is surgically prepared. **Figures 1** to **7** describe tube placement technique in detail. Landmarks for feeding tube placement are usually 1 to 2 cm caudal to the last rib and one-third the distance from the ventral border of the epaxial musculature to the ventral midline. Commercial PEG catheter assembly kits, ranging in size from 16 to 28 Fr., are now available for small animal patients and provide cost-effective, convenient materials for PEG tube placement (**Figure 4**).

Following insertion, the tube is usually incorporated into a light bandage, with the free end brought to a convenient position for feeding. PEG tubes should be left in place for a minimum of five to seven days. Firm adhesions between the gastric serosa and the peritoneum have been reported to form within 36 to 48 hours of PEG tube placement in healthy dogs but do not reliably form in healthy cats. Adhesion formation may also be variable in undernourished animals.

The stomach should be empty when the tube is removed. Sedation or anesthesia is not generally required for tube extraction. Tubes are removed by exerting firm traction on the tube, while simultaneously applying counter-pressure around the exit site (**Figure 8**). An alternative method of removal, suitable for dogs weighing more than 10 kg, is to cut the catheter off flush with the skin, leaving the catheter tip to be passed in the feces. The resulting gastrocutaneous fistula usually heals rapidly.

Complications of PEG tube placement include vomiting, peristomal skin infection, cellulitis and pressure necrosis at the tube exit site.

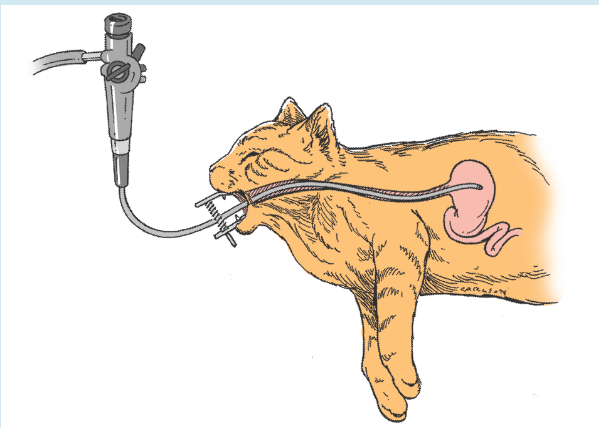

Figure 1. The animal is positioned in right lateral recumbency and an endoscope is introduced. The stomach is insufflated with air so that the gastric wall comes in contact with the body wall and the spleen is displaced caudally.

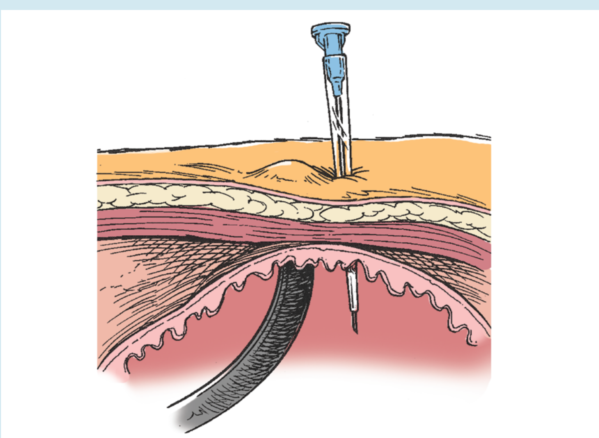

Figure 2. The lighted tip of the endoscope will be seen pressing outward against the abdominal wall. A large-bore needle or over-the-needle intravenous catheter is inserted into the stomach adjacent to the endoscope tip.

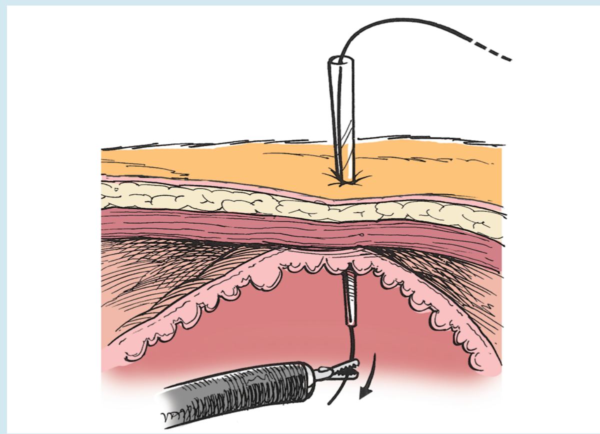

Figure 3. Nylon suture is advanced through the needle or catheter until it can be grasped with endoscopic retrieval forceps. The suture material is pulled out through the mouth as the endoscope is withdrawn.

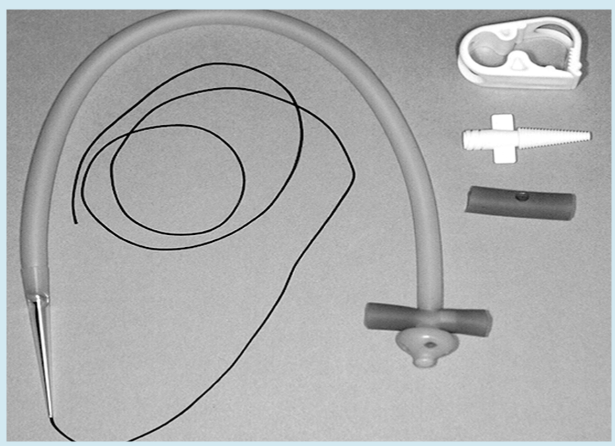

Figure 4. Commercial PEG catheter assembly kits provide the most convenient materials for PEG tube placement. The catheter guide is already secured to the free end of the feeding tube in commercial kits.

These products are usually accepted better than human liquid products containing MCT oil. In most critical care veterinary cases, these liquid foods are the best option currently available in North America when small-diameter nasogastric and jejunostomy feeding tubes have been placed, or when continuous drip feedings are necessary.

Liquid milk replacer products are generally inappropriate to feed to adult dogs and cats because they typically contain some lactose, have high (>300 mOsm/l) osmolarity and some are low in caloric density (<1.0 kcal/ml), which can result in RER constraints due to volume limitations.

Module products are concentrated powdered or liquid forms of nutrients and are primarily supplemental (**Table 25-10**). These products may be added to a liquid product to increase the concentration of a specific nutrient. Protein, fat and carbohydrate modules (e.g., casein powder, vegetable oil or corn syrup) are available. For example, a modular protein product may be added to a human liquid product for a patient with a high protein requirement. A vegetable oil or menhaden-fish oil can be added to increase omega-6 and/or omega-3 fatty acids. Soluble fiber (e.g., psyllium husk fiber or pectin) can be added to modular products, but requires greater than an 8-Fr. tube due to the increased viscosity of the food.

Blended Pet Foods

The term blended pet foods refers to commercial products that are nutritionally complete and balanced according to AAFCO allowances for dogs and cats. Moist veterinary therapeutic foods are available with nutrient profiles that assist in the management of various disease conditions in dogs and cats. Requirements for all other nutrients need not be calculated when the food contains non-energy nutrients properly balanced to the caloric density of the product. When the patient consumes the proper amount of a balanced food, all other

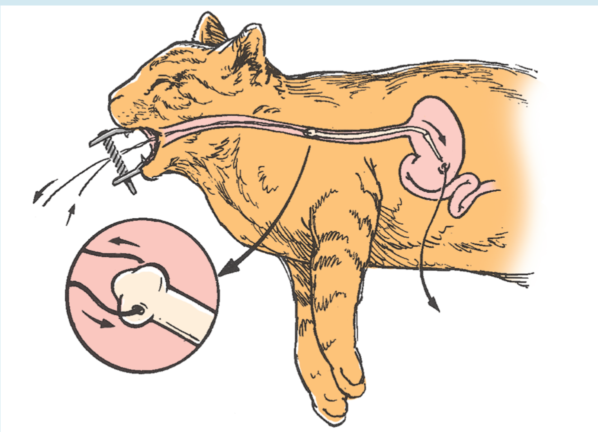

Figure 5. The lubricated catheter is drawn down the esophagus as the suture exiting the body wall is pulled. A second “safety” suture is placed through the openings in the mushroom-tip feeding tube (insert) and exits the mouth. This safety suture is used to retrieve the feeding tube from the stomach if problems occur during the placement procedure.

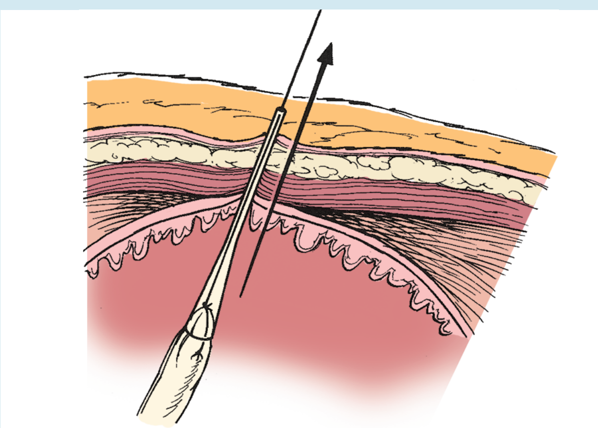

Figure 6. Resistance will be encountered when the catheter tip guide contacts the body wall. Steady traction and firm application of counter-pressure to the body wall will allow the guide tip to emerge through the skin (arrow). A small skin incision (2 to 3 mm) at the point of exit may help.

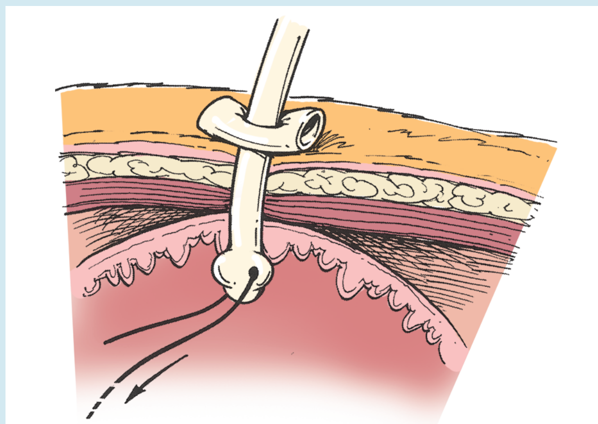

Figure 7. Gentle traction is used to bring the stomach and abdominal wall into loose contact. A rubber flange is fitted down the tube and a piece of tape attached to prevent tube slippage. The tube is not usually sutured or glued to the skin. The safety suture is removed via the mouth (arrow) after the feeding tube is secured.

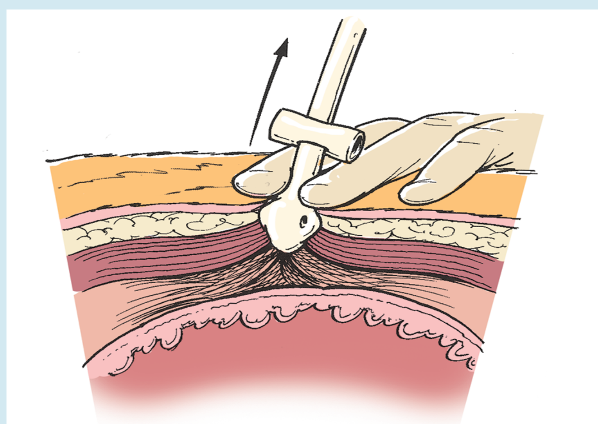

Figure 8. PEG tubes are usually removed by traction. The mushroom tip will usually collapse as it pulls through the abdominal wall. The resulting gastrocutaneous fistula usually heals rapidly.

Box 25-10. Percutaneous Nonendoscopic Gastrostomy Tubes.

Percutaneous gastrostomy techniques have been developed to allow convenient, cost-effective placement of feeding tubes without relying on availability of relatively expensive endoscopes. One nonendoscopic technique uses a commercial feeding tube applicator device (**Figure 1**) as described in **Box 25-7**. The other nonendoscopic technique uses a commercial gastrostomy tube placement device (**Figure 2**) pressed against the stomach wall. Use of either device allows suture material to be placed through the body wall into the stomach and retrieved through the mouth, and a gastrostomy tube to be inserted as described for PEG tube placement.

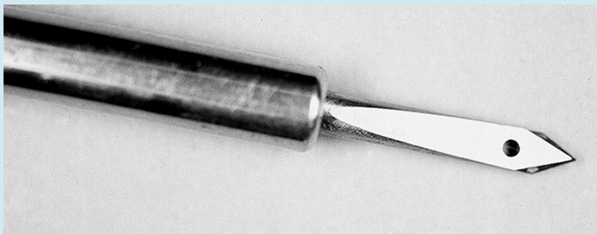

Figure 1. A commercial gastrostomy tube applicator can be used for percutaneous nonendoscopic gastrostomy tube placement in dogs and cats. The rigid outer tube encloses a trocar that can be pushed through the stomach and abdominal wall. A suture is placed through the small hole in the trocar tip, pulled into the stomach and then pulled antegrade out through the mouth. See **Box 25-7**, **Figure 1** for use of this device in esophagostomy tube placement.

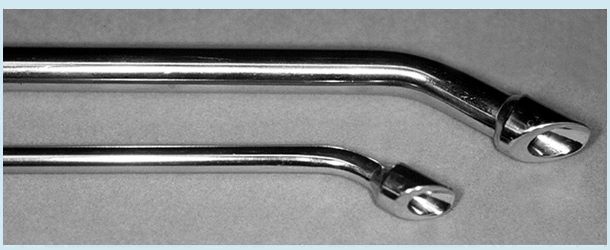

Figure 2. Commercial gastrostomy tube placement devices in various lengths and diameters can be used for percutaneous nonendoscopic gastrostomy tube placement in dogs and cats.

nutrient needs have been met, except when known losses of particular nutrients occur (e.g., protein and electrolytes).

Commercial products used as blended pet foods should provide complete and balanced nutrition for dogs or cats and should have passed AAFCO or equivalent feeding trials. These products are more readily available, better tolerated and less expensive than the human liquid foods. These pet food products contain essential amino acids and micronutrients properly balanced to the caloric density of the food. Fewer medical complications (e.g., diarrhea, hyperglycemia) are likely to result with blended pet foods. However, blended products are more likely to plug the feeding tube if the tube is not properly flushed after feeding and/or the blend is not of appropriate consistency to flow through the feeding tube. Patients may later consume the pet food orally, eliminating a food change when the patient's appetite returns and the tube has been removed. Blended pet foods, particularly the "recovery," "growth" or "performance" type foods, are appropriate for patients in catabolic states that are using fat and protein substrates from body stores.

These foods can be blended with a liquid to form a diet with a consistency that flows easily through a feeding tube. Some products have a blended texture, a high water content and very small particle size and may not need to be mixed with water or can easily be mixed with water depending on the size of the feeding tube. Most moist pet foods must be mechanically blenderized with water (or an appropriate liquid food) and strained to produce slurries or gruels that are administered through medium- and large-bore feeding tubes (i.e., 14 Fr. or larger). **Table 25-11** summarizes food blends commonly used for critical care tube feeding of feline and canine patients. Examples of patients that may benefit from these blended therapeutic formulas include those with renal or hepatic insufficiencies, diabetes mellitus, hyperlipidemia, pancreatitis, congestive heart disease and severe trauma. Appropriate moist foods are listed in the respective disease chapters.

Human Baby Foods

Some canine and feline patients voluntarily eat human baby foods packed in jars. In general, the meat and/or egg baby foods are high in protein (30 to 70% DM) and fat (20 to 60% DM), which, at the lower end of these ranges compares favorably with blended pet food products used for patients with increased protein and calorie needs. However, baby foods that provide upwards of 45% DM protein and 35% DM fat exceed the upper limits of veterinary critical care foods and would have little clinical value. Additionally, baby foods contain only one or two food types (protein, protein/grain) and do not contain a balanced mixture of other essential nutrients (amino acids, vitamins and minerals). For example, these products contain only 10% of the calcium required by dogs and cats and, therefore, have a large inverse calcium-phosphorus ratio. Some products contain onion powder, which can cause Heinz body formation in cats (Robertson et al, 1997). The human and veterinary liquid products have a better nutritional profile for feline and canine patients than do the human baby food products.

REASSESSMENT

Regular reassessment is a critical step in successful nutritional management of hospitalized patients, regardless of whether the enteral route, the parenteral route or both are used. Malnutrition in the form of insufficient nutrient intake to support tissue metabolism undermines medical and/or surgical management of a case. Malnutrition is far more common in veterinary patients than is currently recognized. Patients resting in a cage have been mistakenly assumed to require little or no nutrition when, in fact, the nutrient costs of tissue repair,

immunocompetence and drug metabolism are significant. Therefore, reassessment of nutritional status is important whether the patient remains in the hospital or recovers at home.

Monitoring Parameters

Food intake or administration of nutritional support for hospitalized patients should be reviewed at least daily. Body weight should be recorded daily. Body condition should be noted; however, a patient's BCS is unlikely to change during the course of a hospital stay. Laboratory assessments specific for patients receiving nutritional support are generally not necessary beyond those tests already routinely performed for critically ill patients. The most common alterations that occur in laboratory parameters associated with nutrient administration are decreases in serum potassium, phosphate and magnesium levels, increases in serum glucose concentrations and hyperlipidemia. Even apparently stable patients might develop metabolic complications as a result of ongoing disease processes or from undiagnosed subclinical disease states. However, most patients show subjective improvement in attitude within 36 hours of refeeding.

Most parameters used to assess the nutritional status of patients will not change as a result of assisted feeding during the course of hospitalization. Laboratory parameters (e.g., albumin and total protein concentrations, RBC count and hemoglobin content) are unlikely to change in less than two weeks. Perhaps laboratory parameters that change during a hospital stay as a result of assisted feeding may be detected when acute-phase proteins with half-lives between two and 12 hours can be measured reliably in dogs and cats. The patient's body weight and condition and some laboratory parameters (albumin and total protein concentrations) should improve over the course of weeks (McAdams et al, 1996).

Residual Volume

Despite the numerous benefits of initiating enteral nutrition to hospitalized patients soon after admission, many critically ill patients are frequently intolerant of intragastric feeding due to GI motility dysfunction. The incidence of intolerance in human ICU settings is 43 to 63%, with the development of high gastric residual volumes accounting for 30 to 51% of cases (MacLaren et al, 2008). Although undocumented for veterinary patients, high gastric residual volume due to decreased GI motility is commonly encountered when refeeding. Adverse consequences for the patient include underfeeding needed calories, possible aspiration, increased mortality and prolonged hospital stay. Current therapeutic approaches for managing elevated gastric residual volumes involve administration of a prokinetic agent, alteration of the enteral feeding regimen (i.e., decreased volume, increased frequency, switch from intragastric to postpyloric site), or initiation of parenteral nutrition support. To maximize enteral support and limit complications associated with gastric residuals, measure the residual volume before each bolus tube feeding and intermittently during CRI feeding, then adjust the feeding schedule accordingly. Based on clinical experience, the authors suggest these

guidelines for monitoring residual fluid volumes:

1. Before a scheduled food delivery, attach an appropriate size syringe to the end of the feeding tube. Gently aspirate with the syringe. If more than 20 ml/kg body weight is aspirated, discard that fluid and/or place some portion of that fluid back into the tube and skip that scheduled tube feeding. If less than 20 ml/kg body weight is aspirated, proceed with the scheduled feeding.
2. If a feeding needs to be skipped due to high residual fluid volume, recheck residual volume just before the next scheduled feeding. If less than 20 ml/kg body weight is aspirated, proceed with food delivery at the predetermined volume or at a lesser volume. Slowly work back up to the daily RER feeding amount.
3. If a feeding needs to be skipped due to high residual fluid volume and the next recheck for residual volume yields more than 20 ml/kg body weight, consider diagnostics to evaluate and/or prokinetic agents to manage the GI dysmotility. Consider alternative approaches to nutritional support for the patient.
4. Check the residual fluid volume every 12 to 24 hours when using CRI.

Changing Foods

Sometimes, the patient only needs a specific therapeutic formula for a short time and then may be fed its regular food. Changing from a therapeutic formula to an over-the-counter brand may also be done according to the short schedule in Table 1-1. Should a problem such as vomiting, diarrhea or food refusal occur, the last successful food mixture should be

offered for several more days before proceeding with the food change. Most pets undergo food changes with few or no detectable GI disturbances.

SUMMARY

- The major consequences of malnutrition in all patients are decreased immunocompetence, decreased tissue synthesis and repair and altered drug metabolism.
- A nutritional assessment includes a patient history, a diet history, a physical examination with special attention given to certain risk factors, body condition scoring and laboratory tests.
- Patients with a history of nausea, vomiting and diarrhea are at increased risk for malnutrition because nutrient intake and/or usage has been suboptimal for some time before admission.
- Animals use body carbohydrate, fat and protein stores to maintain blood glucose concentrations throughout the course of food deprivation, trying to maintain vital functions for as long as possible. The proportion of each stored component used varies over the course of food deprivation.
- The adaptation from the fed to the fasting state is one in which fuel use by the patient shifts from primarily a mixture of fuels to one in which the primary fuels are glycerol and fatty acids (fat).
- An understanding of the metabolic changes that occur during simple starvation is essential to understanding the underlying metabolic alterations present during anorexia with concurrent illness.
- Major electrolyte and acid-base abnormalities and blood glucose levels should be corrected or near normal before instituting either enteral or parenteral nutritional support.
- A practical goal is to begin nutritional support within 24 hours of hospitalization for the injury or illness.
- Patients with a suspected or documented food intake less than their calculated daily RER for more than three days are candidates for assisted feeding.
- The optimal target feeding for hospitalized patients is their calculated RER, realizing their actual energy requirement is likely to change over the course of the disease process through the recovery period.
- Nutritional support by an enteral, parenteral or a combination method should initially deliver sufficient calories to meet the patient's RER at its current weight, adjusted for protein and body condition. To begin feeding patients at RER is a rational and safe estimate that decreases the probability of metabolic complications.

Parenteral-Assisted Feeding

Rebecca L. Remillard
Korinn E. Saker

"When the facts change, I change my mind. What do you do?"
John Maynard Keynes

CLINICAL IMPORTANCE

Parenteral nutrition (PN) is valuable in meeting a patient's daily resting energy and amino acid requirements. In veterinary medicine, clinicians attempt to meet the patient's estimated resting energy requirement (RER) and most immediate requirements for essential amino and fatty acids, and selected water-soluble vitamins, electrolytes (macro) and trace minerals. PN does not consistently limit disease activity in patients and therefore is an adjunct (not a primary) therapy. PN support in veterinary patients may prevent nutrient deficiencies, preserve lean body mass and support the functional capacity of most body organs when nutrient intakes fall below requirements. The overriding rationale and criteria for using PN in veterinary patients is to treat subclinical undernutrition due to three or more days of decreased appetite and to avoid the development of clinical undernutrition resulting from insufficient energy intake in the face of increased energy needs (ASPEN, 2002). **Box 26-1** describes PN nomenclature.

Patient selection is very important to the successful use of PN support. Patients with impairment of the small intestine that is unlikely to resolve within three days are candidates for PN support. PN can be used initially to meet energy and amino acid requirements for cases in which enteral access cannot be safely acquired for several days. Depending on patient size, it may not be cost effective to use PN as a method of assisted feeding for less than a three-day course. There is a substantial startup cost to preparing the parenteral solution. The procedure becomes cost effective when the cost is spread over several days or more than one patient.

There is evidence that 48 to 72 hours are required to reverse a catabolic state and begin anabolism (Zeiderman et al, 1989; Wernerman et al, 1986). Thus, proper patient selection mandates that the patient be hospitalized for at least three days because instituting PN for only one or two days is of questionable cost benefit. However, when PN is done in conjunction with enteral feeding, a course shorter than three days may be cost effective and provide nutritional benefit. PN support should not begin until the patient is hemodynamically stable and electrolyte and acid-base abnormalities, severe tachycardia, hypotension and volume deficits have been corrected (**Table 26-1**).

There are many published lists of diseases, disorders and case examples in which PN could or should be instituted. The number and type of veterinary patients that would benefit from PN is greatly expanded; however, if the goal in assisted feeding is to deliver the patient's energy and amino acid needs daily by any means (Remillard and Thatcher, 1989). Parenteral administration of nutrients has value in patients with inflammatory (small and large) bowel disease, parvoviral enteritis and other causes of impaired gastrointestinal (GI) motility, peritonitis, pancreatitis, intestinal lymphosarcoma and short-bowel syndrome (small bowel resection). Neurologic patients and those that are comatose or receiving large doses of pain-control medications that

Box 26-1. Nomenclature.

The term "parenteral nutrition (PN)" indicates administration of nutrients in a manner other than through the gastrointestinal (GI) tract. PN could therefore be administration by intravenous, intramuscular, subcutaneous, intraosseous or intraperitoneal routes. PN has been further characterized in human medicine as total or partial (relative to meeting all nutrient requirements) and central or peripheral (relative to venous access). A common misnomer associated with PN, originally from the human literature, is the term "hyperalimentation." This term incorrectly implies the administration of nutrients via the GI tract in excess of need. The term "parenteral nutrition" is used throughout this text because it simply and accurately identifies a general method of administering nutrients to a patient.

Another common misnomer is total parenteral nutrition (TPN). In veterinary medicine, PN is not total because there is no immediate need to meet all the amino and fatty acid, fat- and water-soluble vitamin and macro, trace and ultra-trace element requirements as there is in people dependent on PN for years.

There are several valid reasons why partial PN, rather than TPN, is used in veterinary medicine. The foremost reason is the comparatively short period PN is administered to animals (three to 14 days for animals vs. weeks to years in people). In people, long-term feeding implies 10 days or longer. The shorter time frame of assisted feeding of pets allows omission of less immediately essential nutrients (e.g., fat-soluble vitamins). Until there is a demand by pet owners for a longer period of support (weeks to months), PN support in animals will remain cost effective by providing only the most immediately essential nutrients (i.e., electrolytes, energy and amino acids).

Only some of the nutrients needed by animals are readily available in water-soluble form for PN solutions. Some water-soluble nutrients are available as multiple single nutrients in specially prepared water-insoluble products. Such nutrients (vitamins A and E) are cost prohibitive and difficult to justify on a short-term basis. As more nutrient preparations are added to PN solutions, the risk for incompatibility and formation of insoluble precipitates increases. PN solutions currently used in veterinary medicine contain only the less expensive essential nutrients. PN solutions are therefore limited by necessity, pharmacokinetics, cost and current nutritional knowledge.

Table 26-1. Patient criteria for administration of parenteral nutrition.

1. The patient is hemodynamically stable and major electrolyte and acid-base abnormalities, severe tachycardia, hypotension and volume deficits have been corrected.
2. Actual or anticipated food intake is less than calculated resting energy requirement for more than three days.
3. Concurrent small intestinal disorder is known or suspected to be present, or a safe enteral nutritional access cannot be established.
4. The patient is expected to be hospitalized for at least the next three days.

cause lateral recumbency with questionable swallowing reflexes and/or risk of aspiration when oral or tube feedings are attempted also benefit from PN. PN has been used successfully in complicated cases of feline hepatic lipidosis, in patients with facial fractures, pneumonia, lung lobe torsion or contusion and diaphragmatic hernias, and in other patients that are poor anesthetic risks.

PN can be administered until patients are more stable and can tolerate placement of a feeding tube. Septic and anemic patients and those with severe upper respiratory infections that cause persistently poor appetites may benefit from PN. Sometimes PN support may be as simple as augmenting oral intake with intravenous lipids to meet RER. Patients with a poor appetite that also have large heat and/or protein losses (e.g., continuous-suction chest or abdominal drains, large areas of skin loss due to burns, degloving injuries) benefit from PN in addition to voluntary oral food intake.

The goal of assisted feeding is to provide adequate nutrition to meet the patient's RER. The logistics of that support should be determined on a case-by-case basis. The guidelines presented here are to help establish a foundation. But never underestimate the need for attentiveness, initiative and ingenuity in meeting the patient's nutritional needs; no two cases are alike.

Because enteral nutrition and PN are often used in conjunction, the reader may want to refer to Chapter 25 for information about:

- Consequences of malnutrition
- Patient assessment, including physiologic state and history of malnutrition
- Anorexia, cachexia and accommodation
- Metabolic changes through days of starvation (simple starvation and disease states)
- Key nutritional and other factors.

PARENTERAL PRODUCTS

Compounding a PN solution is beyond the scope of most veterinary practices; however, most veterinary practices can administer PN to patients. Individual dextrose, lipid and amino acid solutions can be combined as a "three-in-one" solution, also called a total nutrient admixture (TNA). TNA in veterinary medicine refers to one fluid bag containing a sufficient mixture of parenteral solutions to meet a particular patient's fluid, energy, amino acid, electrolyte and B-vitamin needs for a 24-hour period. This is a very convenient method requiring only one bag, one infusion pump and one administration set. Any opaque liquid infusion pump can be used. The formulation is designed specifically for the patient based on its current RER, daily fluid and electrolyte requirements, approximate protein need and ability to handle dextrose vs. lipid.

The TNA solution should be calculated to first meet the patient's RER and protein needs with essential water-soluble vitamins and trace mineral products (if available). The total fluid volume should then be adjusted with a standard crystal-

Table 26-2. Standard total nutrient admixture (TNA) formulations.

PART A. CALCULATION WORKSHEET	
Patient data needed	**Feline example**
1. Current body weight in kg	4.1 kg
2. Calculate resting energy requirement (RER) as kcal/day	200 kcal/day
3. Expected fluid volume in ml/kg/day	70 ml/kg
4. Calories from fat as a percent	80%
5. Protein-calorie ratio as g/100 kcal RER	4 g/100 kcal RER
6. Potassium concentration as mEq/l	30 mEq/l
Parenteral solution formula	
1. Determine volume of fat and dextrose needed daily	
Calculate RER calories from fat	200 x 0.80 = 160 kcal
Calculate volume of 20% lipid needed	160 kcal ÷ 2 kcal/ml = **80 ml/day**
Calculate RER calories from dextrose	200 - 160 = 40 kcal
Calculate volume of 50% dextrose needed	40 kcal ÷ 1.7 kcal/ml = **24 ml/day**
2. Determine volume of amino acid solution needed daily	
Calculate g of protein needed	RER x 4 g/100 kcal = 8 g protein/day
Calculate volume of 8.5% amino acid needed	8 g ÷ 0.085 g/ml = **94 ml/day**
3. Determine volume of B vitamins and trace minerals needed daily	
Calculate B vitamins needed	RER x 1 ml/100 kcal = **2 ml/day**
Calculate trace minerals needed	RER x 1 ml/100 kcal = **2 ml/day**
Daily parenteral nutrition formula	80 ml of 20% lipid emulsion 24 ml of 50% dextrose 94 ml of 8.5% amino acid with electrolytes 2 ml of vitamin-B complex 2 ml of trace elements **Total = 202 ml**
4. Determine volume of crystalloid solution needed to meet daily fluid requirement	
Daily fluid volume requested	4.1 kg x 70 ml/kg = 287 ml/day
Volume required is daily total – PN total	287 – 202 = 85 ml
5. Determine phosphorus supplementation	
Phosphorus from amino acids	94 x 30 mM/l = 2.8 mM
Desired final phosphorus concentration in the TNA	= 10 mM/l x 287 ml = 2.9 mM (no phosphorus is needed)
6. Determine potassium supplementation	
K^+ from lactated Ringer's solution	85 ml x 4 mEq/l = 0.3 mEq
K^+ from amino acid solution	94 ml x 60 mEq/l = 5.6 mEq
Total K^+ in TNA solution	0.3 mEq + 5.6 mEq = 5.9 mEq
Desired final K^+ concentration in TNA	30 mEq/l x 287 ml = 8.6 mEq
KCl (2.0 mEq/ml) required	8.6 mEq – 5.9 mEq = 2.7 mEq ÷ 2.0 = 1.4 ml
PART B. FELINE FORMULA EXAMPLE	
Animal data	
Body weight	4.1 kg
RER	200 kcal/day
Calories from fat	80%
Calories from glucose	20%
Protein-calorie ratio	4 g/100 kcal (adequate for most cats)
Fluid volume	70 ml/kg (maintenance fluid volume)
Potassium concentration	30 mEq/l
Parenteral solution	
50% dextrose	24 ml providing 41 kcal
20% lipid emulsion	80 ml providing 160 kcal
8.5% amino acids with electrolytes	94 ml providing 8 g of amino acids
Potassium chloride	1.4 ml
Vitamin-B complex	2 ml
Trace elements	2 ml
Lactated Ringer's solution	85 ml
Total fluid volume	288 ml
This final solution is a 500-ml bag containing 200 kcal (80% from fat), adequate nitrogen, major B vitamins with the following electrolyte profile	
Sodium	61.6 mEq/l
Potassium	29.5 mEq/l
Magnesium	3.3 mEq/l
Phosphorus	9.8 mM/l
Chloride	55.4 mEq/l
Calcium	0.8 mEq/l
Zinc	2 mg
Copper	1 mg
Manganese	0.2 mg

Table 26-2 continued

Chromium	8 mg
Final osmolarity	768
Approximate cost = $100 per day	
PART C. CANINE FORMULA EXAMPLE	
Animal data	
Body weight	14 kg
RER	507 kcal/day
Calories from fat	90%
Calories from glucose	10%
Protein-calorie ratio	3 g/100 kcal
Fluid volume	70 ml/kg
Potassium concentration	20 mEq/l
Parenteral solution	
50% dextrose	30 ml providing 51 kcal
20% lipid emulsion	227 ml providing 454 kcal
8.5% amino acids with electrolytes	176 ml providing 15 g of amino acids
Potassium phosphate	1.4 ml
Vitamin-B complex	5 ml
Trace elements	5 ml
NormaSol R	543 ml
Total fluid volume	987 ml
This final solution is a 1-liter bag containing 507 kcal (90% from fat), adequate nitrogen, major B vitamins with the following electrolyte profile	
Sodium	88.0 mEq/l
Potassium	20.3 mEq/l
Magnesium	3.5 mEq/l
Phosphorus	9.9 mM/l
Chloride	65.5 mEq/l
Calcium	0 mEq/l
Zinc	5 mg
Copper	2 mg
Chromium	20 mg
Manganese	0.5 mg
Final osmolarity	523 mOsm/l
Approximate cost = $100 per day	

loid solution (e.g., lactated Ringer's solution, Plasmalyte A) to meet the patient's daily fluid requirement. Then electrolytes are adjusted, if necessary (**Table 26-2**). Alternatively, crystalloid fluids with added potassium may be administered by a separate intravenous line piggybacked into the same catheter.

Energy Solutions

A TNA solution should supply sufficient energy to meet, but not exceed, the patient's daily RER. Negative consequences of PN administration (i.e., metabolic complications) are often due to administering energy in excess of the patient's expenditure (Deitel et al, 1983; Chang and Silvis, 1974; VA Study Group, 1991; Lippert et al, 1993). Early PN solutions for people contained dextrose and "liberal" amounts of protein. These solutions were administered at rates providing 3,000 to 5,000 kcal/day (12.55 to 20.92 MJ) to a 70-kg person (Solomon and Kirby, 1990). This "hyperalimentation" actually increased catabolism by exceeding the patients' endogenous usage of energy and produced multiple adverse metabolic effects. Human patients are given 1,000 to 2,400 kcal (4.2 to 10 MJ) with 75 to 100 g of protein per day with fewer metabolic complications (Woolfson, 1983). Currently, people are fed at RER instead of RER times a disease factor (McMahon, 1993; Forse, 1995; DeBiasse and Wilmore, 1994). Energy is routinely provided to veterinary patients receiving PN as a combination of dextrose and lipid. Several companies manufacture dextrose and lipid products of various strengths and attributes (**Table 26-3**). Most TNA solutions formulated for veterinary patients use 50% dextrose and 20% lipid. Dextrose solutions range from 2.5 to 70% glucose, which is usually derived from hydrolyzed cornstarch. Osmolarity ranges from 126 to 3,530 mOsm/l and is directly proportional to the glucose concentration (AHFS Drug Information, 1997). Dextrose solutions are maintained in the pH range of 3.5 to 5.5 and are sterilized by autoclave to prolong shelf life at room temperature.

Lipid (10, 20 or 30%) products (**Table 26-3**) contain emulsified fat particles (0.5 mm) of soybean oil and/or safflower oil, glycerin and linoleic and linolenic acids. Earlier formulations made with cottonseed oil were taken off the market in 1965 because they caused severe adverse reactions in people. Lipid emulsions are maintained in a pH range of 6.0 to 8.9 and have an osmolarity range of 260 to 310 mOsm/l, which effectively decreases the final osmolarity of the TNA (AHFS Drug Information, 1997). Dextrose and lipids are readily available and both are strongly recommended as sources of energy in a TNA solution.

Table 26-3. Nutritional comparison of parenteral products.

Products	Caloric density (kcal/ml)	Osmolarity (mOsm/l)	Amino acids (g/100 ml)	Fat (g/100 ml)	Carbohydrate (g/100 ml)	Electrolytes (kcal/ml)	Comments
Amino acids 8.5% without electrolytes	na	785-860	8.5	0	0	Few	Contains all essential amino acids except taurine, nitrogen 1.3 g/100 ml, pH 5.3-6.5, available in 500- and 1,000-ml sizes.
Amino acids 8.5% with electrolytes	na	1,160	8.5	0	0	Yes	Contains all essential amino acids except taurine, nitrogen 1.3 g/100 ml, pH 5.3-6.5, electrolytes Na, K, Mg, Cl, PO_4, available in 500- and 1,000-ml sizes.
ProcalAmine	0.25	735	3	0	3	Yes	Contains 3% glycerol and 3% amino acids, nitrogen 4.6 g/1,000 ml, pH 6.5-7.0, electrolytes Na, K, Mg, Cl, PO_4, available in 500- and 1,000-ml sizes. Contains 13 nonprotein kcal/ml and 22.5 g amino acids/100 nonprotein kcal as is. Mix 775 ml ProcalAmine with 300 ml 20% lipid to get 1,075 ml of a 3.2 g protein/100 nonprotein kcal solution.
Lipid 10%	1.1	268	0	10	0	No	Contains soybean and/or safflower oil, glycerin, linoleic and linolenic acids, egg yolk as phospholipid emulsifier, pH 6.0-8.9, available in 50-, 100-, 250- and 500-ml sizes.
Lipid 20%	2	268	0	20	0	No	Contains soybean and/or safflower oil, glycerin, linoleic and linolenic acids, egg yolk as phospholipid emulsifier, pH 6.0-8.9, available in 50-, 100-, 250- and 500-ml sizes.
Dextrose 2.5-70%	0.09-2.4	126-3,535	0	0	2.5-70	No	Contains hydrolyzed (various) cornstarch, pH 3.5-5.5, available in 50- and 500-ml sizes.

Key: na = not available.

Dextrose-Fat Ratio

When PN is begun, most patients have not consumed their daily RER for at least three days, and are more likely even further along in the course of food deprivation (Day 5 or more). The proportion of glucose to lipid in the PN solution should mirror the current metabolic condition of the liver. Fewer metabolic complications will arise if the liver tolerates the glucose-lipid ratio in the PN solution.

PN is rarely instituted during the early phases of food deprivation (fewer than three days of anorexia); however, if PN is indicated, canine patients should tolerate a moderate percentage of their calculated RER as dextrose. For example, dogs in

Box 26-2. Complications of Fat Administration.

LIVER PATHOLOGY

Administering parenteral total nutrient admixture (TNA) solutions to human adults and infants for long periods (weeks to months) has been reported to cause steatosis, intrahepatic cholestasis, periportal inflammation and even cirrhosis. Fatty infiltration of the liver is the earliest and most common change noted. This undesirable relationship between long-term parenteral feeding and hepatic changes is thought to be multifactorial, but is not yet well understood. These complications are not specific to parenteral nutrition (PN) or lipid emulsions. Lipid additions are now encouraged, even in patients with hepatic disease, because replacing a portion of the glucose with lipid ameliorates some hepatic pathology. Choline is not routinely included in TNA solutions but is a conditionally essential nutrient in people. Studies have correlated choline deficiency and hepatic steatosis in people receiving total parenteral nutrition (TPN). Investigators studying TPN-fed rats reported reversal of hepatic complications with both oral and intravenous choline administration. Today, it is extremely rare for a veterinary patient to receive a PN solution for more than two or three weeks; therefore, hepatic complications from prolonged PN administration are unlikely, although choline is an essential nutrient in dogs and cats.

COAGULOPATHIES AND THROMBOCYTOPENIA

Lipid infusions have been reported to cause fat overload syndrome in people and, in the past, were associated with hyperlipidemia, hemolytic anemia, coagulopathies, thrombocytopenia and respiratory impairment with liver and renal dysfunction. Most adverse reports were associated with the use of a cottonseed oil emulsion, which was withdrawn from the market in the 1960s. Only isolated cases have been reported to occur with the soybean or safflower oil emulsions used today, and no cases have been associated with the relatively limited use of medium-chain triglyceride (MCT) emulsions. Thrombocytopenia has been reported as a rare complication of soybean oil emulsions and is now considered an idiosyncratic reaction. In vitro, lipids have a limited effect on shortening prothrombin times, but this effect may be due to the phospholipids or vitamin K in emulsions. Reduced aggregation of platelets has also been produced in vitro and at high triglyceride concentrations. It is important to emphasize that slow continuous infusion of lipids has little or no effect on platelet numbers, aggregation or bleeding time. Fat infusion rates for people have been recommended at 0.10 to 0.15 g/kg body weight/hour. Infusing veterinary patients with PN solutions containing 80 to 90% of nonprotein calories as lipid over a 24-hour period is usually within these guidelines.

ALTERED IMMUNE FUNCTION

Lipid infusions have also been associated with altered and impaired immune function. Major controversies exist about the role lipid emulsions play in affecting reticuloendothelial cells and eicosanoid, cytokine and complement synthesis. Many of these effects have not been observed with slow infusion of pure soybean oil or during rapid infusion of MCT emulsions. One review of many studies concluded there was no evidence supporting the opinion that lipid infusions detrimentally alter immune function.

The Bibliography for **Box 26-2** can be found at www.markmorris.org.

the early phase of food deprivation maintain blood glucose levels by glycogenolysis and therefore should receive 60 to 90% of the RER as dextrose. However, feline patients in the early phases of food deprivation maintain blood glucose levels by lipolysis and gluconeogenesis, and should receive 60 to 90% of their RER from lipid.

By Day 5 of food deprivation or longer, patients should receive the majority (60 to 90%) of their calculated RER as lipid because the liver is using glycerol from endogenous fat for gluconeogenesis. Giving high doses of glucose at a time when the patient's natural metabolic response is to minimize glucose usage is unlikely to result in optimal glucose use. This is the most likely cause of hyperglycemia. There is evidence to suggest the proportion of calories needed from fat increases greatly (>60%) in starving and diseased states. For example, in an acute sepsis model, rats given a fat-free glucose solution parenterally had increased and extensive mobilization of endogenous fat. Control, nonseptic rats had no mobilization of endogenous fat when a high glucose solution was given (Stein, 1986). A measurable shift in the preferred fuel (from glucose to endogenous fat) occurred in these septic patients. In people, fat is well oxidized in the septic state, and as the sepsis worsens the amount of fat oxidized increases and the glucose oxidative capacity decreases (Stoner et al, 1983). Dogs with a septic abdomen receiving PN with both glucose and lipid maintained nitrogen balance better than dogs receiving glucose-only PN solutions (Iriyama et al, 1985).

The optimal caloric source is a mixture of glucose and fat; however, the precise ratio is unknown (Stein, 1986). A mixed fuel source should decrease the possibility of fat deposition in the liver when any metabolic pathway that handles either fat or glucose becomes overloaded. Studies have shown that serum glucose, lactate, pyruvate, free fatty acid, triglyceride and insulin concentrations were more stable and more closely approximated the normal postabsorptive state in people when all three substrates were administered (i.e., simultaneous lipid infusion with glucose and amino acids), as opposed to fat-free PN solutions (MacFie et al, 1991). The old recommendation that fat should not compose more than 4 g/kg body weight/day or 60% of the calories has been perpetuated many times.[a] Over the last decade or so, the recommended proportion of calories from fat supplied to burn victims has progressively increased from 5 to 15 to 50%. Furthermore, higher proportions of fat calories (75 to 80%) have been recommended in other disease states (Nordenstrom et al, 1983; Chiarelli et al, 1994; Deitel and Kaminsky, 1974).

The negative effects of high-fat infusions have included reports of liver pathology, coagulopathies, thrombocytopenia,

Table 26-4. Advantages to administering a high fat total nutrient admixture (TNA) solution.

1. The liver is metabolically geared for lipolysis and preferentially uses fat as a source of calories. Therefore, supplying a high-fat solution accommodates that profile, spares endogenous fat stores and does not raise insulin levels.*
2. The osmolarity of the fat solution is 260 mOsm/l and can be administered by peripheral catheter. Fat included in a TNA solution decreases the final osmolarity:

80% calories from 50% dextrose and 20% calories from 20% lipid	= 862 mOsm/l**
20% calories from 50% dextrose and 80% calories from 20% lipid	= 535 mOsm/l**
5% dextrose and lactated Ringer's solution	= 525 mOsm/l
Blood or plasma	= ~300 mOsm/l

3. The pH of the final TNA solution that includes fat is closer to 7.0 than solutions of dextrose and amino acids excluding fat, thus imposing less of an acid load.
4. Patients with compromised pulmonary function are prone to developing respiratory acidosis when given solutions containing a high dextrose concentration. High-fat solutions produce less carbon dioxide to be expelled than high dextrose solutions.***

altered immune function, atherosclerosis and the overall unknown effect of synthetic chylomicrons on blood vessels when administered to people for more than 10 days. These adverse effects occurred in people and other animals during high infusion rates in which lipids were provided in excess of energy need (Klein and Miles, 1994; Mashima, 1979; Meguid et al, 1984; Adamkin et al, 1984). In addition, some of the products used in these studies are no longer available (**Box 26-2**).

To date, there appears to be little in the veterinary literature documenting why lipids could not or should not provide more than 60% of a dog's or cat's RER. In fact, when central venous access is limited and the patient requires fluid therapy at or below maintenance rates, administering a lipid emulsion by peripheral access (providing 100% of the caloric intake as fat) is well tolerated. The use of solutions containing high-fat concentrations (60 to 90%) has gained a wider acceptance with fewer complications as compared to those containing high-glucose concentrations. PN may be successfully administered to ferrets and rabbits using the same overall guidelines. No unusual metabolic or hematologic complications have been associated with these infusions (**Table 26-4**).

Unlike patients in earlier reports, most patients receiving high-fat solutions today do not develop hyperglycemia, based on regular urine glucose checks (VA Study Group, 1991; Lippert et al, 1993). Glycemia is better controlled in patients with diabetes mellitus, pancreatitis and septicemia when a TNA solution is used that provides most of the calories as fat. A TNA solution with 80% fat calories contains 1 to 3% dextrose. Intravenous infusion of a lipid emulsion routinely increases plasma triglyceride levels transiently. However, this should not be considered a true hyperlipidemia because most patients can clear these chylomicron-size lipid particles within 30 minutes. The half-life of chylomicrons in the plasma of dogs from either diet or intravenous infusion of soybean oil and safflower oil emulsions ranges from seven to 16 minutes (Edgren and Meng, 1962; Kesterson, 1978). Therefore, it is sometimes necessary to turn off the TNA infusion pump 20 to 30 minutes before blood is drawn if hyperlipidemia is a problem. Lipid from the TNA solution does interfere with certain serum biochemistry tests (Chapter 28).

The PN guidelines for people state that the role of intravenous artificial lipid emulsions in influencing the course of pancreatitis is not defined. Lipid emulsions are safely used in hyperlipidemic people when serum triglyceride concentrations remain below 400 mg/dl (ASPEN, 2002). PN solutions containing a lipid portion do not stimulate the pancreas (Konturek et al, 1979; Kelly and Nahrwold, 1976; Edelman and Valenzuela, 1983) and should be implemented when enteral nutrition is not tolerated (ASPEN, 2002). Most people tolerate glucose- and lipid-based formulas well because hypertriglyceridemia-induced pancreatitis is rare unless serum concentrations exceed 1,000 mg/dl (Silberman et al, 1982). PN administration without lipid emulsions beyond two weeks is not advised because of the risk for developing essential fatty acid deficiency. There are no similar data available for dogs or cats; however, patients with hypertriglyceridemia and/or pancreatitis have routinely received a high-fat TNA at their RER with no additional problems.[b]

Protein Solutions

Patients must receive a source of essential and nonessential amino acids. Solutions are available containing 3.5 to 15% amino acids. These solutions are maintained in the pH range of 5.3 to 6.5, have an osmolarity between 300 and 1,400 mOsm/l and may contain various combinations of electrolytes and/or dextrose (AHFS Drug Information, 1997). Modified formulas are available with disproportionate concentrations of branched-chained vs. aromatic amino acids. These formulas are designed for patients with renal or liver failure or multiple trauma, but have not been widely used in veterinary medicine due to expense. The most commonly used product in veterinary medicine is the conventional 8.5% amino acid solution either with or without electrolytes (**Table 26-3**). Most amino acid solutions contain all the essential amino acids for dogs and cats, except

taurine. However, some specialized pediatric amino acid products contain taurine.

Protein should be provided to the patient within a ratio of 1 to 6 g protein/100 kcal of nonprotein energy provided. Adult dogs and cats do well on 2 to 3 g/100 kcal and 3 to 4 g/100 kcal, respectively. Ferrets should receive protein intakes similar to those for cats (4 to 5 g protein/100 kcal), whereas rabbits should receive lower protein intakes (1 to 2 g protein/100 kcal). The lower protein-calorie ratios are recommended for patients with renal or hepatic insufficiency. The higher protein intakes are recommended for patients with increased protein needs (e.g., albumin losses, chest-tube drains). The exact protein intake for each patient cannot be determined prospectively but may have a significant effect on outcome. Postoperative patients receiving 1 g amino acids/kg body weight parenterally had less negative nitrogen balance and greater transferrin concentrations and lymphocyte counts compared with people receiving an isocaloric intake of calories as glucose without amino acids (Hwang et al, 1993). Therefore, the ratios recommended here should be used as guidelines only. A reasonable estimate of a patient's protein needs should be made, the patient's response to that particular protein intake should be monitored and the intake should be adjusted accordingly. Patients are rarely azotemic due to PN administration when amino acids are provided within these protein-energy ratios and a product is used that provides mostly essential amino acids.

There are some combination amino acid/glycerin products that provide amino acids and an energy source in a fixed ratio (**Table 26-3**). Some of these combinations are provided as a two-compartment bag with dextrose and amino acid solutions separated by a breakable divider. Most of these prepackaged dextrose/amino-acid mixes contain very high protein-calorie ratios and do not contain fat.

Electrolyte Solutions

The more common electrolyte abnormalities associated with PN occur with the major intracellular cation potassium and the anion phosphorus. Potassium and phosphorus rapidly move intracellularly with refeeding by either enteral or parenteral methods or with the administration of glucose or insulin (Forrester and Moreland, 1989). Potassium moves intracellularly when acidosis is corrected or when insulin is released. A TNA solution composed of 8.5% amino acids with electrolytes and lactated Ringer's solution contains approximately 12 mEq potassium/l, which is inadequate to maintain normal serum potassium levels. Potassium can be added to the PN solution using either a 2 mEq/ml potassium chloride solution or a 4.4 mEq/ml potassium phosphate solution.

If the patient is normokalemic when PN is initiated, 30 to 40 mEq potassium/l will usually maintain normokalemia. However, if the patient is hypokalemic when PN is started, 40 or more mEq potassium/l will be required. If the patient is hyperkalemic when PN is initiated, no additional potassium is recommended; however, serum potassium concentrations should be monitored daily. Administration of crystalloid solutions containing potassium by a second intravenous line is a convenient method of regulating serum potassium levels in difficult cases.

Phosphorus moves intracellularly with refeeding because of increased production of high-energy phosphate compounds (Hardy and Adams, 1989). Patients receiving PN rarely become hypophosphatemic. Sufficient quantities of phosphorus (10 mM/l) appear to be available in the TNA from lipid (15 mM/l) and amino acid/electrolyte (30 mM/l) solutions. However, adding a potassium phosphate solution containing 4.4 mEq potassium and 3 mM phosphorus/ml will increase the potassium and phosphorus content of the TNA. In cases of hyperphosphatemia, the quantity of amino acids, electrolytes and fat must be reduced to decrease phosphate concentrations in the TNA. Alternatively, an amino acid solution without electrolytes and potassium chloride can be used.

Vitamin Solutions

Very few veterinary patients receiving PN have a demonstrable need for fat-soluble vitamins unless there is a history of prolonged weight loss, inappetence and decreased fat absorption (diarrhea/steatorrhea). Dogs and cats usually have sufficient body stores of vitamins A, D, E, K and B_{12} to last several weeks to months if there is no increased demand or losses. Fat-soluble vitamin supplementation is warranted in cases with a history of long-term fat malabsorption (months). One-time administration of 1 ml of a vitamin A, D and E product,[c] divided into two intramuscular sites, is simple, cost effective and supplies fat-soluble vitamins for about three months. Vitamin K_1 injections (3 to 5 mg/cat, b.i.d., subcutaneously) reportedly improved abnormal coagulation times in cases of severe idiopathic hepatic lipidosis (Center, 1995, 1996). Most disease states are associated with increased oxidative stress and free radical-induced cell damage. Administering a PN solution with a high lipid concentration may provide nutritional support, but is also an oxide-rich nutrient source. Early work indicated patients administered highly oxidative nutrient solutions (lipids) may benefit from receiving the antioxidant d-α-tocopherol (24 to 48 IU/g lipid) (Becvarova et al, 2005).

Water-soluble vitamins, however, must be supplied daily by either the enteral or parenteral route. Most veterinary vitamin B-complex products do not contain all 11 B-complex vitamins, because some B vitamins are incompatible (e.g., folic acid and riboflavin in the same solution). Folic acid, therefore, must be administered separately if needed. Based on the National Research Council (NRC, 2006) daily vitamin recommendations for healthy dogs and cats and given the vitamin concentrations available in most solutions[d] the recommended dose of 1 ml of B vitamins/100 kcal exceeds daily B-vitamin requirements by several-fold, except for B_{12}. Most previously healthy patients, however, have sufficient hepatic stores of B_{12}.

Some B vitamins are light labile; therefore, most B-vitamin preparations should be kept in a light-resistant bottle and stored between 15 to 30°C (59 to 86°F). Riboflavin, perhaps the most light-labile B vitamin, still has 50% of its original activity after exposure to indoor fluorescent lighting for eight hours (Chen et al, 1983; Smith et al, 1988). Given the NRC (2006) recommended dose of riboflavin and the concentration of riboflavin in the TNA at 1 ml B vitamins/100 kcal, the patient would receive the daily recommended amount of riboflavin within the first two hours of TNA therapy. Thus, covering the intravenous fluid bag to protect B vitamins is unnecessary. Also, the addition of lipid increases the opacity of the final solution, reduces light penetration and precludes having to cover the PN solution from light (Smith et al, 1988). Adding B vitamins is a low-cost (pennies per day), effective means of improving energy metabolism. However, B vitamins are incompatible with some drugs commonly administered to veterinary patients by continuous intravenous infusion (**Table 26-5**).

Trace-Element Solutions

Trace-element requirements have not been determined for catabolic veterinary patients and dosing recommendations for zinc and copper in PN solutions are still evolving. In studies, dogs receiving a zinc-free PN solution had serum levels 50% of normal after one week; therefore, some zinc supplementation is recommended (Iriyama et al, 1982). Supplementing PN solutions with at least 0.1 to 0.2 mg zinc/100 kcal has been suggested (Buffington, 1991; Hill, 1994). Piglets receiving PN for four weeks with a solution containing 5 mg zinc and 0.3 mg copper/100 kcal had toxic zinc but normal copper hepatic concentrations and evidence of pancreatic necrosis associated with zinc toxicosis. Piglets receiving a similar PN protocol with 1.2 mg zinc and 0.3 mg copper/100 kcal had normal hepatic zinc and copper concentrations and no pancreatic pathology (Gabrielson et al, 1996). Based on the NRC (2006) daily zinc and copper recommendations for dogs and cats and one author's (RLR) experience, PN solutions containing 2 mg zinc and 0.2 mg copper/100 kcal RER approximate the patient's needs or approximately 1 ml of a trace-element solution may be added per 100 kcal RER daily. These elements can be added to the PN solution most economically (pennies per day) using a multiple trace-elemente combination available in multiple-dose or single-dose vials.[e]

DRUG ADDITIONS

Although it is very convenient to administer drugs intravenously with the PN solution, *extreme caution must be taken before any medications are added to the TNA.* Drug and TNA solution compatibility studies are ongoing, and there are published lists of drugs known to be compatible and safe (Trissel et al, 1999). **Table 26-6** lists drugs of most interest to veterinarians that can be incorporated into a three-in-one mixture. The *Handbook on Injectable Drugs* is updated and published every two years and is a good source for current information about drug compatibility with PN solutions (Trissel, 2007). After a medication has been added to the day's PN solution, a decision to discontinue that medication can be costly, because a new bag of PN solution must be compounded. Therefore, use of a second peripheral catheter or a multi-lumen central catheter may be preferable to adding drugs to PN solutions.

COMPOUNDING

PN solutions can be obtained from several sources. Some human hospitals and independent pharmaceutical companies will compound TNA solutions for veterinarians. A prescription must be written indicating the volume or final concentration of each nutrient (fat, dextrose, amino acids and each electrolyte), and the person preparing the TNA is likely to refer to the solution as "TPN." Some veterinary schools, large referral practices and private veterinary hospitals have parenteral solution compounders and supplies for their own use and will compound and sell TNA bags directly to practitioners. Several bags of PN solution (up to 10 days' worth) can be sent by overnight mail services directly to the practice. This is often the safest, most convenient and economical method of obtaining an all-in-one PN solution for the occasional patient in most practices.

TNA solutions can be compounded by one of three basic methods: 1) syringe, 2) gravity flow or 3) computerized flow (Remillard and Thatcher, 1989). All-in-one PN or TNA supplies can be purchased from the same sources that provide

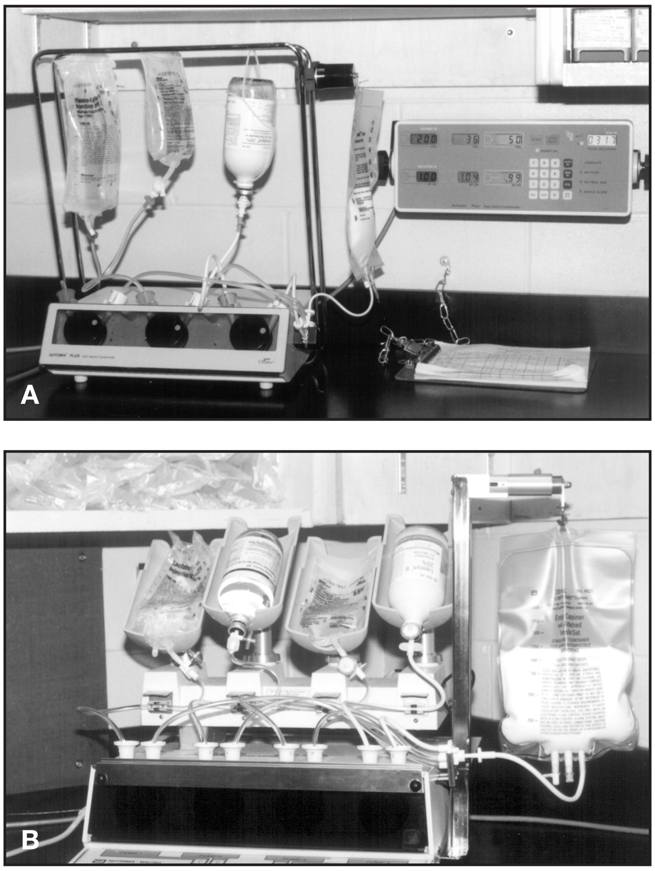

Figure 26-1. A three-station (A) and four-station (B) total nutrient admixture compounder.

nutrient solutions. The least desirable method uses a 35- or 60-ml syringe to transfer each nutrient solution (dextrose, amino acid and lipid) into a sterile, empty fluid bag. This method is the most time-consuming and carries the greatest risk of contamination because of the multiple transfers required. Transfers are ideally done under a laminar flow hood.

The second method uses a closed-circuit fluid system in which the all-in-one bag comes with a pre-attached three-lead transfer set. Each lead, with a vented filter spike, is inserted directly into the individual nutrient solutions (dextrose, amino acid and lipid), and the nutrients are transferred directly into the all-in-one bag by gravity flow. This method is faster and safer than the syringe method, but transfer of exact quantities is impossible. This method may be most economical when few patients require PN. Both syringe and gravity feed methods usually leave partially unused bottles of dextrose, lipid and amino acids.

The third and best method, used by most human hospitals and some large referral veterinary hospitals, employs a high-speed, closed-circuit fluid compounder that pumps three or four solutions (dextrose, amino acid, lipid and fluid) directly into one TNA bag within 60 seconds. Each solution is accurately transferred to within 1 ml. The method has a mean error of less than 3% (**Figure 26-1**). Multiple bags of TNA for several patients can be efficiently compounded at one time using partial bottles of dextrose, fat and amino acids. Making TNA bags with a compounder is safe, fast, accurate and efficient. Veterinary technicians can routinely accomplish this task (McClendon, 1981). A computerized compounder has been used to formulate in one author's (RLR) practice since 1993. To date, no confirmed or suspected cases of microbial contamination have occurred during formulation.[f] All-in-one or TNA solutions can be refrigerated for seven to 14 days (**Box 26-3**).

ADMINISTRATION

The first practical technique for PN administration was demonstrated in the late 1960s (Franga, 2002). At that time, the only form of concentrated non-protein calories for intravenous use was hypertonic dextrose; therefore, a large-diameter, high-flow central vein was needed to avoid phlebothrombosis. Thus, infusion of this high osmolarity PN solution was best delivered into the superior vena cava. The predominant clinical complication with this feeding system was hyperalimentation and subsequent hyperglycemia. It was quickly realized that intravenous delivery of excessive dextrose calories commonly resulted in metabolic and infectious complications. Development and availability of crystalline amino acid and fat solutions helped to address these adverse PN-associated sequelae, because admixtures of lower osmolarity could be formulated for peripheral vein delivery. Additionally, there have been infrequent reports of PN solution delivery through either an intraosseous or intraperitoneal catheter. These alternatives offer additional options for short-term nutritional support.

The route of PN delivery is chosen after consideration of several factors including the underlying disorder and its severity, therapeutic goals for the patient, admixture composition, patient characteristics (e.g., body composition, species, age, vein accessibility), clinician experience and complication risk level (Hansen, 2006; Gallivan and Benotti, 1997). If management of the disease or disorder is thought to require prolonged (more than seven days) parenteral feeding, then the admixture delivery system should be initiated through or changed over to a central venous route. The peripheral route of admixture delivery is best suited to a short-term (less than seven days) nutritional support scenario or when central venous access is unavailable.

Central Vein Infusion

Traditionally, the right external jugular vein is the preferred access route for central venous catheters (CVC). From this site, the external jugular vein joins the cranial vena cava in a straighter line through the brachycephalic trunk, which facilitates catheter passage (Hansen, 2006). Body composition (obese, cachexia) can complicate CVC placement. Imaging techniques help reduce multiple attempts at placing CVCs, thereby minimizing coagulative states (Hunter, 2007; Franga, 2002). The large diameter of a central vein allows for delivery of a high osmolarity solution without concerns about phlebitis caused by fluid shifts in the vein lumen. Practically speaking,

the proportions of dextrose, lipid or amino acids in a PN admixture formulated for delivery through a central vein are not restricted. High- and low-dextrose admixtures are tolerated.

Central venous access can also be obtained by inserting a long catheter into the saphenous vein. This is commonly referred to as a peripherally inserted central catheter. Placing a 10- to 20-cm polyurethane[g] or silicone[h] catheter into the medial saphenous vein at the level of the tarsus and advancing the catheter up the vein places the tip of the catheter into the caudal vena cava of cats. A similar, but longer (20- to 30-cm) polyurethane or silicone catheter, placed in the lateral saphenous vein, is more useful in dogs weighing less than 20 kg. Parenteral admixtures can easily be administered to dogs and cats through a peripherally inserted central line. Cats, compared with most dogs, are smaller, have higher protein requirements and sometimes have restrictive fluid allowances. For cats (more so than for dogs), the final osmolarity of the PN solution will be greater than 600 mOsm/l; therefore, the solution should be administered into a large vein.

Catheters placed in a central vein can have a single lumen or multiple lumina. Although use of central catheters has not been adequately evaluated in veterinary patients, their use for PN administration in people is associated with an increase in septic complications (McCarthy et al, 1987). Many sources advocate that the central catheter must be "dedicated" to PN administration, and should not be used for blood sampling, medication or blood product administration or central venous pressure monitoring. However, when venous access is limited, the PN catheter may be used for blood sampling and administering medications if it is adequately flushed before and after PN administration is interrupted. It is imperative, as with any catheter, that proper aseptic handling technique be used during line interruptions. Likewise, the need for wiping PN lines after handling has not been substantiated; however, precautions are always warranted to reduce the risk of septic complications.

Peripheral Vein Infusion

The lateral saphenous (dog) and medial saphenous (cat) veins are most commonly used for peripheral catheter placement. These sites are preferred because the skin cover is thinner, thus providing better visualization and control over catheter insertion (Hansen, 2006). Less commonly used locations for catheter placement for delivery of PN include the cephalic and/or accessory cephalic veins, femoral veins in some dogs and cats and the ear veins in dogs with pendulous ears.

Based on peripheral vein diameter, there are limitations on the osmolarity of PN solutions that can be administered. In human patients, PN solutions with osmolarities ranging from 550 to 1,250 mOsm/l have been administered peripherally for short periods (three days) (Gazitua et al, 1979; Matsusue et al, 1995; Daly et al, 1985; Isaacs et al, 1977; Maden et al, 1992). Phlebitis, which occurred within the first 72 hours in 26 to 48% of human patients, was the principal complication (Bayer-Berger et al, 1989). Although peripheral vein administration of PN is not new in veterinary medicine, published studies are limited. One study of five dogs evaluated a 3-in-1 admixture delivered over various infusion time periods (Chandler and Payne-James, 2006). An 840 mOsm/l admixture was administered through a peripheral catheter for either 24 hours or 10 to 12 hours/day. Patency of the intravenous line was maintained for a median of 36 hours; no biochemical abnormalities were reported in study dogs. The incidence of line failure, due to thrombus or thrombophlebitis, was decreased by shorter infusion times. In another study, obese cats receiving a high-lipid, low-dextrose admixture through peripheral vein catheters for four days exhibited no mechanical, metabolic or septic complications (Becvarova et al, 2005).

Box 26-3. Complications of Total Nutrient Admixture Solutions.

The diverse composition of total nutrient admixture (TNA) solutions increases the risk of physiochemical incompatibilities. The most likely problem is deterioration of the lipid emulsion within the TNA in which individual fat particles collide forming larger particles creating a potentially dangerous intravenous mixture. TNA solutions containing 10 or 20% lipid have an osmolarity of about 300 mOsm/l, a pH of 7.0 and are stable when stored as directed at room temperature. An egg-yolk phospholipid emulsifier stabilizes the 4- to 5-mm lipid particles by giving the surface a negative charge to maintain a repulsive electrostatic force between particles. Fat breakdown in individual bottles of lipids rarely occurs.

In a TNA, however, fat particles can aggregate and larger particles will migrate to the surface of the solution, creating a whiter band at the top of the TNA solution. This process is called "creaming." It can be easily reversed by gently mixing the TNA solution, and is of no danger to the patient. However, when the negative surface charge is neutralized, the emulsion destabilizes irreversibly and, with repeated collisions between fat particles, the emulsion completely destabilizes. This irreversible coalescence process creates two immiscible oil and water phases. Coalescence is associated with a dark yellow color, either in a line across the top portion of the TNA or as large yellow globules throughout the TNA solution. Adding B-vitamins to a TNA solution gives the solution a light but uniform yellow color, and should not be confused with coalescence. Bags with evidence of coalescence should not be administered to patients because the larger particles can become fat emboli that will plug 5-mm pulmonary capillaries.

Adding divalent cations (e.g., calcium or magnesium) to the TNA solution is not advisable because the positive charge can destabilize the negatively charged surface of fat, break the emulsion and cause coalescence. Adding solutions that reduce the final pH of the TNA to 5 or less will also cause the emulsion to breakdown. Individual dextrose solutions are kept at a pH of 5 to minimize microbial growth, whereas amino acid solutions are buffered and have a pH of 6. When mixing a TNA solution, it is important to add the lipid last when there is a large volume of fluid with a higher pH already in the parenteral nutrition bag.

The Bibliography for **Box 26-3** can be found at www.markmorris.org.

Observed physiologic alterations in study cats were associated with obesity-induced oxidative damage. Calories can easily and safely be administered peripherally to dogs and cats using a TNA of 400 to 650 mOsm/l or an isomolar 20% lipid solution piggybacked with standard fluid therapy at volumes sufficient to meet RER.[1]

Other Routes of PN Infusion

Intravascular complications associated with repeated catheter placements, insufficient blood flow or coagulation abnormalities can limit vascular accessibility. Alternatives for PN support include the intraosseous and intraperitoneal (IP) routes, as reported in several laboratory species, people (adults and children) and dogs. In two separate studies, rats were infused with PN solutions through IP catheters for seven or more days. No adverse effects from the placement or use of IP catheters were found. Weight maintenance was dependent on the caloric profile of the admixture; a PN solution approximating 600 to 700 mOsm/l was preferred (Rubin et al, 1988; LeLeiko et al, 1983). PN solutions (850 mOsm/l) have been infused by IP routes for more than 20 days in 19 normal dogs and in 12 normal dogs that had undergone intestinal resection (Moran et al, 1989; Garcia-Gamito et al, 1991). IP infusion of a 10% lipid solution into three-month-old beagles demonstrated that fat was quantitatively absorbed from the peritoneal cavity over a four-hour period (Klein et al, 1983). Despite this apparent success, the IP route for PN support isn't widely used in veterinary medicine. Intraosseous infusion of drugs and fluids is used as an emergency, last resort access site for human and veterinary patients. Reports of short-term PN infusion (e.g., bolus) are limited, but encouraging. Tibial intraosseous infusion is the preferred site for critically ill children (Koenig, 2000), whereas the sternum is reported to be the most effective site for infusion of lipids in adults (Koenig, 2000). Likewise, a solution containing electrolytes, amino acids, dextrose and vitamins has been successfully infused intraosseously in dogs (Otto et al, 1989). Several precautions exist for intraosseous infusions including appropriate catheter placement, avoiding compromised skin areas and growth plates and extravasation of fluid around bone cortices or vessel foramina (Moss et al, 2005). Although fat embolization is a reasonable consideration, it has yet to be reported in the literature.

Risks and Complications

Catheter placement and management come with potential risks. The most clinically significant problem in administering PN solutions involves the catheter, including loss of access, thrombophlebitis and infection generally in that order of occurrence. Parenteral feeding can introduce additional risks not associated with non-caloric fluid delivery. An overview of the risks and complications associated with central and peripheral vein PN delivery follows.

Infection

Infectious complications with intravenous infusions have been recognized for more than 40 years and are now primarily associated with substandard catheter care. Most catheter-related septicemias are due to microbial invasion at the catheter wound either during or after insertion, but other risk factors include poor patient and personnel hygiene, operator inexperience, method and site of catheter insertion, duration of catheterization and number of catheter manipulations (Bozzetti, 1985; Yilmaz et al, 2007).

Catheters for PN administration must be placed using meticulous aseptic technique. Bandage contamination increases the risk of infection; peripheral vein catheters are more likely to be exposed to and soiled by feces, urine and vomitus compared to CVCs (Hansen, 2006). For either peripherally- or centrally-placed catheters, bandage and administration sets should be changed at least every other day, and preferably daily. When the bandage is changed, the venipuncture site should be cleaned with an iodine solution and examined for redness, edema or swelling. A topical antibiotic ointment (e.g., povidone iodine) that contains antifungal properties should be applied to the catheter-skin junction. If redness, edema or swelling is noticed, the catheter should be removed and cultured and the site should be kept clean and hot packed, if necessary, to reduce swelling. Appropriate antibiotics should be given if culture and antimicrobial sensitivity testing show the catheter or PN solution is contaminated.

Cut-down incisions may be necessary for catheter placement at any location and can increase the risk of infection. Infected or wounded skin at the catheter placement site increases the risk of infection (Hansen, 2006). If there is no other option for a catheter insertion site other than in close proximity to wounded or infected skin, aseptic placement is absolutely necessary. Extreme care should be exercised when assembling and disassembling the admixture flow system and frequent bandage changes are highly recommended. Tunneling or the "indirect catheterization" method forms a subcutaneous tunnel between the point of entry through the skin and the point of entry into the vein. Catheter tunneling helps prevent infection. This technique is more commonly performed when placing a CVC for long-term use. Tunnels serve as a barrier to bacterial migration (Hansen, 2006; Franga, 2002).

In human intensive care units, catheter-related infections are the third most common cause of nosocomial infections (CDC, 1997). Although these data are not reported for veterinary patients, the findings most likely would be similar. Catheter infections are either related to cellulitis from contamination at the catheter exit site (type I) or microorganism contamination within the catheter lumen (type II). Both are due to a failure in aseptic technique (Kaminski, 1997). Adding extra lumina to the same catheter appears to potentiate the risk for type II infections (Kaminski, 1997; Early, 1990; Kemp, 1994). Data are controversial regarding the practice of maintaining a dedicated catheter line for PN administration. In the event a line cannot be dedicated to PN administration, stopping PN delivery, flushing the line adequately before and after delivery of medications, then restarting the PN delivery, will help minimize complications associated with potential solution incompatibilities.

CVCs vary in size and composition (i.e., polyethylene, polyurethane, polyvinyl, silicone, Teflon). Selection of catheter material has implications for catheter-related infections. Silicone catheters reduce the sensitivity of *Staphylococcus aureus* to antibiotics (Williams, 1997). CVCs impregnated with antibiotics reduce the incidence of catheter-related infections (Hanley, 2000). Reports indicate that minocycline/rifampin-coated catheters are less likely to become colonized and have a significantly decreased number of catheter-related infections compared to chlorhexidine/silver sulfadiazine-impregnated catheters (Darouiche, 1999).

Other sources of catheter-related infection include urinary tract infections, abscesses, pneumonia, bacterial translocation from the GI tract or other infected sites (Ryan et al, 1974), resulting in thrombus formation at the catheter tip. Infusion of contaminated fluid is another potential source of infection. Using a closed-circuit fluid system minimizes this route of contamination. Whether individual nutrient solutions within the PN solution promote bacterial or fungal growth if stored inappropriately is still controversial. The crystalline amino acid products now used in PN formulations prohibit bacterial growth (Goldmann et al, 1971; Wilkinson et al, 1973). As a safety precaution, the Centers for Disease Control and Prevention has recommended that lipid-only emulsions be administered for no longer than 12 hours, except in PN systems, which can be administered over a 24-hour period (Simmons et al, 1982). Infection associated with PN administration is a rare complication, most often attributed to substandard catheter care.

Thrombosis

Thrombophlebitis is a response of the vein intima to the unique combination of the infusate, the catheter material and placement and the ratio of catheter to vessel size. Ideally, the smallest catheter necessary to deliver the desired therapy should be selected. Cannulating a vein always poses a risk for thrombosis formation. The longer the catheter remains in place, the greater the risk. Any indwelling catheter becomes covered by a fibrin sheath and platelets within several hours of placement (Hansen, 2006). The likelihood of thrombosis increases in a small vein (i.e., peripheral vein relative to catheter size) that has lower blood flow; when a catheter traverses a mobile joint, when a pre-existing disease exists such as glomerulonephritis, protein-losing enteropathy, autoimmune hemolytic anemia, phlebitis or any disorder causing systemic inflammation. The catheter material is thought to be the single most important factor in the severity of infusion thrombophlebitis (Gaukroger et al, 1988; McKee et al, 1989). Three major characteristics of catheter material have been identified that contribute to thrombus formation: roughness, stiffness and propensity for platelet adhesion (Linder et al, 1984). Numerous studies comparing catheter types are available for review. Catheter choice is multifactorial; minimizing thrombus formation during PN administration should an important consideration. The primary complication from thrombosis is loss of vessel patency, although other complications of deep venous thrombosis include septic thrombophlebitis, venous gangrene, extravasation of infusate, pulmonary embolism and death (Gallivan and Benotti, 1997). Although the risk of thrombosis in a catheterized jugular vein is much lower, the consequences are much more severe compared to those that might occur in a peripheral vein.

Extravasation

When a catheter is displaced, fluid leaks into or infiltrates surrounding tissues (extravasation) causing pain and swelling. Stiff plastic catheters are more likely to perforate vessels during and after placement compared to softer polyurethane or silicone catheters.

Complications with CVC extravasation may not become evident until large volumes of fluid are administered. Fluids (solution) tend to accumulate in the mediastinal and pleural spaces resulting in labored breathing. When catheters are advanced into the right atrium, blood and fluid will accumulate in the pericardial sac causing cardiac tamponade. Thoracic radiographs, physical signs and possibly fluid analysis can be used to document PN solution extravasation.

Swelling and tenderness at peripheral vein infusion sites may indicate extravasation of the PN admixture. The skin overlying the catheter tip may feel cool, and/or the catheter insertion site may be swollen, red and hot, and left unattended, may lead to tissue necrosis and sloughing.

Catheter Damage

Catheters placed in limbs are more accessible for patients to chew or tear. Placement of an Elizabethan collar may help prevent damage to the PN system after the catheter has been placed and the feeding system constructed. Catheters placed in an ear vein may be dislodged by scratching and head shaking. A well-fitted Elizabethan collar will minimize this concern. Catheters placed in the jugular vein are at least risk for damage because patients are less likely to disturb this site. Loss of venous access is caused by catheter kinking, catheter tip migration or blockage. In these instances, the catheter should be removed and a new catheter placed in another vein. Chewing and/or scratching at bandages that conceal a catheter may indicate that the catheter or bandage is irritating the patient. Check the bandage and catheter for tightness, wetness, inflammation or infection. Immediately remove the bandage if any of these problems arise. Assess catheter viability, vein patency, presence of inflammation or infection and immediately make changes to rectify the problem(s).

Guidelines for parenteral feeding of human patients clearly recommend central vein delivery for long-term (months) intravenous nutritional support. However, intravenous nutritional support for most companion animals lasts two to seven days; in some extreme cases, parenteral feeding may be used for several weeks. Catheter placement for PN delivery in small animals should be based on catheter complication risks, duration of feeding, catheter placement and monitoring experience and cost and solution composition (**Table 26-7**).

Table 26-7. Summary of catheter placement sites for parenteral nutrition administration in small animals.

Site/Technique	Pros	Cons	Indications
External jugular	Central vein (large) access Exchangeable High osmolar solution compatible Long-term use (>7 days) Less bandage damage	Placement technically difficult Infection rate higher Intensive patient monitoring required	Inability to use GI tract for nutritional support Electrolytes stable Interruption of oral alimentations for >7 days; catabolic <7 days Non-septic patients Hospitalization required
Tunneled catheters	Lower infection rate of CVC Long-term use (>7 days) Central venous access Hospitalization compatible	Operative placement recommended Placement technically difficult	Long-term CVC required for PN
PICC (femoral vein)	Central vein access Hospitalization compatible Exchangeable	Thrombophlebitis risk higher Infection rate higher Short-term use (<3 days) Blood draws not predictable	To accommodate hospitalization in cats and small dogs No jugular access
Peripheral (saphenous, cephalic)	Easy insertion Lower infection rate Amendable to 3-in-1 solutions Less intensive patient monitoring Exchangeable Lower cost	Requires low osmolar solution (<650 mOsm/l) Short-term use (<7 days) Increase risk of bandage damage Elizabethan collar recommended	High risk of catheter sepsis from CVC Patient can tolerate lipid emulsions Patient in mild metabolic stress/ malnutrition Central vein access not available/ contraindicated Short duration PN Adjunct to enteral or oral nutrition on short-term basis
IO, IP	Venous access not required	Ultra short-term use (IO) Placement technically difficulty (IO) Limited documentation	Emergency situations when venous access is unavailable

Key: GI = gastrointestinal, CVC = central venous catheter, PN = parenteral nutrition, PICC = peripherally inserted central catheter, IO = intraosseous, IP = intraperitoneal.

COMBINED ENTERAL AND PARENTERAL FEEDING

In human medicine, there has been increased acceptance and use of PN in combination with tube feeding (Adams et al, 1986; Moore and Jones, 1986). Feeding enterally minimizes the disadvantages of PN. Prolonged fasting (more than three days) results in enterocyte deterioration and decreased GI immunity (Alverdy et al, 1985). Translocation of enteric bacteria due to a compromised intestinal mucosal barrier represents a possible source of infection with PN administration. Enteral infusion of small quantities of a liquid diet helped prevent intestinal mucosal deterioration during PN administration in piglets (2 ml/kg body weight b.i.d.), human infants (4 to 5 ml/kg body weight/hour) and adults (0.7 ml/kg body weight/hour) (Remillard et al, 1998; Andrassy et al, 1979, 1985). Intestinal adaptations after disease and intestinal hypertrophy after surgery require intraluminal nutrients. Food intake promotes intestinal hyperplasia and brush border enzyme activity (Herman-Zaidius, 1986). Therefore, current recommendations encourage some enteral feeding for patients receiving PN support, if at all possible. Feeding both the small bowel and the patient is important (Daley and Bistrian, 1994).

Either central or peripheral vein delivery systems can be used together with enteral feeding (voluntary or assisted). If PN complements a tube feeding system, avoid the central vein-esophagostomy feeding tube combination. Close proximity of the jugular vein catheter and the feeding tube insertion site may increase the risk of infection and mechanical problems. Other PN and enteral feeding combinations work predictably to optimize nutritional support and GI health.

REASSESSMENT

Regular reassessment is a critical step in successful nutritional management of hospitalized patients, regardless of whether the enteral route, the parenteral route or both are used. Malnutrition in the form of insufficient nutrient intake to support tissue metabolism undermines medical and/or surgical management of a case. Malnutrition is far more common in veterinary patients than is currently recognized. Patients resting in a cage have been mistakenly assumed to require little or no caloric intake when, in fact, the nutrient costs of tissue repair, immunocompetence and drug metabolism are significant. Therefore, reassessment of nutritional status is important whether the patient remains in the hospital or recovers at home.

Monitoring Parameters

Food intake or administration of nutritional support for hospi-

Table 26-8. Metabolic complications of parenteral-nutrition administration, treatment and potential patient considerations.

Complications are listed in descending order of likely occurrence and treatments are listed from immediate to longer term solutions. To minimize complications, patients should be hemodynamically stable and any electrolyte and acid-base abnormalities, severe tachycardia, hypotension and volume deficits should be corrected before starting PN.

Complication	Treatment	Patient considerations
Hyperglycemia	Stop infusion, recheck in two to four hours, decrease PN infusion by 50% until normal, then increase infusion rate slowly Subcutaneous insulin therapy Change caloric sources: Increase lipid fraction of calories Decrease glucose fraction of calories	Glucose intolerance
Hypokalemia	Add KCl or KPO_4 to PN bag Correct serum magnesium as needed Change caloric sources: Increase lipid fraction of calories Decrease glucose fraction of calories	GI or renal losses Drug therapies that increase urinary excretion Insulin therapy
Hypophosphatemia	Add $NaPO_4$ or KPO_4 to PN bag	Diabetic ketoacidosis
Hyperlipidemia	Stop infusion, recheck in two to four hours, decrease infusion by 50% until normal, then increase infusion rate slowly Change caloric sources: Decrease lipid fraction of calories Increase glucose fraction of calories	Decreased lipid clearance
Phlebitis	Change catheter and infusion site Lower PN osmolality: Increase lipid fraction of calories Decrease glucose fraction of calories Add heparin to PN bag	Proper hydration Endogenous site of infection
Hyperkalemia	Change PN bag and decrease potassium	Acidosis, renal failure, sepsis Drug therapies that decrease urinary excretion
Hyperammonemia	Decrease PN infusion by 50% until normal Change PN bag, decrease amino acid concentration Use branched-chain amino acid sources	Liver dysfunction, GI bleeding
Hypomagnesemia	Add $MgSO_4$ to PN bag	GI or renal losses Drug therapies that increase urinary excretion
Hypoglycemia	Piggyback 50% dextrose drip until normal Change caloric sources: Decrease lipid fraction of calories Increase glucose fraction of calories	Sepsis Insulin therapy Insulinoma
Infected catheter site	Change catheter and infusion site Culture catheter and PN solution Give antibiotics based on culture and antimicrobial sensitivity tests Hot pack the site	Substandard catheter care Endogenous site of infection Properly hydrated

Key: PN = parenteral nutrition, GI = gastrointestinal.

talized patients should be reviewed at least daily. Body weight should be recorded daily. Body condition should be noted; however, an animal's body condition score is unlikely to change during the course of a hospital stay. Laboratory assessments specifically for patients receiving nutritional support are generally not necessary beyond those tests already routinely performed for critically ill patients. The most common alterations that occur in laboratory parameters associated with nutrient administration are decreases in serum potassium and phosphate levels, increases in serum glucose concentrations and hypertriglyceridemia (**Table 26-8**). Even apparently stable patients might develop metabolic complications as a result of ongoing disease processes or from undiagnosed subclinical disease states. However, most patients' attitude improves subjectively within 36 hours of refeeding.

Most parameters used to assess the nutritional status of patients will not change as a result of assisted feeding during the course of hospitalization. Laboratory parameters (e.g., albumin and total protein concentrations, RBC count and hemoglobin content) are unlikely to change in less than two weeks. The patient's body weight and condition and some laboratory parameters (albumin and total protein concentrations) should improve over the course of weeks (McAdams et al, 1996). Laboratory parameters that change during a hospital stay as a result of assisted feeding may be detected when acute-phase proteins with half-lives between two and 12 hours can be measured reliably in dogs and cats.

Changing Foods

Parenterally fed patients should be fed enterally as soon as pos-

sible, but may continue to receive PN as enteral intake increases to meet RER. The food offered enterally may be a fixed-formula therapeutic food intended as the food to be fed to the patient at home because of an ongoing disease condition (Chapter 25). When the patient has a decreased appetite, a highly palatable, fixed-formula food may be offered initially to stimulate oral consumption. This food may then be mixed in gradually decreasing proportions with the food to be fed on a long-term basis (Chapter 1). Vomiting and diarrhea are the most common problems seen when refeeding patients orally. Foods should be introduced in amounts equal to RER in small frequent meals, and the amounts increased if well tolerated over several days.

CASE 26-1

Peripheral Parenteral Nutrition in a Dog

Korinn E. Saker, MS, DVM, PhD, Dipl. ACVN
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina, USA

Patient Assessment

A six-year-old, intact male, mixed-breed dog weighing 29.5 kg with a body condition score (BCS) of 3/5 was presented for evaluation of suspected sepsis following a severe neck wound. A large open wound on the right side of the dog's neck was first noticed five days earlier. The local veterinarian flushed and closed the wound and initiated antibiotic therapy (enrofloxacin[a], amoxicillin[b] and a single dose of cephalexin[c]). The dog's clinical condition continued to deteriorate; therefore, the dog was referred for further evaluation.

On physical examination, the dog was depressed and laterally recumbent. The wound on the right side of the dog's neck extended from the dorsal margin of the ear pinna to the ventral midline. There was a necrotic odor originating from the wound. A fluid-filled pocket ventral to the wound was incised, releasing a large volume of purulent material. Specimens were collected for bacteriologic studies. When skin sutures were removed, a large wound extending deep into the tissues on the left side of the neck was found. The trachea, jugular vein and several nerves were visible at the wound margins, along with large amounts of green necrotic tissue. Skin surrounding the wound was indurated and necrotic. The dog's right ear was swollen and edematous with a creamy exudate originating from wounds on the medial aspect. Crackles could be auscultated in the right caudal lung field and the patient was mildly dyspneic.

Laboratory abnormalities included neutrophilia with a left shift, thrombocytopenia, decreased total protein (5.2 g/dl [normal 5.5 to 7.4 g/dl]) and albumin (2.3 g/dl [normal 2.8 to 3.6 g/dl]) values, lymphopenia, elevated bilirubin (5.0 mg/dl [normal 0.1 to 0.5 mg/dl]) concentration and increased alanine aminotransferase (367 U/l [normal 13 to 100 U/l]) and alkaline phosphatase (2,954 [normal 20 to 167 U/l]) activities.

After initial presentation to the teaching hospital, the dog was sedated twice daily for aggressive wound management and bandage care with wet-to-dry bandages. Aerobic and anaerobic wound cultures grew *Pseudomonas aeruginosa, Eubacterium aureofaciens, Bacteroides bivius* and *Clostridium perfringens.* The patient regurgitated white foam numerous times during the first three days of hospitalization and was dysphagic.

Assess the Food and Feeding Method

The dog had not eaten during the five days before presentation and was not offered food for the first three days of hospitalization while undergoing wound exploration and débridement and diagnostic cultures, radiography, bronchoscopy and esophagoscopy. Although nutritional support was not offered, a physiologic replacement fluid (lactated Ringer's solution) containing 20 mEq of potassium chloride/l was administered in the first 12 hours to replace an estimated fluid deficit of 10%. Fluids were reduced to maintenance rates thereafter.

Questions

1. What techniques and parameters could be used to assess the nutritional status of this patient?
2. Which nutrients would be beneficial in enhancing tissue repair and immunocompetence?
3. When and by what method should nutritional support be initiated?

Answers and Discussion

1. Currently, nutritional assessment is limited to the veterinary equivalent of anthropometric measures (i.e., body weight and condition), routine laboratory tests (e.g., total protein and albumin levels, lymphocyte counts) and clinical examination. Weight loss of more than 10% in sick or injured patients is considered a guideline for implementing nutritional support. Albumin has a half-life of eight days in normal dogs, thus it may remain within the normal range during short-term (one week) nutritional deprivation. The albumin concentration will decrease as the period of anorexia and lack of nutritional support is prolonged. The lymphocyte count also is altered in a relatively short period (days) as a result of nutrient deprivation. However, both hypoalbuminemia and lymphopenia can result from non-nutritionally related causes.
2. The patient's immune system was not responding optimally because of the infection and sepsis related to the neck injury. As a result of eight days of nutritional deprivation, the patient's body was now metabolizing fat and protein stores for energy and tissue repair. The labile protein pool (free amino acids) was becoming depleted and visceral and muscle protein was mobilized, which will result in atrophy and wasting in prolonged states of food deprivation in the face of accelerated catabolism. Immune cells and damaged muscle tissue benefit from dietary protein and fat. Research has shown that protein-energy malnutrition (PEM) results in immune system dysfunction. PEM increases the risk of mortality from infection, because it compromises innate and adaptive barriers to disease challenges. Specific alterations include: 1) a decreased marrow pool of neutrophils, 2) depressed neutrophil and monocyte phagocytic activity, 3) depressed antigen-presenting capacity of macrophages, 4) atrophy of lymphoid organs, 5) alterations in critical CD4 and CD8 cell subsets, 6) increased adhesion of organisms to mucosal epithelia and 7) alterations in regulation of inflammatory mediators. Micronutrients such as zinc, copper, iron, selenium and vitamins A, E and C should also be supplied because they are integral components in enzyme systems that promote antioxidant activity, antibody formation, cell activation and proliferation and protein synthesis.
3. Nutritional support should be instituted immediately. The twice daily wound débridement and bandage changes with sedation limit the time this patient is alert enough to assimilate oral nutrients. Additionally, this patient has a history of regurgitation and dysphagia since being admitted to the teaching hospital. In light of these factors, as well as the physical inaccessibility to the neck region because of the wound and bandages, this patient is an excellent candidate for peripheral parenteral feeding. The peripheral route of intravenous feeding can supply 100% of resting energy requirement (RER), amino acids plus maintenance electrolytes, minerals, vitamins and trace elements.

   The intravenous admixture should be formulated as a high-fat, low-carbohydrate solution to mirror the patient's current metabolic profile. A total admixture containing 3 g protein/100 kcal with 80 to 90% fat calories and 10 to 20% dextrose calories plus maintenance fluid therapy will ensure an osmolarity less than 600 mOsm/l and that the admixture can be administered peripherally. This high-fat admixture will also reduce the incidence of hyperglycemia and hyperinsulinemia, and improve nitrogen balance, which is particularly important in this case because of the patient's extensive tissue necrosis. A high-fat diet has also been recommended in cases with pulmonary compromise as observed in this patient. Metabolism of fat calories produces less carbon dioxide for excretion than carbohydrate metabolism. Feeding fat decreases the pulmonary work to excrete carbon dioxide and thereby reduces ventilatory work.

   This nutrient admixture, administered through a peripheral access, should be done using a silicone or polyurethane catheter. Sodium heparin can be added to the admixture (0.5 to 1 U/ml of total admixture) to prevent formation of fibrin clots around the catheter tip when it is placed in a small vessel. To promote or maintain gastrointestinal health, the patient should also be fed small amounts of a high-protein, high-fat liquid or moist food per os as soon as clinically possible. The oral food should be enriched with glutamine, arginine and omega-3 fatty acids to enhance enterocyte proliferation and immune cell function.

Progress Notes

The patient received peripheral parenteral feeding (**Table 1**) for eight days during which time the frequency of wound débridement and bandage changes was decreased to once daily. The patient's food assimilation and swallowing reflex improved so that the patient was able to eat a food with high protein, fat and moisture content (Prescription Diet a/d Canine/Feline[d] gruel and then Prescription Diet p/d Canine[d] meatballs) to meet its RER. Just before the patient was discharged, its laboratory values were normal except for mild hypoalbuminemia (2.4 g/dl). The patient was discharged with antibiotic therapy and instructions to the owners for daily wound care. The dog returned for weekly evaluations. Tissue healing was marked but not complete four weeks after hospitalization. The owners were advised to feed 4.5 cups of a moderately high-protein, calorie-dense food (Science Diet Puppy Original[d] dry) to meet the dog's daily energy requirement (DER) of 1,595 kcal (DER = 1.8 x RER) (6.67 MJ) until tissue healing was complete.

CASE 26-2

Central Parenteral Nutrition in a Cat

Kathryn E. Michel, DVM, MS, Dipl. ACVN
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania, USA

Patient Assessment

A 10-year-old, spayed female, domestic shorthair cat presented to the emergency service with a three-week history of poor appetite and weight loss. The chief complaint was facial swelling (especially around the nose) and nasal discoloration. The cat's problems were originally associated with an episode of pollakiuria and inappropriate urination, which resolved with antimicrobial therapy

(sulfadimethoxine[a]). About two weeks before presentation, the cat became lethargic and tachypneic and its appetite deteriorated further. At that time the owners noticed that the cat's normally pink nose had become discolored. They initially observed a small bloody spot on the bridge of the nose overlying bluish skin. Over the course of a week the nose became progressively swollen and the skin blackened. The cat developed mild epistaxis.

On physical examination, the patient was depressed, moderately dehydrated (8 to 10%) and hypothermic (36.7°C [98.2°F]). The cat weighed 3 kg and its body condition was considered cachectic (body condition score [BCS] of 1/5). Mucous membranes were pale and slightly tacky. Ecchymoses and petechiae were present on the sclera, pinnae and gingiva. Harsh lung sounds were auscultated bilaterally. Swelling and discoloration were noted on the nose, upper lip and tail.

Initial laboratory work included a serum biochemistry analysis, a complete blood count (CBC), a coagulation profile, activated clotting time (ACT) and blood typing. The cat had previously tested negative for feline leukemia virus and feline immunodeficiency virus. Results of the serum biochemistry profile were within normal limits. Abnormalities on the CBC included a hematocrit of 11% (normal 27 to 45%), hemoglobin of 3.5 g/dl (normal 8 to 15 g/dl) and an inflammatory leukogram with a left shift. The cat had a platelet count of 88,000/µl (normal 175,000 to 425,000/µl) and a corrected reticulocyte count of 8.28% (normal 1 to 10%). The coagulation profile was within normal limits, although the ACT was abnormal and the blood never completely clotted. Thoracic radiographs revealed an alveolar pattern in the cranioventral lung fields and overall increased density in the caudodorsal lung fields. Active inflammation and hemorrhage were noted on the tracheal wash. Biopsy specimens were submitted from the nose and upper lip. A cardiac consult revealed no evidence of primary heart disease and an occult heartworm test was negative.

The problem list included cachexia, anemia, neutrophilia, thrombocytopenia and alveolar disease. The differential diagnosis included thromboembolic disease, pneumonia and cold agglutinin disease. Microscopic thrombi consistent with cold agglutinin disease were found on biopsy specimens. Cold agglutinin disease was confirmed by a positive Coomb's test at 7°C (44.6°F).

Assess the Food and Feeding Method

The cat showed no interest in food even though a variety of foods were offered and efforts were made to coax it to eat. The cat had been fed a commercial grocery brand dry cat food (Purina Cat Chow[b]) free choice for several years. It would accept only a small amount of food when given by syringe. The necrotic condition of the cat's nose probably affected its ability to smell food and that in combination with dyspnea and anemia caused the lack of appetite. The cat's poor body condition, the severity of its illness and the likelihood of a prolonged clinical course prompted a more aggressive approach for providing nutrition to this patient.

Initial therapy included a maintenance infusion (65 ml/kg body weight/day) of 0.9% NaCl with 20 mEq K/l, antibiotic therapy (enrofloxacin[c] and ampicillin[d]) and a transfusion with whole blood and fresh frozen plasma. The cat was admitted to the intensive care unit where it was placed in an oxygen cage with orders to keep it warm. The cat was started on cyproheptadine[e] (2 mg per os, t.i.d.) with orders to offer a variety of warmed foods and to coax it to eat. A central venous polyurethane catheter was placed in the left femoral vein and a parenteral nutrition (PN) admixture containing 50% dextrose, 20% lipid emulsion, 8.5% amino acid solution without electrolytes, potassium phosphate, potassium chloride, trace elements and injectable B complex was begun (**Table 1**). The PN solution was delivered at a rate of 5 ml/hour for the first 24 hours to deliver two-thirds of the calculated resting energy requirement (RER). On subsequent days, it was delivered at a rate of 7 ml/hour (56 ml/kg body weight/day) to deliver 100% of the RER ($[3.0]^{0.75}$ x 70 = 160 kcal/day [670 kJ/day]). The peripheral catheter infusion rate of the NaCl solution was reduced to 9 ml/kg body weight/day to accommodate the central PN infusion and meet the cat's daily maintenance fluid requirement.

Table 1. Central parenteral TNA for one day.*

Nutrients/fluids	Quantities (ml)
50% dextrose	38
20% lipid emulsion	48

Questions

1. Which other feeding routes might have been considered to support this patient and why were they rejected in favor of centrally administered PN?
2. Were any micronutrients absent from the PN formulation that might be important for erythropoiesis?
3. What types of metabolic complications should be anticipated in a critically ill patient receiving PN?

Answers and Discussion

Figure 1. A 10-year-old, domestic shorthair cat with cold agglutinin disease on Day 19 of hospitalization.

1. A number of enteral feeding routes and PN infusion via peripheral venous access were considered for this patient. The nasoesophageal route was rejected for several reasons. The most obvious reason was the condition of the patient's nares, which were partially obstructed due to necrosis. Also, there was the concern of provoking epistaxis in a thrombocytopenic and severely anemic patient as the tube was advanced through the nose. Finally, there was the issue of blocking the nares in an animal already experiencing difficulty breathing through its nose. All other routes of enteral feeding (i.e., esophagostomy, pharyngostomy, gastrostomy and enterostomy) require heavy sedation or general anesthesia with varying degrees of surgical intervention. The cat's compromised pulmonary function and thrombocytopenia were considered contraindications for these procedures. (There was a missed opportunity later on in this case to place a less invasive type of enteral feeding tube [e.g., an esophagostomy tube]. On Day 10 of hospitalization the cat was anesthetized for a bronchioalveolar lavage and a bone marrow aspirate). Central infusion of PN was selected instead of peripheral infusion because there was a concern of fluid overload, given the extent of alveolar disease in this patient. Therefore, a more concentrated, smaller volume admixture was conservatively infused via a central vein rather than peripherally.
2. Two micronutrients important for red blood cell production, and which are associated with anemia when deficient, were omitted from the PN admixture because of noncompatibility issues. The first was iron. Parenteral iron solutions are not approved for mixing with any vehicle including PN admixtures and are therefore commonly given separately by intramuscular or intravenous routes. However, the concern that this patient would become iron deficient was minor because the cat had received multiple red blood cell transfusions during the course of hospitalization.

   The other missing nutrient was folic acid. Folic acid is omitted from standard veterinary parenteral B-complex formulations because of noncompatibility and stability issues. Some human parenteral vitamin formulations contain folic acid; however, at the time this case presented, there was a severe shortage of these products and their use in a veterinary patient could not be justified. Although omission of folic acid from this cat's nutritional support was not optimal, the extent of folic acid deficiency may have been limited due to ongoing efforts to feed the cat per os throughout the time it received PN.
3. Common metabolic complications associated with PN include hyperglycemia, lipemia and electrolyte disturbances. Hyperglycemia and lipemia were not noted at any time during PN infusion in this patient, probably due in part to the conservative estimate of its caloric requirements and because the cat received only 40% of its nonprotein calories as dextrose. Serum potassium, sodium, chloride and ionized calcium levels were monitored daily. Serum phosphorus and magnesium levels were monitored two or three times per week.

Progress Notes

The patient continued to require oxygen therapy. The thrombocytopenia resolved, but the anemia persisted with a poor regenerative response. *Pasteurella multocida* was cultured from a tracheal wash but it was unknown whether this isolate was the cause of the alveolar disease or a contaminant. The patient's appetite was poor despite continued efforts to coax the cat to eat. The cyproheptadine was discontinued after four days. On Day 4 of PN, a low serum magnesium concentration was detected and corrected with an infusion of magnesium sulfate at a rate of 1 mg/kg body weight/day via the peripheral catheter. The serum magnesium level returned to normal within 24 hours and the magnesium sulfate infusion was discontinued. Mild hypokalemia also occurred and was corrected by increasing the admixture potassium concentration to 30 mEq/l. Low serum phosphorus levels were not detected in this patient.

On Day 7, the cat was still receiving most of its nutrition parenterally. Therefore, injections of fat-soluble vitamins were given (1,000 IU vitamin A, 100 IU vitamin D, 3 IU vitamin E intramuscularly and 7.5 mg vitamin K subcutaneously). On Day 10, the cat was anesthetized for bronchoscopy, an ultrasound-guided fine-needle lung aspirate and a bone marrow aspirate. There were no abnormalities found grossly at bronchoscopy and when the bone marrow aspirate was examined. Cultures of the bronchoalveolar lavage revealed different organisms from the tracheal wash; however, the pulmonary disease seemed to be improving. The decision was made to start immunosuppressive therapy (prednisolone acetate 1 mg/kg, subcutaneously, b.i.d.) because the cat's red blood cells were still agglutinating.

The patient started to improve, and by Day 13 no longer required oxygen therapy. The necrotic tissue on the cat's nose had begun to scab over. By Day 19 (**Figure 1**), the Coomb's test was negative at 4°C (39.2°F), the nares became clear of scabs and the cat's appetite returned. The patient started to eat a maintenance dry cat food (Science Diet Feline Maintenance[f]) voluntarily with an excellent appetite and consumed sufficient quantities of food to exceed its RER. On Day 20, central venous access was lost, but

because the cat was eating well, there was no concern about continuing PN. On Day 22, the necrotic portion of the cat's tail was removed using local ring-block anesthesia. The patient continued to improve and was discharged from the hospital on Day 25. At the time of discharge, the cat weighed 3.2 kg and had a hematocrit of 19%. The cat continued to do well at home. At two weeks after discharge it weighed 3.4 kg, was still thin (BCS 2/5) but no longer cachectic and had a hematocrit of 22% with a corrected reticulocyte count of 6.2%. One year later on a routine annual examination, the cat weighed 4.1 kg (BCS 3/5), had a normal PCV with no reticulocytes and was reportedly doing very well.

CASE 26-3

Combined Parenteral and Enteral Feeding in a Cat

Donna Raditic, DVM
MSPCA Angell Animal Medical Center
Boston, Massachusetts, USA

Patient Assessment

A five-year-old, neutered male, domestic shorthair cat was presented for anorexia and weight loss. The patient lived in a large multiple-cat household and had been missing for one week. The owners found the cat and thought it had lost weight, but couldn't coax the cat to eat. On physical examination, the cat was lethargic, dehydrated with a body weight of 4.5 kg and a body condition score of 2/5. The cat had excessive skin folds, which supported the owner's report of recent weight loss. The cat was icteric with palpable liver enlargement. All cats in the household were fed a dry grocery brand cat food fed free choice.

Results of a complete blood count included a regenerative anemia; *Bartonella* was detected on a blood smear. The patient also had elevated liver enzyme activities, increased blood urea nitrogen values and hypoalbuminemia. Serum electrolytes were within normal limits.

The patient was stabilized with an intravenous bolus of crystalloid solution followed by appropriate fluid management, antibiotics and antiemetics. Although therapy stabilized the cat's laboratory values, the patient continued to vomit bilious fluid throughout the day and evening. Plans included radiography, ultrasonography and liver biopsy.

Abdominal ultrasonography showed hepatic enlargement. An ultrasound-guided liver biopsy was performed. Histopathology revealed neutrophilic and lipid infiltrates. A diagnosis of hepatic lipidosis with *Bartonella* infection was made.

Because the patient's vomiting was unresponsive to antiemetics, a parenteral solution of Aminosyn II (a parenteral nutrition [PN] admixture containing 3.5% amino acids and 5% dextrose solution) was started. The PN was given at a rate of 20 ml per hour and supplied 144 kcal/day. The patient became more alert and seemed to be responding positively to PN feeding.

Two days later the cat was sedated for placement of an esophagotomy tube for possible home care. Feeding instructions were given early afternoon, to start a continuous rate infusion of a monomeric solution[a] that contained 1.3 kcal/ml. This solution was given at a rate of 5 ml/hour, providing the cat with 156 kcal/day (653 kJ/day). PN and supportive care were continued. The next day the cat was unresponsive, febrile, more anemic and had increased liver enzyme activities. An electrolyte panel was performed (**Table 1**).

Questions

1. What is this cat's resting energy requirement (RER)?
2. How many kcal did the combination of PN and enteral feedings provide?
3. How should the serum electrolyte abnormalities, seen after 24 hours of enteral feedings, be interpreted?
4. How should these electrolyte imbalances be addressed given the patient's deterioration?

Answers and Discussion

1. RER is calculated as 70(weight in kg)$^{0.75}$. This cat's RER was 216 kcal/day. PN and/or enteral feeding should begin at the patient's RER. No "illness factors" should be used to avoid possible complications.
2. The PN supplied 144 kcal/day and the enteral feedings added 156 kcal/day. Therefore, the patient was receiving 300 kcal/day or 1.4 times above its RER.
3. Potassium decreased to 2.7 mg/dl (normal = 3.5 to 5.2) and phosphorus decreased to 1.2 mg/dl (normal = 2.6 to 8.3), whereas sodium, chloride and magnesium remained normal.

   This cat's hypophosphatemia and hypokalemia are classic signs of refeeding syndrome. These electrolyte changes occur most commonly when a patient is force fed an amount that is greater than is needed (i.e., above RER). Initially the cat was fed below RER with PN alone, and then total caloric intake increased above RER with the addition of enteral feedings. All patients fed with PN, enteral nutrition or both should initially be fed at RER. Glycogen stores are first rapidly depleted in cats with anorexia. With ongoing anorexia, fat mobilization and skeletal muscle degradation provide energy and support blood glucose.

   When refeeding, potassium and phosphorus move into intracellular spaces as normal cellular function (gluconeogenesis and ATP production) returns. Providing calories in excess of whole body potassium and phosphorous stores drives these electrolytes into intracellular spaces creating a deficient in the vascular space. Hypophosphatemia is the most serious electrolyte imbalance because it can result in hemolytic anemia and even death.
4. The patient's PN was discontinued and an intravenous crystalloid solution supplemented with potassium and phosphorous was started to replete body stores and normal serum levels. Enteral nutrition was continued at 25% of RER for two days simultaneously to maintain intestinal integrity until serum electrolyte levels returned to normal. Intestinal absorption of potassium and phosphorus should not cause electrolyte imbalances at a flow rate below RER. **Table 2** depicts the electrolyte panel 24 hours after feeding adjustments were made.

Progress Notes

Phosphorus was delivered by intravenous administration for another 24 hours to correct deficits. The patient continued to eat well in the hospital and was discharged three days later.

Chapter 27

Obesity

Philip W. Toll
Ryan M. Yamka
William D. Schoenherr
Michael S. Hand

"If we could give every individual the right amount of nourishment and exercise, not too little and not too much, we would have found the safest way to health."
Hippocrates

CLINICAL IMPORTANCE

Obesity is a real disease and is thought to be the most prevalent form of malnutrition in pets of westernized societies. Large studies in Great Britain and the United States indicate that the prevalence of overweight and obese dogs is between 24 to 30% (Lund et al, 2006; Armstrong and Lund, 1996; Mason, 1970; Meyer et al, 1978; Edney and Smith, 1986). Similar studies indicate the prevalence of overweight and obesity in cats is between 25 to 35% (Lund et al, 2005; Armstrong and Lund, 1996; Scarlett et al, 1994). Being overweight appears to be more problematic in middle-aged dogs and cats; 42% of dogs and 44% of cats between the ages of five and 11 years are overweight in the United States (Lund et al, 2005, 2006).

Deciding when a given animal is in ideal, overweight or obese body condition has clinical relevance because overweight and obesity may adversely affect an animal's health. By definition, obesity is the accumulation of excess body fat. Body weight increases as fat accumulates; thus, having excessive body fat and being overweight are related. Although body weight can increase for multiple reasons (Burkholder and Toll, 2000), the majority of overweight dogs and cats have excess body fat.

Body weight relative to an animal's optimal (ideal) weight has been used as a defining criterion for obesity because body weight is easier to measure than body fat. Relative body weight (RBW) is simply an animal's current weight divided by its estimated optimal weight. People are defined as mildly obese when actual body weight exceeds optimal body weight by 15 to 30% (NIH, 1985, 1998; Owen, 1988). Similar definitions have been proposed for dogs and cats (Joshua, 1970; Lewis et al, 1987). Arbitrary ranges for RBWs for overweight dogs and cats are between 10 and 20% above optimal weight. Obese dogs and cats are characterized by RBWs above 20%.

Fat mass, expressed as a percentage of body weight, can also be used to define obesity. People are considered obese when percent body fat (%BF) exceeds 20 to 30% of total weight (NIH, 1985; Owen, 1988). Body composition studies of dogs and cats indicate that animals judged to be in ideal body condition have 15 to 20% body fat (Stanton et al, 1992; Laflamme et al, 1994, 1995; Burkholder, 1994; Laflamme, 1997, 1997a).

Health Risks of Obesity

Excessive deposition of body fat has detrimental effects on health and longevity. In people, these detrimental effects begin, and thus obesity has been defined, when body fat exceeds 20 to 30% of body weight (NIH, 1985; Lew and Garfinkel, 1979).

Even being moderately overweight throughout life reduces lifespan. In a lifelong study of two groups of Labrador retriever dogs, the treatment group was fed 25% less than the control group (Kealy et al, 2002). Over the course of the study, the control group became moderately overweight. The median lifespan of the leaner group was 13.0 years compared to 11.2 years for the moderately overweight dogs. Many pet dogs and cats are

overweight to this degree (Lund et al, 2005, 2006).

Numerous diseases are associated with obesity (Laflamme, 2006). **Table 27-1** lists abnormalities associated with or exacerbated by obesity. Potential common threads exist between excess body fat and many of these diseases including cytokines, hormones and oxidative stress. A growing body of evidence suggests that body fat is no longer thought of as simply an energy storage depot. Adipocytes produce and secrete numerous cytokines and hormones, sometimes collectively referred to as fat-derived peptides (**Table 27-2**) (Trayhurn, 2006; Gayet et al, 2004; Coppack, 2001; Miller et al, 1998). Many of these fat-derived peptides are proinflammatory and probably are important in several of the diseases discussed below. Thus, obesity is likely a chronic, low-grade inflammation affecting many body systems.

Other studies show that obesity increases oxidative stress. The consequences of prolonged oxidative stress to cell membranes, proteins and DNA have been associated with cancer, diabetes mellitus, urinary tract disease, heart disease and liver disease (Tanner et al, 2006; Sonta et al, 2004; Urakawa et al, 2003; Ha and Le, 2000; Thamilselvan et al, 2000; Kesavulu et al, 2000; Freeman et al, 1999; Cheng et al, 1999; Center, 1999; Knight, 1999; Ames et al, 1993).

Obesity in people is closely associated with insulin resistance, type 2 diabetes mellitus, hypertension, hyperlipidemia and cardiovascular disease. In 1999, the World Health Organization (WHO) clustered these ailments and characterized the condition as metabolic syndrome. Metabolic syndrome was defined as impaired glucose tolerance/insulin resistance with two or more of the following: elevated blood pressure, obesity (body mass index [BMI] >30), reduced high-density lipoprotein cholesterol, high triglyceride concentrations and microalbuminuria. Although metabolic syndrome has not been identified in dogs and cats as defined by the WHO, they are prone to many diseases that have been linked to and are associated with obesity.

Similar to findings in people, obese dogs and cats have increased risk of dyslipidemia (high triglycerides and cholesterol). Obese dogs and cats have elevated levels of triglycerides, cholesterol and altered lipoprotein profiles (Yamka et al, 2006; Yamka and Friesen, 2006; Jeusette et al, 2004, 2005; Sunvold and Bouchard, 1998). As in people, cholesterol and triglyceride levels decrease in dogs undergoing weight loss (Diez et al, 2004). Note that in these studies, although triglyceride and cholesterol levels were elevated, both were still within normal published ranges.

Obese dogs have an increased prevalence of cardiovascular disease in the form of congestive heart failure (Edney and Smith, 1986). Increases in blood pressure have been documented to occur in dogs under experimental conditions immediately after increases in body weight (Rocchini et al, 1987, 1989; Buffington, 1994). Structural changes in the heart have been documented in as little as nine weeks in obesity-related hypertension in dogs. Pathology included marked changes in the right atrium and left ventricle (Philip-Couderc et al, 2003). The liver and adipose tissue produce the peptide angiotensinogen (**Table 27-2**). The strong correlation between obesity and hypertension implies that excess adipose tissue may play a direct role in blood pressure regulation (Frederich et al, 1992).

Grossly obese dogs have an increased prevalence of traumatic and degenerative orthopedic disorders (Edney and Smith, 1986). Furthermore, the severity of osteoarthritis is greater in dogs with body condition scores (BCS) above ideal. Also, the mean age at which 50% of dogs required long-term treatment for osteoarthritis was significantly younger (10.3 years) in mod-

erately overweight dogs compared to dogs with normal BCS (13.3 years) (Kealy et al, 2002). In addition to increased mechanical stress on joints resulting from excess body weight, the associated body fat produces several inflammatory mediators (Eisele et al, 2005; Trayhurn and Wood, 2004) that could contribute to, or conceivably cause, osteoarthritis (Sowers et al, 2002). In a study that investigated multiple biomarkers for early indicators of disease, obese dogs had significantly higher levels of alkaline phosphatase and type 2 cartilage synthesis indicating increased risk for osteoarthritis (Yamka et al, 2006).

Obesity has also been reported to predispose dogs and cats to diabetes mellitus or exacerbate this illness (Mattheeuws et al, 1984, 1984a; Nelson et al, 1990; Nelson, 1990; Panciera et al, 1990). Certain of the hormones and inflammatory mediators produced by adipose tissue (**Table 27-2**) are thought to play a role (Plomgaard et al, 2005). For example, adiponectin is a non-cytokine, fat-derived peptide and is the only one protective against inflammation. Unlike most fat-derived peptides, circulating levels are inversely proportional to obesity; low levels of adiponectin cause insulin resistance (Pischon et al, 2004). Another fat derived peptide, resistin, is up-regulated in obesity. Increased resistin levels participate in the pathogenesis of insulin resistance (Muse et al, 2004; Steppan et al, 2001). Also, overweight dogs have increased levels of tumor necrosis factor-α, insulin-like growth factor-1 and glucagon-like protein-1; all of these peptides have been associated with insulin resistance (Gayet et al, 2004; Yamka et al, 2006).

Obesity is a predisposing factor to idiopathic hepatic lipidosis in anorectic cats (Armstrong, 1989; Biourge et al, 1994). A less well-documented effect of obesity in dogs and cats is an increased risk for anesthetic complications, a belief held by many veterinary practitioners (Clutton, 1988). Decreased heat tolerance and stamina are also purported consequences of obesity in dogs and cats (Anderson and Lewis, 1980; Edney, 1974). Other health problems thought to be associated with or exacerbated by obesity include dyspnea, dystocia, dermatologic problems and reduced immune function, although the association between obesity and these clinical effects is less than definitively documented (Buffington, 1994; Newberne, 1966; Williams and Newberne, 1971). Oral disease and urinary disease have also been linked to obesity (Lund et al, 2005). **Table 27-1** lists abnormalities associated with or exacerbated by obesity.

Overweight and obesity in people, dogs and cats are strongly associated with an increased risk for urinary stone formation. Overweight dogs have twice the risk for developing uroliths (Lekcharoensuk et al, 2000). Overweight cats have nearly three times the risk of calcium oxalate urolithiasis compared to lean cats (Lekcharoensuk et al, 2001). In people, this correlation is reported to be due to increased urinary excretion of promoters, but not inhibitors of calcium oxalate urolith formation. Also, a significant positive relationship was shown for BMI and urinary excretion of uric acid, sodium, ammonium and phosphate. An inverse correlation was shown between BMI and urinary pH (Siener et al, 2004).

An indirect relationship between obesity and cancer has been reported to occur in overweight dogs. A case control study was conducted to determine if exposure to secondhand cigarette smoke, household chemicals and topical insecticides was associated with transitional cell carcinoma of the urinary bladder. Bladder cancer risk was unrelated to cigarette smoke or household chemicals but was significantly increased by topical insecticide use, depending on the number of applications per year. This risk was enhanced in overweight and obese dogs (Glickman et al, 1989).

PATIENT ASSESSMENT

The assessment goals for overweight and obese patients should be to: 1) review the medical record for associated concurrent health issues, 2) conduct a thorough feeding assessment and 3) determine the degree to which the patient is overweight or obese. Attaining these goals is central to the development of an effective feeding plan for weight management.

History and Physical Examination

Medical Record Review

A review of the medical record provides objective historical information and documents the pet's previous health status and whether the pet is currently receiving any medications that might be associated with an overweight or obese condition.

Obesity can be a clinical sign accompanying the endocrinopathies listed in **Table 27-1**. Hyperadrenocorticism, hypothyroidism and diabetes mellitus are the endocrinopathies most amenable to treatment. In these cases, obesity is caused by the physiologic alterations resulting from hyperadrenocorticism and hypothyroidism. Although hypothyroidism is commonly associated with obesity in dogs, hypothyroidism is not a common cause of obesity. The prevalence of hypothyroidism in dogs is only 1% (Chastain and Panciera, 1995). No more than one-fourth of hypothyroid dogs are obese, whereas the prevalence of obesity in dogs is 25% (Chastain and Panciera, 1995). Obesity may either cause or occasionally result from diabetes mellitus. In either case, weight loss in an obese diabetic will improve the chances for better regulation of blood glucose concentrations and perhaps decrease or eliminate the need for insulin administration to achieve glycemic control (Chapter 29).

Treatment of the remaining endocrinopathies in **Table 27-1** is often unrewarding. They are listed for completeness and reference, and should be considered after the more common diagnoses are excluded and when patients do not lose weight with even the most severe caloric restriction. A veterinarian presented with an obese patient should use historical information and physical and clinical pathologic findings to include or exclude the possibility of a systemic problem causing or contributing to the obesity.

Current Feeding Plan Assessment

A thorough feeding assessment should be conducted, particularly in regards to food intake, physical activity and changes in body weight. The food history should include the name of the

Box 27-1. Feeding History and Food Records.

A quantitative food record can provide important information for use in a weight-loss program. Knowledge of total calories being consumed can be used to determine the amount to feed for weight loss. The process of a pet owner providing a feeding history to a veterinary health care team can help with compliance to a weight-loss program by making pet owners aware of all the sources of calories that could conceivably contribute to the pet's overweight condition.

The food record should include amounts of all foods and account for all calories the patient consumes. Caloric content of commercial pet foods and treats can be obtained from the manufacturer or calculated (Chapter 1). Tables 13-4 (dogs) and 20-4 (cats) list caloric content for several commercial foods. Most packaged human foods include caloric content on the label. The clinical cases at the end of this chapter demonstrate the utility of a quantitative food record for determining appropriate amounts of food for achieving weight loss.

The owner's quantitative descriptions of how much pet food, how many treats and access to table food and consumable chew toys must be evaluated. Terms such as "bowls," "cups" and "handfuls" reported by owners come in all sizes; thus, the amount of food and calories these objects can hold varies as well. The veterinary nutritionist's "cup" is a standard 8-oz. volume measure. The amount of dry dog or cat food reportedly fed by owners needs to be converted to this standard or to weight (as fed) for accurate determination of caloric intake. Treats, consumable chew toys and table food can supply significant calories, especially if the owner is unaware of their caloric content or how many the animal eats daily.

Whether the pet has access to any other sources of food also needs to be determined. Other sources include other pets' food in multi-pet households. Having multiple people feed the pet can result in multiple sources of food, particularly if different people have different opinions about the body condition of the pet. The previous two situations can condemn a weight-reduction program to failure before it ever begins if the owner cannot, or will not, feed the overweight pet separately and keep the overweight pet from eating other pets' food. Dogs and cats that roam unsupervised also have the opportunity to obtain other sources of food.

If an owner insists on feeding treats to a pet entering a weight-loss program, the number can be controlled by placing a specific quantity of treats containing the number of calories reserved for treats in a "treat container" each day. No additional treats are allowed for that day after the treat container is empty.

food, its form and how much is fed. Also, it should be determined whether commercial treats and/or table foods are fed and if so, how much. Accurate accounting of the total amount of food (calories) fed can be very important in the development of a feeding plan for weight loss (**Box 27-1**). It is also important to know what feeding methods are used for the pet and who feeds and/or provides treats. Most owners supplement their pets' food regimen with treats and/or table foods (Buffington et al, 2004).

Determining the Degree of Overweight and Ideal Body Weight

Determining whether a cat or dog is overweight is usually not difficult. However, accurately determining the degree of overweight and the patient's ideal weight can be challenging. In the clinical setting, the subjectivity inherent in determining the degree of body fat makes irrefutable, objective measurement difficult. This subjectivity results from variation in body conformation across breeds, variation of frame size within breeds, especially for dogs and the veterinarian's and owner's bias for what constitutes a patient's ideal body weight and conformation. For example, most dog and cat owners underestimate their pet's body condition (Singh et al, 2002; Allan et al, 2000). Even veterinarians overlook obesity (Lund et al, 1999). There is no ideal, definitive method for deciding whether a dog or cat is in a thin, ideal, overweight or obese body condition. In reality, a continuum exists from emaciation to morbid obesity, making absolute definitions and divisions arbitrary.

Clinically, it is important to assess body condition of cats and dogs objectively. The ability to assess body condition is necessary to determine when a dog or cat is likely to benefit from weight loss, and to substantiate a diagnosis of obesity for the patient's owners and convince them that their pet needs to lose weight. Radiographic and ultrasound images can be used to help convince an owner his or her pet is overweight (**Box 27-2**); however, these aids do not quantify the degree to which a pet is overweight. Quantifying excess body weight and determining ideal body weight are essential to the effectiveness of a weight-loss program. The most practical method for making these determinations is body condition scoring.

BODY CONDITION SCORING

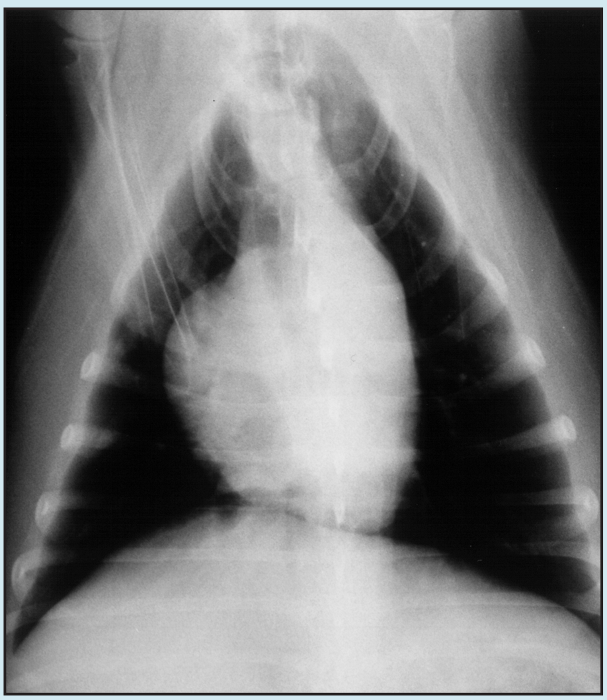
The BCS is a subjective assessment of an animal's body fat, and to lesser extent its protein stores, that takes into account the animal's frame size independent of its weight. Scoring systems using defined criteria help objectify the process, but cannot remove all subjectivity involved in assigning a score to a given patient. Body condition scoring like other physical examination techniques is a learned skill. Within the range of defined criteria, the scorer still must learn by experience what visual and palpable characteristics correspond with a given BCS. Standardization of scores between observers scoring a given animal can be problematic. What one scorer feels to be an excessive amount of fat covering the ribs, another scorer may assess as appropriate. However, once learned, body condition scoring is a reliable indicator for determining the proportion of body fat or body composition (Mawby et al, 2004; Laflamme, 1993, 1997, 1997a; Laflamme et al, 1994; Graham et al, 1982; Croxton and Stollard, 1976).

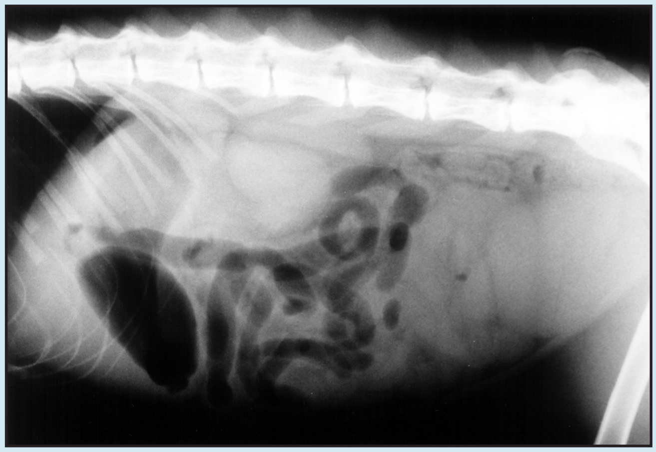
Different body condition scoring systems for dogs and cats

Box 27-2. Other Diagnostic Procedures.

Radiographic or sonographic images can often help an owner appreciate the degree of excess fat deposited subcutaneously or intra-abdominally, particularly when viewed next to radiographs or sonograms of similar size animals that are in optimal body condition (**Figures 1A** and **B** and **2A** and **B**). However, radiographs should not be taken solely for diagnosing obesity. Many veterinary schools now have dual energy x-ray absorptiometry, which can be effectively used for weight-reduction/maintenance programs.

Figures 1A and 1B. Ventrodorsal radiographs of a normal dog (BCS 3/5, above) and an obese dog (BCS 5/5, below). Compare the body wall thickness of the two dogs.





Figures 2A and 2B. Lateral abdominal radiographs of a normal cat (BCS 3/5, above) and an obese cat (BCS 5/5, below). Note the enlarged abdomen and ventral fat deposition in the obese cat.

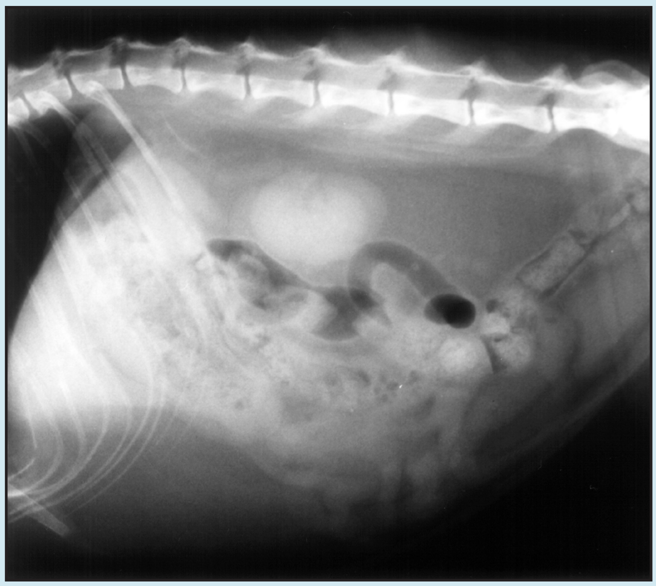


Table 27-3. Relationships between body condition score (BCS; 5-point system) and actual body weight, ideal body weight, resting energy requirement (RER; kcal metabolizable energy [ME]/day) and estimated percent body fat (%BF). Actual body weight and BCS can be used to estimate a patient's ideal weight* and associated RER, which can be further used for determining the amount of food to feed for weight loss.

BCS	**%BF**	**BCS**	**%BF**	**BCS**	**%BF**
5	**≥40**	**4**	**30**	**3**	**20**

*The formula used to derive the relationship between body weight and BCS is described in **Box 27-3**.

Example: A 32-kg dog has a BCS of 4/5. What is its ideal weight and associated RER and approximate %BF?

1. Find the closest value for its current body weight (31.7 kg) in the row for BCS 4/5.
2. Locate the corresponding body weight for BCS 3/5 (ideal weight) in the same number column. In this case it is 27.8 kg.
3. Below the ideal body weight of 27.8 kg, find the RER value for that weight; in this case it is 846 kcal/day (to convert to kJ, multiply kcal by 4.184).
4. At its current BCS (4/5), the dog's approximate %BF is 30.

contain from three to nine categories for body condition and have been assessed to different extents for precision, accuracy and repeatability (Armstrong and Lund, 1996; Mason, 1970; Edney and Smith, 1986; Scarlett et al, 1994; Joshua, 1970; Laflamme et al, 1994, 1995; Burkholder, 1994; Laflamme, 1993). Chapter 1 presents a 5-point body condition scoring system in detail. Systems with either five or nine categories are used most commonly. A 5-point system scored to the nearest half score and a 9-point system scored to the nearest whole score each have nine total scores for body condition. A 5-point system scored to the nearest half score subdivides into three categories each for insufficient, ideal and excess body conditions, with a score of 3.0 falling in the middle of the optimal range.

In general, dogs and cats in ideal body condition have: 1) normal body contours and silhouettes, 2) bony prominences that can be readily palpated but not seen or felt above skin surfaces and 3) intraabdominal fat insufficient to obscure or interfere with abdominal palpation. The most critical division points in a 5-point system are between the scores of 2.0 vs. 2.5 and 3.5 vs. 4.0, because assignment of a BCS less than 2.5 or greater than 3.5 suggests action should be taken to return the patient's BCS to the optimal range. These same criteria (i.e., what contours are absent that otherwise should be present and what bony prominences should be easily felt but are not readily palpable) can be demonstrated to the patient's owner as part of the educational process to obtain agreement that the patient needs to lose weight.

BCS and body weights should always be recorded in the hospital record whenever a veterinarian or another health-care team member examines a patient. An accurate estimate of the patient's ideal weight is important for a successful weight-loss program. Deciding on an optimal weight can be problematic for the veterinarian and the pet owner, especially if the two disagree. However, after a patient's BCS has been determined, its ideal body weight can be estimated using **Table 27-3**. This is done by locating the patient's body weight for the BCS determined during the physical examination and finding the

patient's corresponding body weight for its ideal BCS (3/5) on the table.

BCS can also be used to estimate %BF because body condition can be defined as the ratio of fat to nonfat tissues (Murray, 1919). If 15 to 20% body fat is accepted as optimal for dogs and cats, then a patient with a BCS of 3 out of 5 (3/5) should have between 15 to 20% body fat. Research to critically assess the capability of BCS to predict body composition suggests that %BF changes by roughly 10% for each change in BCS on a 5-point scale (or 5% on a 9-point scale) (Laflamme et al, 1994; Laflamme, 1997, 1997a). Using the upper end of the range of %BF (20% body fat) for dogs and cats with a BCS of 3/5, a BCS of 4/5 correlates with approximately 30% body fat and a BCS of 5/5 correlates with 40% (or more) body fat (**Table 27-3**). Thirty percent body fat (BCS 4/5) is similar to the critical %BF for assessing when people are at risk for ill effects from being overweight. Most studies critically assessing the precision of BCS against some criterion measure of body fat indicate that %BF is estimated with a standard deviation of ± 4 to 5% (Laflamme et al, 1994; Burkholder, 1994; Laflamme, 1993; Graham et al, 1982; Croxton and Stollard, 1976).

One misconception that could arise about body condition scoring is the implication that some maximum amount of body fat corresponds to the maximum BCS. BCS have a maximum upper number assigned to the fattest animals used to define the scoring criteria, which consequently is associated with the mean %BF of those animals. However, the maximum amount of body fat compatible with life is unknown and is very likely more than the approximate value of 40% body fat of all dogs or cats with a BCS of 5/5. The correct interpretation for %BF based on assigning a maximum BCS should be that the animal has at least 40% body fat, but the %BF could be considerably higher. **Box 27-3** reviews obesity classification in people and proposes a similar method be considered for obese dogs and cats.

OTHER METHODS

Although not as practical as BCS, other means exist to determine whether a dog or cat is at optimal weight, overweight or obese. These include ultrasound, morphometric analysis and methods that are currently too expensive or otherwise impractical for use in private practice.

Ultrasound has been used to estimate back fat thickness in livestock including swine, cattle, sheep, horses and ponies. Ultrasound has also been used in people to determine %BF (Stouffer, 2004). Because ultrasound is routinely used as a diagnostic tool in small animal medicine, it has potential for determining %BF in dogs and cats. In combination with specific morphometry, it predicts %BF in beagles (Yamka et al, 2007).

%BF can also be estimated with morphometry (i.e., measurement of form). Morphometric analyses are routinely used in people to estimate body composition and %BF from measurements of various anatomic circumferences and lengths (Houmard et al, 1991; Weltman et al, 1987, 1988; Davis et al, 1985). The success for measurements made in specific locations to estimate overall body composition depends on correlation of measurements to total body composition. In people, BMI is practical because of the small range of body types. Even in people, the accuracy of BMI is influenced by differences in bone size. However, because of the immense diversity of body types within the canine species (e.g., English bulldog vs. greyhound), the use of morphometric analysis to estimate body fat requires more measurements and complex math to provide reasonable estimates of body fat than it does in people. Furthermore, fat is deposited in slightly different body sites in cats compared to dogs. Cats store most of their fat subcutaneously along their ventral abdomen, in their faces and intra-abdominally. Dogs deposit significant amounts of fat intra-abdominally and subcutaneously in thoracic, lumbar and coccygeal areas.

Methods for morphometric analysis of dogs and cats have been determined (Laflamme et al, 2001; Burkholder, 1994; Stanton et al, 1992). Besides the shortcomings mentioned above of using this technology in dogs and cats, repeatability is a concern. Differences in measurements occur due to: 1) variations in coat thickness, 2) operator variability (i.e., tension on the tape measure), 3) operator variability in determining the precise location of anatomic landmarks for measurement and 4) patient restraint, particularly in cats. Cats usually require anesthesia to obtain accurate measurements (Burkholder and Toll, 2000).

Weight at the time the dog or cat reaches adult age is often a good indicator of optimal weight if body condition assessments are unavailable. However, weight at maturity may not automatically be optimal if the animal was underfed or overfed during growth. For most dogs and cats, maturity occurs around 12 months of age. Giant-breed dogs, however, may require up to 18 months to reach mature adult weight.

For purebred dogs, determining optimal weight from published optimal weights by breed is often not accurate enough for an individual within a breed. A similar approach has been considered for cats based on body type and the fact that cats have less variability of body weights than dogs (Burkholder and Toll, 2000). Neither method is accurate enough to be used routinely as the basis for an effective weight-reduction feeding plan. Appendices 14 and 15 list proposed optimal weights for dog breeds by gender based on data from the American Kennel Club and other sources.

There are multiple methods that vary widely in cost, sophistication and precision for estimating %BF in people (Brodie, 1988, 1988a; Lukaski, 1987). Some are used for determining %BF in dogs and cats in research settings. Several methods are available for determining body composition, and thus, %BF: 1) magnetic resonance imaging, 2) computed tomography, 3) neutron activation, 4) hydrodensitometry, 5) total body water by isotope dilution, 6) total body potassium, 7) ultrasound, 8) bioelectrical impedance and 9) dual energy x-ray absorptiometry (Brodie, 1988, 1988a; Lukaski, 1987). Unfortunately, at this time, most of these methods are impractical for use in private veterinary hospitals.

Box 27-3. Proposed Refinement of Body Condition Score (BCS) Classification of Obese Dogs and Cats (BCS 5/5).

In people, body mass index (BMI) is a very useful tool for classifying the degree of overweight and obesity. Furthermore, BMI is related to the risk for the development of diseases associated with obesity, because BMI, which describes relative weight for height, is significantly correlated with body fat content. BMI is calculated by dividing body weight (kg) by height squared (m^2). The resultant BMI value is not the same as percent body fat. In people, **Table 1** is used for classification of overweight and obesity, by BMI.

The rationale behind these definitions is based on epidemiologic data that show increased mortality with BMIs greater than 25. The increase in mortality, however, tends to be modest until a BMI of 30 is reached. For persons with a BMI greater than 30, mortality rates from all causes, but especially from cardiovascular disease, are generally increased by 50 to 100% above that of people with BMIs in the range of 20 to 25. For people with BMIs greater than 35 (obesity II) and 40 (extreme obesity), mortality rates are further increased.

BMI has not been determined for dogs and cats. Morphometric measures established for companion animals are similar but much more complicated to obtain and therefore, less reliable.

Assessing BCS combined with data from **Table 27-3** (See text.) is a simple and reliable method for determining the degree of overweight and obesity in dogs and cats. However, after a patient reaches a BCS of 5, there is potential for considerable variability regarding how obese the patient could be. Thus, as for obesity classifications in people using BMI, the BCS 5/5 (>40% body fat) could be further categorized to indicate degrees of obesity in cats and dogs. **Table 2** presents such a proposed classification.

The added dimension of BCS 5/5 subcategories 5 (a,b,c) would better define the degree of obesity and could be used to improve the estimation of ideal weight in very obese and extremely obese patients, which could lead to a more appropriate amount of food to feed these patients for weight loss.

The discrepancy in food dosage that can result from whether a patient with a BCS of 5/5 has 40% body fat or 60% body fat is significant. For example, if a patient has 40% body fat and a current (obese) weight of 30 kg, its estimated ideal (target) weight would be 22.5 kg and its estimated resting energy requirement (RER) would be 745 kcal/day. However, a 30-kg patient with 60% body fat would have an ideal weight of 15 kg and its RER would be 520 kcal/day; a considerable difference of 225 kcal/day (**Table 27-3** and **Table 3**).

However, currently there are no descriptive and/or visual standards for subdividing the obese category of either the 5-point or 9-point systems. Until such tools are developed, the initial phases of weight-loss programs should be closely monitored and further restrictions of caloric intake should be instituted if weight loss does not occur within two weeks (**Figure 27-1**). Underestimation of percent body fat and resultant overestimation of ideal weight can be problematic when designing weight-loss programs for extremely obese patients.

Topeka, KS, USA

Table 1. Human overweight and obesity classifications.

Class	Obese class	BMI (kg/m^2)
Underweight	-	<18.5
Normal	-	18.5 to 24.9
Overweight	-	25.0 to 29.9
Obesity	I	30.0 to 34.9
	II	35.0 to 39.9
Extreme obesity	III	≥40

Table 2. Proposed classification scheme for BCS and degrees of obesity in companion animals.

Class	BCS	Body fat (%)
Very thin	1	<5
Underweight	2	10
Normal	3	20
Overweight	4	30
Obese	5(a)	40
Very obese	5(b)	50
Extremely obese	5(c)	≥60

Table 3. The ideal weight formula used to develop the body weights in **Table 27-3** and in the examples above.

Ideal weight = current weight x (100 - percent body fat [%BF]) ÷ 0.80

The assumptions and definitions used to derive this formula include:

a) Current weight (overweight due to excess adipose tissue); obtain by weighing patient
b) Body weight = fat mass + lean body mass (LBM)
c) LBM is constant between ideal and current weights
d) %BF can be estimated from BCS
e) Ideal %BF = 20%; thus, ideal LBM = 80%
f) %LBM = 100 - %BF
g) Ideal weight = LBM ÷ 0.80
h) LBM = current weight x %LBM

The steps for deriving the formula include:
Ideal weight = current weight (100 - %BF) ÷ 0.80

a) If ideal weight = LBM (g)* ÷ 0.80
b) And if LBM = current weight x %LBM (h)*
c) Then, ideal weight also = current weight x %LBM ÷ 0.80
d) And if %LBM also = 100 - %BF (f)*
e) Then ideal weight also = current weight (100 - %BF) ÷ 0.80

*Letters refer to the assumptions and definitions immediately above.

Etiopathogenesis and Risk Factors

Energy Balance and Body Composition Control

Positive energy balance results when consumption of calories exceeds daily energy expenditure. This may result from energy intake increases and/or energy expenditure decreases. When positive imbalance is sustained, excess energy is stored in adipose tissue and overweight or obese body conditions develop due to excess body fat. An understanding of the components that contribute to the energy input side of the equation (i.e., the daily energy requirement [DER]), explains why animals of similar body weight and frame size can have different caloric requirements independent of genetics or neuter status. Understanding DER components simplifies the rationale behind recommendations and alterations made to correct obesity. Multiple components contribute to DER. The DER to maintain body weight of an animal can be subdivided into: 1) resting energy requirement (RER), 2) exercise energy requirement (EER), 3) thermic effect of food (TEF) and 4) adaptive thermogenesis (AT). In people, RER correlates closely with lean body mass and accounts for 60 to 80% of the total DER for adult maintenance (Danforth, 1985; Horton, 1983; Wilson, 1990). RER represents energy used to maintain normal physiologic functions at rest in a thermoneutral environment several hours after eating (Horton, 1983). Very little energy is required to maintain adipose tissue.

EER is the energy expended for muscular activity. The contribution of EER to DER is determined by the animal's body weight plus the duration and intensity of muscular activity. Animals that are less active or have little opportunity to exercise expend less energy compared with active animals of similar size. EER can account for 10 to 20% of total daily energy expended by nonathletic people (Danforth, 1985).

TEF represents the obligatory cost of digesting and absorbing food. TEF constitutes approximately 10% of total expenditure and is affected by food composition and the number of meals eaten per day (Danforth, 1985; Horton, 1983). The obligatory cost associated with digesting and absorbing each meal is the reason weight-reduction programs recommend multiple small meals per day rather than one or two large meals. RER, EER and TEF make up the majority of DER; thus, these are the components that can be manipulated to affect the amount and rate of weight loss.

AT makes up the smallest proportion of the DER for most pets. AT is the energy expended to regulate body temperature during exposure to ambient temperatures below or above the thermoneutral zone or during transient periods of excess caloric consumption.

Most dogs and cats maintain an ideal, constant body weight due to a complex system of neural, hormonal and biochemical mechanisms that keep the balance between energy intake and expenditure within fairly precise limits (**Boxes 27-4** and 25-2) (Druce and Bloom, 2003). Thus, under normal circumstances, homeostatic mechanisms control energy intake and maintain body composition at or near some "set point." Set point can be defined as the physiologic regulation of energy balance that maintains stable body condition. When certain abnormal conditions are imposed on these set point mechanisms, positive energy balance occurs and excess body fat accumulates. Several of these risk factors are discussed below.

Box 27-4. Central Regulators of Food Intake and Energy Balance.

Numerous feedback mechanisms exist to control eating and energy stores (Box 25-2). These mechanisms are designed to store energy as fat when energy sources are plentiful so animals can survive when food is not readily available (famine or hibernation). Three regulators of food intake and energy balance that have received attention recently include neuropeptide Y (NPY), leptin and ghrelin.

NPY is a hypothalamic hormone; its synthesis increases when an animal is deprived of food. Repeated injections of NPY into the brain results in consumption of larger meals, weight gain and obesity.

Leptin is a polypeptide hormone synthesized by white adipose tissue and secreted into the bloodstream. Leptin regulates energy intake, energy expenditure and acts at the hypothalamus to reduce synthesis of NPY, thereby down regulating food intake. Leptin secretion is proportional to the amount of lipid stored in adipocytes. As a result, serum leptin concentrations are highly correlated with obesity in rodents, dogs, cats and people.

The obese gene ("ob gene") codes for leptin and is absent in one strain of genetically obese mice ("ob mice"), thus this mouse strain readily becomes obese. Long-term treatment of ob mice with exogenous leptin causes a decline in eating and is associated with loss of body weight. In dogs, leptin injections resulted in decreased food intake and body weight. The reduction in body weight and food intake in both species is believed to be an attempt by the animal to limit weight gain.

Ghrelin is a gastric peptide and a secretagogue of growth hormone. Ghrelin controls feeding behavior, energy homeostasis, gastric acid secretion and gastric motor activity and is essential for growth hormone release. Ghrelin levels increase during fasting and decline shortly after eating. In obese dogs and cats, ghrelin and leptin levels are inversely related. The lower ghrelin levels observed in obese animals likely result from down regulation of this peptide due to excess energy storage.

The Bibliography for **Box 27-4** can be found at www.markmorris.org.

Risk Factors

Several risk factors contribute to positive energy balance and affect the body's compositional set point. They can be grouped under the headings of genetic and environmental. Although genetic risk factors make it easier for positive energy balance and obesity to develop, environmental risk factors dictate the expression of that potential and, thus, the overweight/obesity condition. Although the greater opportunity for intervention is in managing environmental risk factors, the opportunity for prevention includes management of both. Prevention of obesity is critical (Chapters 13 through 17 and

Box 27-5. Lipoprotein Lipase and Obesity Recurrence.

Following weight loss of an obese patient, weight regain is likely if there is not strict adherence to appropriate diet and exercise programs. This may be due in part to the change in lipoprotein lipase (LPL) activity.

After digestion and absorption, dietary fat is transported to adipose tissue via chylomicrons. LPL is an enzyme located in the capillaries of body fat and facilitates removal of dietary fat (triglycerides) from the chylomicrons in the bloodstream and its entry through capillary walls into adipocytes. LPL hydrolyzes triglycerides into free fatty acids and glycerol. Fatty acids enter adipocytes, where they are re-esterified into triglycerides and stored. When needed by other body cells for energy, stored triglycerides are hydrolyzed once again to fatty acids and glycerol by hormone sensitive lipase (HSL) and reenter the circulation.

LPL increases during periods of weight gain in both obese and non-obese people. After weight is lost, LPL returns to normal levels in non-obese people; however, in obese patients that have lost weight, LPL increases. This increase is probably one of the factors contributing to the rapid weight regain that is common in obese human patients and could also be a culprit in weight regain in previously overweight dogs and cats.

The Bibliography for **Box 27-5** can be found at www.markmorris.org.

20 through 24); weight loss is more difficult after body fat is gained and maintained (Laquatra, 2000) (**Box 27-5**). Under these conditions, the body essentially has a new set point. All risk factors should be understood if obesity is to be prevented and treated effectively.

Genetics

Obesity in people has a large propensity for being heritable, accounting for 37 to 40% of BMI (Coady et al, 2002). Genetics likely determine the concentration and activity of various metabolic regulators, their receptors and, thus, metabolic efficiency (Bogardus et al, 1986; Campfield et al, 1995; Halaas et al, 1995; Pelleymounter et al, 1995). Various genetic factors also influence the risk of obesity in dogs; breed accounts for 30 to 70% of the risk (Buffington et al, 2004). Some breeds are more likely to be overweight. Breed prevalence within a geographic area influences the prevalence of obesity in specific breeds. Labrador retrievers, golden retrievers, Cairn terriers, cocker spaniels, long-haired dachshunds, Shetland sheepdogs, basset hounds, cavalier King Charles spaniels, pugs, Dalmatian dogs and beagles have a greater prevalence of obesity than other breeds (Mason, 1970; Edney and Smith, 1986; Lund, 2007). In contrast to dogs, cats of mixed breeding are more likely to be obese than purebred cats (Scarlett et al, 1994). These findings suggest that genetics influence body condition set points and the tendency for weight gain or loss in dogs and cats.

Certain genes appear to be related to obesity. Compared to lean beagles (BCS 2.2/5), overweight beagles (BCS 4.3/5) had higher expression of genes associated with fatty acid metabolism, purine metabolism and platelet-derived growth factor signaling. In addition, the overweight beagles had lower expression of genes associated with nucleotide metabolism, carbohydrate metabolism, peroxisome proliferator-activated receptor signaling, insulin-like growth factor-1 signaling, insulin receptor signaling, amino acid metabolism, branched-chain amino acid degradation and lipid metabolism (Yamka et al, 2007a).

Food and Feeding

Specific attributes of foods and how foods are fed can overwhelm normal body condition set point systems and result in positive energy balance. Such food attributes include palatability and energy density. Feeding methods that further aggravate food attributes include how much is fed and how it is offered (e.g., free-choice feeding of highly palatable, energy-dense foods).

Food palatability is a highly competitive attribute in the pet food industry. Feeding pets and watching them eagerly eat is part of the pleasure people derive from having pets and apparently contributes to the human-animal bond. Palatability is also an attribute that owners perceive reflects a food's quality. Thus, pet food companies continuously strive to improve the palatability of their food, because having a highly palatable food is a competitive advantage. If the amount of a highly palatable food isn't limited, it stands to reason that a pet is more likely to overeat. Normal body condition set point systems may not have been designed to deal with some of the highly palatable foods that exist today.

Caloric density of a food is primarily a function of its dietary fat content. On a weight basis, in typical commercial pet foods, dietary fat provides 8.5 kcal (35.6 kJ) metabolizable energy (ME)/g compared to 3.5 kcal (14.6 kJ) ME/g for carbohydrate and protein. Most of the lipid in fat cells comes directly from dietary fat. In general, the fatty acid composition of body fat mirrors the fatty acid composition of the food (Laquatra, 2000). Conversely, inclusion of dietary fiber, water or air can decrease caloric density by taking up space in the food while providing few to no calories.

One study found no difference in types of food given to overweight pets compared with foods given to those in optimal body condition (Edney and Smith, 1986). Other studies demonstrated an increased risk for being overweight when certain food categories were fed (Mason, 1970; Scarlett et al, 1994). In these studies, all of the associated foods, whether commercial or home prepared, were considered calorically dense, although caloric density per se was not the variable tested for increased risk of being overweight.

Free-choice feeding can also contribute to excessive caloric intake. Feeding unlimited amounts of highly palatable, energy-dense foods to dogs and cats may encourage energy consumption that exceeds requirements, particularly if a genetic predisposition exists. Likewise, excessive use of treats or substitution of food (and treats) for other types of interaction between the owner and pet may also encourage excess energy intake.

Determining amounts to feed based on manufacturer recom-

mendations may also lead to excessive caloric intake. This results not because manufacturers make inappropriate or self-serving recommendations, but rather because manufacturers base recommendations on ranges and average caloric requirements for a given body weight. Recommendations often list a minimum and maximum amount of food to feed within a given range of body weights (e.g., two to four cups for a 5.9- to 11.4-kg dog). The maximum amount can be one and one-half to four times the minimum amount listed for a given range of body weights. Excess caloric intake can occur if pet owners interpret that a smaller dog should be fed the larger amount. Furthermore, excess caloric intake can occur because pet owners overestimate the activity of their pet. Many pets today are relatively inactive due to the lifestyle of their owners. (See Activity below.) Also, cat and dog owners underestimate the body condition of their pets (Singh et al, 2002; Allan et al, 2000), increasing the likelihood that pets will be overfed.

Activity

Many pets, particularly cats, live indoors, which is often associated with reduced physical activity. Physical activity is the most variable component of energy expenditure. Adequate exercise can contribute markedly to daily energy expenditure. Furthermore, the risk of obesity decreases with each hour of weekly exercise in dogs (Robertson, 2003). Thus, it is not surprising that animals with decreased activity or restricted opportunities for exercise are at greater risk for becoming overweight (Scarlett et al, 1994). Unfortunately, most owners consider their dogs to be moderately or very active (Slater et al, 1995).

Caloric intake can also become excessive if changes occur in a pet's lifestyle or daily routine that markedly reduce activity without reducing calories. Such changes include moving to smaller dwellings, musculoskeletal injuries and diseases that require persistent long-term use of central nervous system depressants or corticosteroids.

Age

Caloric requirements decrease as some animals age. Requirements for a given weight are less for maintenance of adults than for growing individuals of similar weight. Age has been correlated with the prevalence of excess body weight in dogs and cats (Armstrong and Lund, 1996; Mason, 1970; Scarlett et al, 1994; Sloth, 1992; Kronfeld et al, 1991). Dogs and cats have the highest prevalence of obesity from five to 11 years of age (Lund et al, 2005, 2006). After about 12 years of age, the prevalence tends to decrease markedly in most cross-sectional studies (Armstrong and Lund, 1996; Scarlett et al, 1994; Sloth, 1992; Kronfeld et al, 1991). These observations have bearing on two theories concerning obesity and aging. First, one theory suggests that aging causes a decrease in energy requirement as a result of concomitant loss of lean body tissue and that obesity will result if energy intake fails to decrease. Except for one study (Mason, 1970), the data from other cross-sectional studies appear not to support this theory on initial examination (Armstrong and Lund, 1996; Scarlett et al, 1994; Sloth, 1992; Kronfeld et al, 1991). Instead, dogs and cats 12 years of age or older become thinner and tend to be in less than optimal body condition (Armstrong and Lund, 1996; Scarlett et al, 1994; Kronfeld et al, 1991).

However, an alternate hypothesis suggests that overweight dogs and cats die sooner and do not reach ages attained by thinner animals because excess weight is detrimental to overall health (Armstrong and Lund, 1996). Caloric consumption has been inversely related to lifespan of dogs (Kealy et al, 2002), rodents (Masoro, 1984, 1988, 1992) and rhesus monkeys (Lane et al, 1997). Cats may be similarly affected.

Gender and Neuter Status

Small differences in body composition and energy intake between intact male and intact female cats have been reported (NRC, 1986; Jewell et al, 1996). The differences in energy intake appear to be due to gender-related differences in lean body mass (Jewell et al, 1996; Klausen et al, 1997).

No controlled studies have been done in dogs to measure differences between energy requirements of intact males compared to intact females. As in other mammals (e.g., cats) intact females probably require less caloric intake than intact males. This assumption is probably due to gender-related differences in lean body mass. The lean body mass of an animal accounts for nearly all of its RER (Blaxter, 1989).

One study showed that female dogs had an average of 16% more body fat than male dogs (Meyer and Stadtfeld, 1980). These findings suggest that intact female dogs need fewer calories than intact male dogs. Surveys found a much higher prevalence of overweight and obese female than male dogs (Edney and Smith, 1986; Mason, 1970).

Neutering increases the risk of obesity in dogs and cats (Jeusette et al, 2006; Lund et al, 2005; McGreevy et al, 2005; Kanchuk et al, 2003; Scott et al, 2002; Martin et al, 2001; Harper et al, 2001; Robertson, 1999; Fettman et al, 1997; Root et al, 1996). Neutered cats are more likely to be overweight than are intact cats of either gender (Scarlett et al, 1994; Root and Johnston, 1995; Flynn et al, 1996). Neutered female dogs are about twice as likely to be overweight than are intact female dogs (Edney and Smith, 1986). A similar trend occurs in castrated male dogs (Edney and Smith, 1986). Neutering predisposes dogs and cats to weight gain and eventual obesity for several reasons. Neutered cats had resting metabolic rates 20 to 25% below those of intact cats of similar age, as measured by indirect calorimetry (Root et al, 1996). In practical terms, this finding indicates that neutered cats require only 75 to 80% of the food needed by intact cats to maintain optimal body weight. These studies confirm the previously suspected decrease in metabolic rate caused by loss of estrogens and androgens from neutering. This reduction in resting metabolic rate appears to be in addition to any decrease in physical activity that might occur from decreased roaming and sexual behavior (Hart and Barrett, 1973; Hopkins et al, 1976).

Furthermore, estrogens suppress appetite in several animal species (Czaja and Goy, 1975). Neutered female beagles and cats will eat more food and gain more weight than sham-operated females fed an identical food (Flynn et al, 1996; Houpt et

Table 27-4. Key nutritional factors for calorie-restricted dog foods for weight loss and prevention of weight regain.

Factors	Dietary recommendations (dry matter basis)
Energy density	Foods for weight loss and prevention of weight regain should contain ≤3.4 kcal (≤14.2 kJ) metabolizable energy (ME)/g
Fat	Foods for weight loss should contain ≤9% Foods for prevention of weight regain should contain ≤14%
Fiber	Foods for weight loss should contain 12 to 25% Foods for prevention of weight regain should contain 10 to 20%
Protein	Foods for weight loss should contain ≥25% Foods for prevention of weight regain should contain ≥18%
Lysine	Foods for weight loss should contain ≥1.7%
Carbohydrate	Foods for weight loss should contain ≤40% Foods for prevention of weight regain should contain ≤55%
L-carnitine	Foods for weight loss and prevention of weight regain should contain ≥300 ppm
Antioxidants	Foods for weight loss and prevention of weight regain should contain:
Vitamin E	≥400 IU vitamin E/kg
Vitamin C	≥100 mg vitamin C/kg
Selenium	0.5 to 1.3 mg selenium/kg
Sodium	Foods for weight loss and prevention of weight regain should contain between 0.2 to 0.4%
Phosphorus	Foods for weight loss and prevention of weight regain should contain between 0.4 to 0.8%

Table 27-5. Key nutritional factors for calorie-restricted cat foods for weight loss and prevention of weight regain.

Factors	Dietary recommendations (dry matter basis)
Energy density	Foods for weight loss should contain ≤3.4 kcal (≤14.2 kJ) metabolizable energy (ME)/g Foods for prevention of weight regain should contain ≤3.8 kcal (≤15.9 kJ) ME/g
Fat	Foods for weight loss should contain ≤10% Foods for prevention of weight regain should contain ≤18%
Fiber	Foods for weight loss should contain 15 to 20% Foods for prevention of weight regain should contain between 6 to 15%
Protein	Foods for weight loss and prevention of weight regain should contain ≥35%
Carbohydrate	Foods for weight loss should contain ≤35% Foods for prevention of weight regain should contain ≤40%
L-carnitine	Foods for weight loss and prevention of weight regain should contain ≥500 ppm
Antioxidants	Foods for weight loss and prevention of weight regain should contain:
Vitamin E	≥500 IU vitamin E/kg
Vitamin C	100 to 200 mg vitamin C/kg
Selenium	0.5 to 1.3 mg selenium/kg
Sodium	Foods for weight loss and prevention of weight regain should contain between 0.2 to 0.6%
Phosphorus	Foods for weight loss and prevention of weight regain should contain between 0.5 to 0.8%

al, 1979). Thus, removal of the metabolic effects of estrogens and androgens by gonadectomy may lead to increased food consumption, when at the same time the animal's energy requirement is lower because of its decreased metabolic rate and physical activity.

Thus, prudent postneutering feeding recommendations for young adult dogs and cats include: 1) feeding low-calorie foods or restricted feeding of regular foods (three-fourths of previous amount) and 2) obtaining body weight and BCS every two weeks for four or five months after neutering to ensure maintenance of normal body weight and condition.

Viral Infections

To date, eight viruses have been shown to cause obesity in animals (Atkinson, 2008). Several viruses cause obesity in laboratory animals (Dhurandhar, 2001). Canine distemper virus can disrupt hypothalamic function and down regulation of genes for melanin production, causing obesity (Verlaeten et al, 2001). Adenoviruses have been associated with viral-induced obesity in people, monkeys, chickens, mice and rats (Atkinson, 2007).

Key Nutritional Factors: Calorie-Controlled Foods for Weight Loss and Prevention of Weight Regain in Dogs and Cats

The traditional method to achieve weight loss in overweight pets and to prevent regain of lost weight is to feed calorie-restricted foods. Such foods should provide amounts of the key nutritional factors listed in **Tables 27-4** (dogs) and **27-5** (cats). Key nutritional factors are described in more detail below.

Energy Density

Decreasing the daily caloric intake of overweight dogs and cats is the primary strategy for producing weight loss and subsequently maintaining reduced body weight. Most typical maintenance-type pet foods are nutritionally balanced according to their energy density and the expected intake required to support a given body weight. If energy restriction is attempted by simply reducing the amount of the maintenance food currently being fed, the intake of all nutrients is restricted, not just energy. A deficiency in energy and other nutrients can occur if the amount of a maintenance food being fed is markedly decreased to produce weight loss.

A better approach is to use an energy-restricted food. A properly formulated restricted-calorie food will be replete in all nutrients except energy so that protein, essential fatty acids, vitamins and minerals are present in amounts sufficient to support normal physiologic processes and retention of lean body tissue, even when calorie intake is insufficient to maintain body weight. The goal of a weight-management food should be to restrict only energy, not other nutrients.

Thus, foods sufficiently restricted in energy content are more suitable for weight management. Pet foods marketed as restricted in calories can vary widely in caloric content, including the proportion of nutrients contributing calories, fiber and digestibility. Regulatory definitions for the terms "light," "lean," "reduced calorie" and "reduced fat" have been implemented in the United States (**Box 27-6**).

For optimal performance, the energy content of dog foods for weight loss and prevention of weight regain should be no

Box 27-6. Regulatory Definitions for Descriptive Terms Indicating Restricted Calories or Fat.

Model Pet Food Regulation PF10 of the Association of American Feed Control Officials (AAFCO) defines limits and labeling requirements for claims related to restricted calorie and fat content. The regulation was implemented in the United States in January 1998.

Maximum calories or fat allowed for "light" or "lean" claims depending on moisture content and intended species*

	Dry foods (<20% moisture)	**Semi-moist foods** (20 to <65% moisture)	**Moist foods** (≥65% moisture)
		Dogs	
Light (also "lite," "low calorie")	3,100 kcal ME/kg as fed	2,500 kcal ME/kg as fed	900 kcal ME/kg as fed
Lean (also "low fat")	9% fat as fed	7% fat as fed	4% fat as fed
		Cats	
Light (also "lite," "low calorie")	3,250 kcal ME/kg as fed	2,650 kcal ME/kg as fed	950 kcal ME/kg as fed
Lean (also "low fat")	10% fat as fed	8% fat as fed	5% fat as fed

Key: ME = metabolizable energy.
*"Light" (or similar terms) on pet food labels must bear a calorie content statement as described in AAFCO PF9. "Lean" and "low fat" pet food labels must bear a maximum percentage crude fat guarantee.

"Less" or "Reduced Calories"
For dog or cat food labels bearing a claim of "less calories," "reduced calories" or similar words, a maximum level of calories is not stipulated in the regulations. However, the percentage of reduction and the product of comparison must be explicitly stated on the label. The product label must also bear a calorie content statement and feeding directions should reflect a reduction in calories compared with feeding directions for the product of comparison. Comparisons between products in different categories of moisture content are considered misleading.

"Less" or "Reduced Fat"
For dog or cat food labels bearing the claims of "less fat," "reduced fat" or similar words, a maximum percentage of fat is not stipulated in the regulations. However, the percentage of reduction and the product of comparison must be explicitly stated on the label. The product label must also bear a maximum crude fat guarantee immediately after the minimum crude fat guarantee in the mandatory guaranteed analysis information. Comparisons between products in different categories of moisture content are considered misleading.

Dzanis Consulting & Collaborations
Santa Clarita, CA, USA

more than 3.4 kcal (14.2 kJ) metabolizable energy (ME)/g on a dry matter (DM) basis.

For energy-restricted foods for weight loss in cats, the energy density should be no more than 3.4 kcal (14.2 kJ) ME/g DM. For prevention of weight regain in cats following weight reduction, the energy density of the food should be no more than 3.8 kcal (15.9 kJ) ME/g DM. Pet food manufacturers decrease the energy density of foods by reducing fat and simultaneously increasing the fiber, air or moisture content of the food.

Fat

Most typical maintenance-type pet foods contain more fat than do energy-restricted foods. Fat has about 2.25 times the calories of an equivalent weight of carbohydrate or protein. In addition, fat is a very efficiently digested and metabolized source of energy. In one study, overweight dogs fed restricted calories from a food containing more fat lost less body weight and body fat than did overweight dogs fed equivalent calories from a food containing less fat (Borne et al, 1996). The thermal effect of dietary fat is less than the TEF of dietary carbohydrate or protein in obese people (Swaminathan et al, 1985). Studies in people have also determined that the lipid in body fat stores comes primarily from dietary fat, whereas an increased TEF is more closely correlated with carbohydrate intake (Danforth, 1985). Thus, a food with more calories supplied from fat will tend to support retention of body weight and body fat even when total calories consumed are reduced.

The recommended upper limit for dietary fat for weight loss in dogs is 9%, DM; for preventing regain of weight, the upper limit is 14% DM fat. The recommended upper limit for dietary fat for weight loss in cats is 10%, DM; foods for preventing weight regain should contain no more than 18% DM fat.

Fiber, Water and Air

There is some debate regarding the use of calorie-diluting agents in foods intended for weight management. Typical calorie-diluting agents are dietary fiber, water and air. Air is sometimes used to reduce caloric density in dry foods only. Water is a factor in moist foods. Water and air are removed from the gastrointestinal (GI) tract and contribute only transiently to GI fill. However, dietary fiber, besides diluting calories (Laflamme and Jackson, 1995; Jackson et al, 1997; Fekete et al, 2001), offers several physiologic and nutritional effects.

Dietary fiber helps produce weight loss by diluting calories, increasing satiety and limiting food consumption as a result of more bulk being present during its transit through the GI tract (Levine and Billington, 1994). Fiber may also help produce weight loss by decreasing the availability of calories by interfering with the digestion and absorption of fat, protein and digestible carbohydrate (Levine and Billington, 1994). Many of the effects of dietary fiber depend on the specific type, form and amount of fiber used.

Increased levels of dietary fiber contribute to satiety via prolonged distention of the GI tract. Fiber types affect the duration of gastric and intestinal distention differently. Insoluble fibers have little effect on gastric emptying, whereas soluble fibers slow gastric emptying (Levine and Billington, 1994; Vahouny, 1987; de Haan et al, 1990). Although both soluble and insoluble fibers slow intestinal transit, insoluble fiber (e.g., purified cellulose) produces the greater effect (Bueno et al, 1981). Thus, even though the type of fiber affects the two segments of the GI tract differently, total transit time through the entire GI tract is increased and is approximately the same for soluble and insoluble fibers.

Besides affecting transit time, mixed fibers are thought to promote weight loss through delayed gastric emptying, increased ileal transit time and increased gastric distention. Gastric distention stimulates cholecystokinin secretion, thus affecting appetite. However, the ratio of slowly to rapidly fermentable fibers is important (Kritchevsky, 2001). Dog foods with mixed fiber sources provide good weight loss performance (Yamka et al, 2007b).

Actual documentation of increased satiety from dietary fiber is difficult to prove in people and more so in other animals, because satiety is a subjective feeling of fullness and a lack of desire to eat. Indirect evidence for satiety can be obtained from animals by measuring decreases in food consumption and food-seeking activities. In people, increased intake of dietary fiber decreases food intake for variable periods lasting up to eight hours (Burley et al, 1987; Delargy et al, 1993; Stevens et al, 1987). Studies in dogs have produced variable results. Some studies in dogs showed no effect on caloric intake when foods containing 12 to 14% of DM as soluble or insoluble fibers were fed (Fahey et al, 1990, 1990a). In one study, foods containing either 2.2 or 15.6% fiber did not produce any measurable difference in satiety (Butterwick et al, 1994). However, the dogs in this study were fed quantities of food supplying only 40% of calories for adult maintenance, and this degree of caloric restriction may have overshadowed any effect of fiber between the two groups. In another study, dogs offered maintenance calories from food containing 21% insoluble fiber consumed significantly less food and calories than when offered equivalent calories from foods containing less fiber (Jewell and Toll, 1996). These dogs also ate less food when subsequent meals were offered 30 to 45 minutes after consuming the high-fiber food, indicating a satiety effect (Jewell and Toll, 1996). Other reports support a satiety effect of dietary fiber in dogs and cats (Jackson et al, 1997; LaFlamme and Jackson, 1995; Fekete et al, 2001).

Fiber decreases the apparent digestibility of energy-providing nutrients in the food by 2 to 8% (Levine and Billington, 1994; de Haan et al, 1990; Fahey et al, 1990a; Kelsay et al, 1978; Farrell et al, 1978). Fiber decreases pancreatic enzyme activity in vitro and pancreatic lipase secretion in vivo (Isaksson et al, 1982; Stock-Damge et al, 1983). Fiber also increases the fecal excretion of bile acids and fat (Vahouny, 1987). It is well documented that some dietary fibers slow the absorption rate of carbohydrate and fat, but the total quantity absorbed during the entire period of digestion is not significantly less than the quantity absorbed from fiber-free foods (de Haan et al, 1990; Edwards, 1992; Nelson et al, 1991). Increased dietary fiber decreases the apparent digestibility of dietary protein when fecal nitrogen is measured (de Haan et al, 1990; Fahey et al, 1990a; Kelsay et al, 1978; Farrell et al, 1978). However, it is unclear whether the increased fecal nitrogen is from dietary protein that would normally be digested and absorbed, or whether the nitrogen is from increased numbers of fecal bacteria, endogenous loss of mucosal cells or a component of the fiber itself. The effect of dietary fiber on mineral availability depends on the specific fiber(s) and mineral(s). In general, insoluble fibers such as cellulose are less likely to reduce mineral availability than are soluble fibers (Chapter 5).

Pet owners need to be advised that increased levels of dietary fiber will have noticeable effects on normal defecation habits. Dietary fiber increases the amount of fecal material and frequency of defecation (Vahouny, 1987; Fahey et al, 1990a). Dogs fed soluble fiber produced more feces than dogs fed similar amounts of predominantly insoluble fiber (Fahey et al, 1990). Dogs may not tolerate beet pulp and pectin when fed in amounts greater than 10% (Fahey et al, 1990a) or 13% DM (Nelson et al, 1991). Pet owners should be informed that the quantity of feces the animal produces will probably increase when their cats and dogs are fed foods containing more than 10% DM fiber. Excessive flatus can also be an unwelcomed side effect of feeding high-fiber foods. Fiber solubility roughly equates with fiber fermentability (Chapter 5). Increased amounts of highly fermentable fiber in a food are more likely to result in excessive flatulence than if insoluble fibers are used.

Depending on the combination, mixed fibers would be likely to result in less flatulence than using only soluble fibers and less fecal volume than using only insoluble fibers.

Taken together, study results support the use of dietary fiber in foods intended for weight loss and weight maintenance. For the reasons noted above, most commercial calorie-restricted foods with increased fiber contain primarily insoluble fiber.

The recommended range for fiber content of dog foods intended for weight loss is between 12 and 25% DM; for prevention of weight regain, the range is between 10 to 20% DM. The range for dietary fiber content of cat foods used for weight loss is between 15 and 20% DM; for prevention of weight regain following weight loss, the range is between 6 and 15% DM.

Protein and Amino Acids

Dietary protein has several effects that benefit weight loss. Increased dietary protein and amino acids are necessary for animals undergoing a weight-loss regimen to prevent loss of lean body mass (Hannah and Laflamme, 1998; Bierer and Bui, 2004; Laflamme and Hannah, 2005). Dog foods for weight loss should contain at least 25% DM crude protein (higher is better) to help prevent loss of lean body mass (Jewell and Toll, 2007). Dog foods intended for prevention of weight regain should contain at least 18% crude protein (higher is better). Cat foods for weight loss should contain at least 35% DM crude protein (higher is better) for the same reason. These same values are recommended for prevention of weight regain in cats.

Not only is the amount of protein important in protecting against loss of lean body mass during weight loss, so is the protein quality (Yamka et al, 2007b). The quality of a protein depends on the makeup of its constituent amino acids. When amino acids are used for protein synthesis, each necessary amino acid must be available in adequate amounts. The amino acid that is in the shortest supply is referred to as the first limiting amino acid. The idea of an ideal or perfect protein was first established in swine. The purpose of optimizing the amino acid profile of feeds for swine was to maximize lean tissue and minimize fat in finished swine carcasses. This required determining the first limiting amino acid, usually lysine, then balancing the content of the other essential amino acids in the feed to the lysine content. This resulted in swine feeds with ideal or perfect protein content; protein for which the potential for amino acid antagonism and imbalances were minimized (Chapter 5). The result was a leaner, more readily marketable carcass and more efficient growth. Later, researchers used the same idea for determining the ideal or perfect amino acid profile for dogs and cats (Baker and Czarnecki-Mauldin, 1991).

The use of this technology in foods for overweight dogs has shown promising results in weight loss and maintenance of lean body mass during weight loss. Overweight dogs (>30% body fat) were fed either a commercial veterinary therapeutic weight-loss food (control food) or two experimental weight-loss foods for two months. The control food provided 28% DM protein and 21% DM crude fiber. The two experimental foods were only slightly different and contained about 33.5% DM protein and about 10.5% DM crude fiber; the soluble fiber fraction was increased vs. the control food. The experimental foods also had optimized amino acid ratios based in part on higher lysine content. Compared to dogs fed the control food, dogs fed the experimental foods lost significantly more body weight (-2.1 kg vs. -1.3 kg, respectively) and had better lean body mass responses (approximately +0.3 kg vs. -1.1 kg, respectively) (Yamka et al, 2007b).

The lysine content of a food for weight management is not reflected by crude protein content. Individual ratios of essential amino acids to lysine are useful but are cumbersome to use for key nutritional factor targets. Although not an ideal representation of how "perfect" a food's protein content is, the total amount of lysine in dog foods for weight management is somewhat indicative. The recommended amount of DM lysine in dog foods for weight loss is at least 1.7% (Yamka et al, 2007). Dietary protein stimulates increased postprandial thermogenesis and protein turnover. The heat generated during the postprandial period is approximately 68% greater than that generated from carbohydrate sources. Therefore, when an animal consumes protein, it burns more energy (more heat), which appears to be associated with increased protein turnover (increased protein synthesis). Also, the efficiency of the body to convert protein to ATP via oxidation is decreased substantially when compared to fat or carbohydrate. Thus, less net energy is available when animals consume high-protein compared to high-carbohydrate foods (Laflamme and Hannah, 2005).

Carbohydrates

Carbohydrates are an excellent source of energy in canine and feline foods. There are three main categories of carbohydrates: simple sugars, complex carbohydrates and dietary fiber (Flickinger and Sunvold, 2005) (Chapter 5). The importance of dietary fiber has been discussed above.

Simple sugars and complex carbohydrates (grain sources) have received much attention in human nutrition and weight loss because of their effects on the glycemic index. The glycemic index is a ranking system for carbohydrates based on their immediate effect on blood glucose levels. Similar to effects in people, consumption of different sugars and carbohydrate sources alters postprandial glucose levels and insulin secretory patterns in dogs and cats (Flickinger and Sunvold, 2005; Bouchard and Sunvold, 2000; Nguyen et al, 1998; Sunvold and Bouchard, 1998). As a result, it has been suggested that foods producing low glycemic responses be fed to animals that are diabetic, obese and for the prevention of both conditions. Consumption of foods with a low glycemic index improves blood glucose and lipid control (Nguyen et al, 1998).

In a study that evaluated the effects of feeding five different carbohydrate sources (corn, wheat, barley, rice and sorghum) on glucose and insulin responses in dogs, rice had the highest postprandial glycemic response (i.e., increased postprandial glucose and insulin response). Barley, corn and sorghum were the best carbohydrate sources for dogs with impaired glucose control

(i.e., diabetes and obesity) because of their low-insulinogenic responses (Sunvold and Bouchard, 1998).

Another study evaluated the effects of feeding the same five carbohydrate sources on glucose and insulin responses in cats. Rice had the highest postprandial insulin response and higher glucose levels early in the postprandial period. This study found that barley, corn and sorghum were the best carbohydrate sources for cats with impaired glucose control (Bouchard and Sunvold, 2000). When considering which weight-management food to use in a canine or feline weight-loss program, it is important to evaluate the carbohydrate sources. Based on these data, it is best to avoid foods based primarily on rice when selecting weight-loss foods. Note that the earlier listing of rice on a specific product's ingredient label, the more rice the product contains. Arbitrarily, rice should not be one of the first three or four non-water ingredients on a weight-loss or weight-control food's label (Chapter 9).

The recommended upper limit for DM carbohydrates in foods for weight loss in dogs is 40%; for prevention of weight regain, the upper recommended limit should not exceed 55% DM. For cat foods intended for caloric-restriction weight loss, the DM carbohydrate content should not exceed 35%; for prevention of weight regain, the recommended upper limit should not exceed 40% (DM).

L-Carnitine

L-carnitine is a vitamin-like, amino acid compound present in all animal cells. Biochemically, it is involved in a variety of functions including fat metabolism and energy production (Chapter 6). In food animals during active growth, among other things, L-carnitine improves nitrogen balance, increases protein accretion and reduces fat deposition (Odle et al, 2000).

The food animal industry has long been interested in nutrients that influence partitioning away from body fat and toward muscle deposition. L-carnitine supplementation results include improved nitrogen balance, increased protein accretion and reduced body fat (Gross et al, 1998). In a 12-week study involving obese dogs (>1.3 RBW) fed a dry, low-fat, high-fiber food with or without added L-carnitine, dogs were fed to achieve weight loss equal to 2.5% of their initial obese weight per week. Food, energy and protein intakes were similar in both groups. Although dogs in control and study groups lost similar amounts of weight, the L-carnitine-supplemented dogs maintained lean body mass and had a trend towards greater body weight loss (Gross et al, 1998).

Results were similar in another controlled study of obese dogs (42 to 43% body fat) in a 19-week weight-loss program. Dogs were fed dry, low-fat, high-fiber foods with or without added L-carnitine. In the first seven-week phase of the study, both groups were fed free choice. The L-carnitine-supplemented dogs lost more body weight. During the last 12 weeks of the study, the dogs' food intake was adjusted to provide just less than 1% loss of their initial body weight per week. The L-carnitine-supplemented dogs tended to have a higher lean body mass percentage, lower percent fat mass and lost more weight than the other group (Sunvold et al, 1998, 1999). Another study in healthy obese-prone dogs fed a low-fat, high-fiber, L-carnitine-supplemented food for six months showed similar results (Allen et al, 1998).

Several studies demonstrated the effectiveness of L-carnitine supplementation for overweight cats. One 18-week study of obese (>1.2 RBW) pet cats either supplemented with an aqueous source of L-carnitine or a placebo, were fed a moist, high-protein, low-carbohydrate commercial cat food intended for weight loss. Weight loss was safely achieved in study and control groups; however, the L-carnitine-supplemented cats had significantly more weight loss than the placebo group (Center et al, 2000). In a study involving obese colony-housed cats, cats receiving L-carnitine supplements lost significantly more weight than cats without supplements (both groups were fed a low-fat food) (Ibrahim et al, 2003). Thus, weight-loss foods with supplemental L-carnitine have improved weight-loss performance in overweight dogs and cats.

L-carnitine supplementation during fasting and experimental induction of hepatic lipidosis may be protective (Armstrong et al, 1992; Blanchard et al, 2002).

The recommended level of L-carnitine in foods intended for weight loss in dogs is at least 300 ppm (DM). For cat food intended for weight loss, the recommended level is at least 500 ppm (DM). The recommended levels for prevention of weight regain in dogs and cats are the same as for weight loss.

Antioxidants

Obesity increases oxidative stress, which may also contribute to diseases associated with obesity (Tanner et al, 2006; Sonta et al, 2004; Urakawa et al, 2003). Studies also show supplemental antioxidants help blunt oxidative stress. For example, serum levels of vitamin E and β-carotene were significantly lower in obese children than for normal weight cohorts consuming similar amounts of these nutrients (Strauss, 1999). Obese rats receiving dietary vitamin E supplementation had lowered oxidative stress biomarkers compared to those in similarly supplemented lean rat cohorts (Laight et al, 1999; Blakely et al, 2003). Furthermore, as in other species, antioxidant combinations seem to work best because they participate in networks to regenerate and/or spare each other to extend/improve their positive effects on oxidative stress in dogs and cats (Jewell et al, 2000; Milgram et al, 2002; Devlin et al, 2001). Effective inclusion levels have been studied for vitamins E and C and selenium for their antioxidant benefits in dog and cat foods. Although other sources of antioxidants are available (e.g., carotenoids, thiols and various fruits and vegetables), the following discussion focuses on vitamins E and C and selenium as antioxidant key nutritional factors because: 1) they are biologically important, 2) they act synergistically (e.g., vitamin C regenerates vitamin E after reacting with free radicals), 3) they are safe and 4) information about inclusion levels in pet foods is usually readily available.

VITAMIN E

Vitamin E is the main lipid-soluble antioxidant in plasma, erythrocytes and tissues (NRC, 2006). It functions as a chain-

breaking antioxidant that prevents propagation of free radical damage of biologic membranes. Vitamin E inhibits lipid peroxidation by scavenging lipid peroxyl radicals much faster than these radicals can react with adjacent fatty acids or membrane proteins. Levels of vitamin E higher than recommended requirements confer specific biologic benefits. Based on antioxidant biomarker studies in dogs and cats, for improved antioxidant performance, weight-management foods for dogs and cat should contain at least 400 and 500 IU/kg (DM), respectively (Jewell et al, 2000).

VITAMIN C

Besides regenerating vitamin E, vitamin C (ascorbic acid) also: 1) regenerates glutathione and flavonoids, 2) quenches free radicals intra- and extracellularly, 3) protects against free radical-mediated protein inactivation associated with oxidative bursts of neutrophils, 4) maintains transition metals in reduced form and 5) may quench free radical intermediates of carcinogen metabolism.

Dogs and cats can synthesize required amounts of vitamin C. However, their ability to synthesize vitamin C may be much less than for other mammalian species (Chatterjee et al, 1975). Dogs can rapidly absorb supplemental vitamin C (Wang et al, 2001). In people, high levels of oral vitamin C increased urine oxalate excretion and risk of urolithiasis (Massey et al, 2005). Cats given vitamin C supplements (0, 200, 400 and 1,000 mg/day) had a small progressive reduction of urinary pH from 6.9 to 6.5 (Kienzle and Maiwald, 1998). Moderate supplementation (193 mg vitamin C/kg of food, DM; approximately 10 mg/day) of foods for healthy adult cats with vitamin C did not seem to increase the risk of oxalate production (Yu and Gross, 2005). Supplemental vitamin C (224 mg/kg DM), in combination with supplemental vitamin E and β-carotene improved antioxidant status in dogs (Wedekind et al, 2002). Until more studies are available, for improved antioxidant performance, and in conjunction with recommended levels of vitamin E, weight-management foods for adult dogs and cats should contain at least 100 mg vitamin C/kg DM and 100 to 200 mg vitamin C/kg DM, respectively.

SELENIUM

Glutathione-peroxidase is a selenium-containing antioxidant enzyme that defends tissues against oxidative stress by catalyzing the reduction of H_2O_2 and organic hydroperoxides and by sparing vitamin E. In addition to the antioxidant function of selenium-dependent glutathione-peroxidase, it affects regulation of proinflammatory cytokines including leukotrienes, thromboxanes and prostaglandins, which might benefit the adipokine component of the pathology associated with obesity (**Table 27-2**) (Surai, 2002, 2003). The minimum requirements for selenium in foods for dogs and cats are 0.10 and 0.13 mg/kg (DM), respectively (Wedekind et al, 2002a, 2003, 2003a). Animal studies and clinical intervention trials in people have shown selenium to be anticarcinogenic at much higher levels (five to 10 times) than recommended human allowances or minimal requirements (Combs, 2001; Neve, 2002). Several mechanisms have been proposed for this effect, including enhanced antioxidant activity via glutathione peroxidase (Neve, 2002). Therefore, for increased antioxidant benefits, the recommended range of selenium for weight-management dog and cat foods is 0.5 to 1.3 mg/kg (DM). There are no data to base a safe upper limit of selenium for dogs or cats, but for regulatory purposes, a maximum standard of 2.0 mg/kg (DM) has been set for dog foods in the United States (AAFCO, 2007).

SODIUM AND PHOSPHORUS

Dogs and cats that are overweight may be experiencing some degree of hypertension (See Health Risks of Obesity discussion, above and **Table 27-1**). Also, because they may be fed weight-management foods for extended periods of time, and subclinical renal disease is relatively common, sodium and phosphorus levels in weight-management foods are important. Therefore, the recommendations for sodium in foods for weight management in dogs and cats are 0.2 to 0.4% and 0.2 to 0.6% (DM), respectively. The recommended phosphorus levels for weight-management foods for dogs and cats are 0.4 to 0.8% and 0.5 to 0.8% (DM), respectively.

Key Nutritional Factors: Metabolic-Control Foods for Weight Loss in Cats

The use of metabolic-control foods is an alternative to calorie-control foods for weight loss in overweight cats. This approach is similar to the "low carb" human weight-loss programs that have resurged in popularity. The first low-carbohydrate diet that enjoyed popular success in people was used in the 1860s (Bravata et al, 2003). Contemporary variations on the low-carbohydrate theme for people include programs such as the Atkins and South Beach diets. The metabolic approach to weight loss in cats is probably more like the South Beach diet in that it is less restrictive in carbohydrate and lower in fat than the Atkins diet approach. Although the popular emphasis is on lowering carbohydrate intake, both the Atkins and South Beach diets rely on a multifaceted approach. Dietary protein is also important, as with traditional calorie-restricted foods discussed above. The South Beach diet recommends less fat, lower glycemic index carbohydrate sources and, to a lesser extent, increased dietary fiber. The basic premise of the metabolic approach is to shift energy metabolism from energy storage to energy use.

Clinical trials have shown the efficacy of metabolic-control foods to be equivalent to traditional low-calorie foods for safe weight loss in cats.[a] The key nutritional factors for metabolic-control cat foods for weight loss are discussed below and summarized in **Table 27-6**.

Carbohydrate

Limiting dietary carbohydrate is an important component of metabolic control for weight loss. There are three key advantages to limiting dietary carbohydrate to 20% (DM) or less: 1) lower glycemic index, 2) metabolic shift from energy storage to energy usage and 3) increased satiety.

As discussed for the key nutritional factors for calorie-

Table 27-6. Key nutritional factors for metabolic-control cat foods for weight loss.

Factors	Dietary recommendations (dry matter basis)
Carbohydrate	≤20%
Protein	At least 47% but not exceed 55%
Fat	≤25%
Fiber	≥5%
L-carnitine	≥500 ppm
Antioxidants	Foods for weight loss and prevention of weight regain should contain:
Vitamin E	≥500 IU vitamin E/kg
Vitamin C	100 to 200 mg vitamin C/kg
Selenium	0.5 to 1.3 mg selenium/kg
Sodium	Foods for weight loss should contain between 0.2 to 0.6%
Phosphorus	Foods for weight loss should contain between 0.5 to 0.8%

restricted foods, simple sugars and complex carbohydrates (i.e., grain sources) have received much attention in human weight-loss programs because of the known effects of various carbohydrates on the glycemic index. As in people, consumption of different sugars and carbohydrate sources alters postprandial glucose levels and insulin secretory patterns in cats and dogs (Flickinger and Sunvold, 2005; Bouchard and Sunvold, 2000; Nguyen et al, 1998; Sunvold and Bouchard, 1998). Therefore, foods producing low glycemic responses should be recommended for obese or diabetic patients.

The stimulatory effect of increased carbohydrate intake on insulin secretion provides for a metabolic shift to support fat deposition, given the potent lipogenic effects of insulin. In contrast, low-carbohydrate foods, particularly in combination with fat, protein and fiber, result in a more blunted insulin response that helps set the stage for fat use. Also, as discussed above, by using less available carbohydrate sources, the glycemic index can be modified to further shift energy use to be more dependent on amino acids (protein), fat and ketones. Furthermore, in the calorie-restriction approach to weight loss, different sugar and starch sources variably affect postprandial glucose levels and insulin secretory patterns in cats (Bouchard and Sunvold, 2000). Carbohydrate sources that result in a lower glycemic index are more desirable for metabolic weight control. Compared to barley, corn and sorghum, rice as a starch source produces the highest glycemic index in cats. Therefore, as with energy-restricted foods, it is probably best if rice is not one of the first three or four non-water ingredients on the product's label (Chapter 9).

A reduced ratio of dietary carbohydrate to protein in people has a satiety effect (Layman et al, 2003). Lowering the glycemic index could have an effect on satiety because a rapid increase in blood glucose typically evokes an equally intense insulin response that can lead to a period of hypoglycemia followed by hunger. In people, this occurs approximately two hours after a meal (Roberts, 2000). However, increasing protein can also have a satiety effect (see below). The satiety effect of a reduced dietary carbohydrate to protein ratio may be due to both components.

For metabolic weight-loss foods for cats, dietary digestible carbohydrates should not exceed 20% (DM); lower is probably better. When foods containing this level of dietary carbohydrate in combination with increased protein and moderate fat are fed in appropriate amounts, they result in controlled weight loss in cats (Butterwick and Markwell, 1994, 1996).[a]

Protein

Cats have an innate metabolic capacity to readily use protein (amino acids) for energy (Chapter 19). The natural diet of cats is primarily animal tissue and contains only small amounts of digestible carbohydrate. Cats, therefore, typically have lower levels of hepatic glucokinase than do omnivorous species and have higher levels of transaminases and deaminases that do not down regulate, even when protein intake is reduced. Thus, cats have a higher protein requirement and are metabolically geared to use protein for energy. Cats rely heavily on glucogenic amino acids to generate glucose for glucose-dependent tissues (Macdonald et al, 1984) (Chapter 19).

Increasing its protein content can reduce the carbohydrate content of a food. As discussed for the key nutritional factors for the energy-restriction approach to weight loss, relying on dietary protein as a major energy source has beneficial metabolic effects for weight loss. These effects include reduced energy efficiency, satiety effects and preservation of lean body mass.

In people, increasing a food's protein content increases its thermic and satiety effects (Crovetti et al, 1998). The TEF is the obligatory cost of digesting and absorbing food. TEF constitutes approximately 10% of total expenditure. Thus, increasing a food's thermic effect reduces its energy efficiency (Danforth, 1985; Horton, 1983). In a human study, 10 people received, in randomized order, high-protein, high-fat and high-carbohydrate meals. The high-protein meal was the most thermogenic ($p < 0.001$) and it determined the highest sensation of fullness ($p = 0.002$). There were no differences in the sensation and thermic effects between the high-fat and high-carbohydrate meals. A significant relationship linked TEF to fullness sensation ($r = 0.41$, $p = 0.025$) (Crovetti et al, 1998).

Increasing the dietary protein level during weight loss spares lean body mass. In one study in cats, 47% DM dietary crude protein preserved lean body mass during controlled weight loss (1% per week). In this study, weight loss did not differ significantly between cats fed a high-protein food and those fed a control food with less protein. However, the high-protein group had significantly greater loss of body fat and significantly less loss of lean body mass (Laflamme and Hannah, 2005).

Theoretically, prolonged, excessive protein intake poses some risks. Consumption of high-protein diets in people (i.e., two to three times the U.S. Recommended Daily Allowance) increases urinary calcium loss and may, over time, predispose to bone loss (Eisenstein et al, 2002). However, cats have a relatively high protein requirement because of their obligatory use of amino acids in gluconeogenesis (Chapter 19) and are well adapted to using dietary protein. The protein require-

ment for an adult cat is twice as much as that for an adult dog (NRC, 2006).

The recommended dietary protein level for cat foods for metabolic-control weight loss is at least 47%, but should probably not exceed 55% (DM).

Fat

When dietary digestible carbohydrate is limited, cats rely more on fat as an energy source. This approach, to a degree, mimics fasting metabolism. During fasting, carbohydrate intake is interrupted and plasma insulin levels decrease while glucagon levels increase. Body fat is then stimulated to release long-chain fatty acids that are transported to the liver where some are converted to ketones, which can be used as energy to fuel hepatic gluconeogenesis. Those ketones not used by the liver are released into the bloodstream for use by peripheral tissues, some of which cannot use long-chain fatty acids for fuel. Fasting ketosis is physiologic and is not harmful because ketones do not reach the level they do during diabetic ketoacidosis (Bruss, 1997). Typically, fasting ketosis results in ketone levels of only 7 to 20% of the levels associated with diabetic ketoacidosis. Thus, low dietary carbohydrate intake sets the stage for a greater reliance on fat and protein for energy usage. Ketones reduce protein catabolism, which may in part explain the preservation of lean body mass observed when low-carbohydrate/high-protein foods are used for weight loss (Volek and Westman, 2002).

In cats, high dietary fat, low-carbohydrate intake (29.5 and 11.8%, DM, respectively) results in a lower glycemic index than low dietary fat, high-carbohydrate intake (15.1 and 38.4%, DM, respectively). Higher dietary fat also reduces the digestibility of the carbohydrate portion of the food (Thiess et al, 2004). However, as has been discussed, dietary fat provides considerably more energy per unit weight than does protein or carbohydrate. Therefore, as in energy-restricted foods, dietary fat levels in metabolic weight-loss foods should be kept as low as possible. However, metabolic-control foods containing 20% fat (DM) have achieved weight-loss performance equivalent to that of low-fat, energy-restricted foods.[a]

Thus, dietary fat should not exceed 25% (DM).

Fiber

Dietary fiber promotes weight loss by diluting calories, increasing satiety and limiting food consumption due to more bulk in the GI tract (Levine and Billington, 1994). Fiber may also help produce weight loss by decreasing the availability of calories by interfering with the digestion and absorption of fat, protein and digestible carbohydrate (Levine and Billington, 1994). Refer to the fiber discussion above in the Key Nutritional Factors: Calorie-Controlled Foods for Weight Loss and Prevention of Weight Regain in Dogs and Cats section, for detailed information about the advantages of dietary fiber in weight-loss foods. Inclusion of fiber in metabolic-control foods for weight loss in cats allows for further reduction of digestible carbohydrate and/or fat content.

Dietary fiber levels in metabolic-control foods for weight loss in cats should be at least 5% (DM).

L-Carnitine

L-carnitine nutriture is important for safe weight loss in overweight cats (see expanded discussion of L-carnitine in the Key Nutritional Factors: Calorie-Controlled Foods for Weight Loss and Prevention of Weight Regain in Dogs and Cats section, above). Adequate intake of L-carnitine protects against the development of hepatic lipidosis and improves weight-loss performance in cats fed high-protein, low-carbohydrate, low-fat foods (Center et al, 2000). The recommended level of dietary L-carnitine should be at least 500 ppm.

Antioxidants

Because oxidative stress is increased in overweight patients and oxidative stress contributes to diseases associated with obesity, supplemental antioxidants are recommended for weight-loss foods. Also, combinations of antioxidants are more effective in relieving oxidative stress than are individual antioxidants. Thus, for improved antioxidant performance, weight-loss foods for cats should contain at least 500 IU vitamin E/kg DM (Jewell et al, 2000); 100 to 200 mg vitamin C/kg DM and 0.5 to 1.3 mg selenium/kg DM. (See the Antioxidant section in the Key Nutritional Factors: Calorie-Controlled Foods for Weight Loss and Prevention of Weight Regain in Dogs and Cats section, above.)

Sodium and Phosphorus

Overweight cats may also be experiencing some degree of hypertension. (See Health Risks of Obesity discussion, above and **Table 27-1**.) Also, because these patients may be fed weight-management foods for extended periods of time, and subclinical renal disease is relatively common (Chapters 20, 21 and 37), sodium and phosphorus levels in metabolic weight-control foods are important. Therefore, the recommendations for sodium and phosphorus in foods for metabolic weight loss for cats are 0.2 to 0.6% (DM) and 0.5 to 0.8% (DM), respectively.

FEEDING PLANS FOR OVERWEIGHT AND OBESE DOGS AND CATS

Weight Reduction

A successful weight-reduction program is a multi-step process that requires: 1) pet owner commitment (**Box 27-7**), 2) proper food, 3) an appropriate feeding method, 4) an exercise plan (**Box 27-8**), 5) pet owner communication (**Box 27-9**) and 6) patient monitoring (reassessment). This six-step program is listed in **Figure 1**, **Box 27-9**.

In people, the combination of reduced-calorie foods, regular exercise and behavior modification has the greatest chance of achieving and maintaining weight loss (Wilson, 1990; Vasselli et al, 1983; Leaf, 1990; Caterson, 1990; Council on Scientific Affairs, 1988). For overweight dogs and cats, formulation of a program for achieving weight reduction consists first of select-

Box 27-7. Obtaining Pet Owner Commitment.

An important step in a successful weight-loss program is for everyone who feeds the pet to recognize, accept and understand the reason why the pet should lose weight, and to make a commitment to accomplish that goal. Satisfactory weight loss is unlikely to occur unless the pet owners recognize the problem and are committed to take corrective steps. Such commitment will greatly improve compliance (Chapter 3) with a feeding plan and increase the likelihood of a successful outcome. The good news is that owners care whether or not their pets are overweight as evidenced by the results of a survey of cat owners: more than 90% said that maintaining their pets' proper weight was important or extremely important.[a]

Several techniques can be used to help owners recognize and accept that their pet is overweight and not just "stocky." Some of these techniques have already been discussed in the accompanying chapter. Past body weights and body condition scores (BCS) in the patient's medical record can be used along with relative body weights to show an owner how excessive present body weight relates to the animal's frame size and optimal body weight (Appendices 14 and 15). BCS illustrations may help (Chapter 1). Because they typically underestimate their pets' body condition, owners should be taught to feel where bony structures should be readily palpable but are not, and where body contours differ from optimal. The BCS can be used to estimate percent body fat; for additional body composition information, see **Table 27-3**.

If thoracic or abdominal radiographs have been taken, a side-by-side comparison with similar radiographic views from an animal of similar size at optimal body weight can quite effectively demonstrate to the owner the pet's excess subcutaneous or intra-abdominal fat (**Figures 1** and **2** in **Box 27-2**). Practitioners should consider keeping a reference set of radiographs for cats and dogs in optimal body condition for this specific purpose. Also, a side-by-side comparison of the overweight animal and one of the same breed and frame size in optimal body condition can serve the same purpose if an animal of optimal weight is available. Sequential dual energy x-ray absorptiometry scans can also be used for this purpose.

A free web-based program is available in which the patient's silhouette is matched to a dog/cat visual and an ideal weight is automatically calculated; this program could also be a persuasive aid (**Box 27-10**).

After the owners recognize and accept that the pet is overweight, the next step is for them to commit to a weight-loss program. There are several strategies to help owners make this commitment. Owners can be informed about documented problems associated with obesity and how returning the animal to optimal weight will reduce the risk of one or more of these problems. The risks can be quantified economically for animals likely to suffer orthopedic or metabolic problems because of their degree of obesity. Often, a strong motivating factor for commitment is to improve or even resolve a problem caused or exacerbated by obesity. Weight loss in these cases becomes part of the overall therapeutic plan and can be crucial for realizing clinical improvement and benefit from other treatments.

ENDNOTE

a. Weight Management Study, Pet Owner Summary #D02-284. Hill's Pet Nutrition, Inc. September 2002.

The Bibliography for **Box 27-7** can be found at www.markmorris.org.

ing a specific food and determining the feeding method. The feeding method includes setting a goal for the amount of weight to lose and determining how much of the new food to feed to achieve the weight loss. Although not a nutritional consideration, obtaining owner agreement about a realistic exercise plan should be part of the process. Reassessment of the weight-loss part of weight management should include monitoring the progress of weight loss and, as necessary, adjusting food intake and exercise to achieve the agreed upon weight-loss goal. Finally, it is very important to stabilize caloric intake of the animal at its reduced weight to ensure that weight is not regained.

Assess and Select the Food for Weight Reduction

The calorie-restriction strategy should be used for overweight dogs and, initially, for overweight cats. **Tables 27-7** for dogs and **27-8** for cats compare the key nutritional factor targets to the key nutritional factor content of selected commercial veterinary therapeutic foods marketed for weight loss. Select the food that is most similar to the key nutritional factor targets and/or has the best efficacy evidence for managing weight loss in dogs or cats (Roudebush et al, 2008).

If an energy-restriction strategy has been tried in cats, but has not achieved the desired weight loss, a metabolic weight-loss program should be considered. **Table 27-9** compares the key nutritional factor targets to the key nutritional factor content of available veterinary therapeutic cat foods marketed for a metabolic approach to weight loss. Again, select the food that is most similar to the key nutritional factor targets and/or has the best efficacy data (Roudebush et al, 2008).

Another criterion for selecting a food that may become increasingly important in the future is evidence-based clinical nutrition. Practitioners should know how to determine risks and benefits of nutritional regimens and counsel pet owners accordingly. Currently, veterinary medical education and continuing education are not always based on rigorous assessment of evidence for or against particular management options. Still, studies have been published to establish the nutritional benefits of certain pet foods. Chapter 2 describes evidence-based clinical nutrition in detail and applies its concepts to various veterinary therapeutic foods.

Ideally treats, snacks and human foods should be eliminated from the feeding plan to maximize the chances for successful

Box 27-8. Exercise and Environmental Enrichment Programs as Part of a Weight-Loss Plan.

Moderate, regular exercise is advocated in all pet weight-management programs because increased physical activity can enhance weight loss. Exercise is the only practical means of increasing energy expenditure to create or widen a deficit between energy consumed and energy expended for overweight patients. The metabolic rate of people undergoing weight reduction decreases more than expected after corrections have been made for decreased thermogenic effects of food due to decreased intakes and decreased resting energy requirement (RER) due to loss of lean body mass. The only way to successfully sustain or increase overall energy expenditure during weight reduction is to increase the amount of physical activity. Exercise may also benefit obese patients by supporting retention of lean body mass and maintaining or increasing RER. In some cases, pets fail to lose weight unless exercise is part of the weight-reduction plan, regardless of the severity of caloric restriction. Thus, modifying physical activity has been a key target of behavioral intervention to change body weight in people and pets.

Besides increasing energy expenditure, moderate, regular physical activity can help regulate food intake and improve lean body mass. This seems to hold true for weight-loss and weight-maintenance programs. Exercise improves insulin sensitivity, partially reverses leptin resistance and suppresses the enhanced proinflammatory burden induced by obesity. In obese people, physical activity appears to have an independent effect on health-related outcomes compared to body weight. It is unknown if exercise creates beneficial health effects in obese or overweight pets independent of weight loss.

In people, exercise appears to be critical for prevention of significant weight gain and maintenance of weight loss. In dogs, the risk of obesity appears to decrease with each hour of weekly exercise. Owners of overweight cats play less with their cats than do owners of normal weight cats. In people, concomitant changes in food and exercise are more important in women than men.

Specific recommendations for increasing exercise should consider the patient's previous level of activity, presence of any physical problems for which exercise is contraindicated and time constraints of the owner.

For dogs, 15- to 30-minute walks at least five to seven times per week are recommended. Up to an hour of walking has been reported to be practical and enjoyable for some owners and pets. The daily energy requirements of dogs covering 5 km per day are estimated to increase between 7 to 15%. Exercise should be implemented gradually, starting with amounts the patient can comfortably tolerate, especially if orthopedic, cardiovascular or pulmonary disease is also present. It is more important that the animal increase its activity by some amount each day even if it initially is able to walk only out the door to the sidewalk and back inside. The goal should be to work up to 15 to 30 minutes of uninterrupted walking if the animal cannot do this initially. Exercise may need to be omitted initially for patients recovering from orthopedic surgery because walking may exacerbate joint pain. Swimming is an alternative to walking that sometimes works for orthopedic patients if facilities are available to the owner. Because swimming uses more calories per minute than walking, the same number of calories can be expended in less time (5- to 15-minute swim vs. 15- to 30-minute walk).

Some creativity is often required to increase the activity of an overweight cat. Although cats do not readily walk on a leash, they can be trained to do so if the owner is patient and persistent. Sometimes a cat will walk back home on a leash if an exceptionally dedicated owner is willing to carry the cat on the out-bound half of the walk. The type of harness used for cats to be walked on a leash should be secure so the cat cannot escape the leash. This can be a challenge. Less extraordinary ways of increasing a cat's daily activity are to engage the cat in supervised play with string, balls, laser "mice," other toys or other pets. Such methods can make a difference. In a study of overweight cats, encouragement to play and environmental enrichment increased activity enough to cause a 1% loss in body weight over a four-week period.

Options exist for indoor cats to safely be outdoors. Being outdoors provides cats with more opportunity for spontaneous exercise, compared to that which occurs with their typical indoor lifestyle. Such experiences have the additional benefit of environmental enrichment. The outdoor options for indoor cats include a wide variety of pet doors and safe cat-proof fencing. **Table 1** provides a partial listing of websites for doors and fencing; internet searches and pet supply stores are additional sources.

Environmental enrichment can be important to a weight-loss program. A recent study evaluated the effects of environmental enrichment on weight loss in cats. Cat owners were given feeding guidelines to reduce their obese cats' body weight and were randomly assigned to either include environmental enrichment or not. Enrichments included additional food dishes, water bowels and litter boxes, plus climbing towers, window perches, scratching posts, cat spas, grooming supplies and toys. Cats were weighed weekly and some were monitored for activity levels. Environmentally enriched cats had increased activity levels and a trend towards increased weight loss. Owners of the environmentally enriched cats had a more positive image of their cat and felt they were playing a more active role in their cat's weight loss.

There may also be benefits when people and pets exercise together during weight loss. In one study, people exercising with their dogs reported a significantly improved quality of life for themselves and a combined dog/owner weight-loss program was more effective at maintaining participation in a canine weight-loss program.

weight loss. A portion of the total daily calories for weight loss (10% or less) can be reserved if the owner insists on feeding treats or snacks (Yaissle et al, 2004). Some treats are specifically formulated for use in veterinary patients and are appropriate for overweight pets (**Table 27-10**). Treats can also be low-calorie foods such as the dry form of the reducing food, popcorn (air popped), low-fat, low-starch vegetables or low-fat commercial treats. The calories supplied by the treats must be accounted for within the total calories allowed in the feeding plan. (See below.) Cats in a metabolic weight-loss program should not receive treats, unless the treats conform nutritionally to the key nutritional factor content of the food.

Assess and Determine the Feeding Method for the Weight-Reduction Program

Feeding method considerations include determining the amount of food to feed for weight loss and selecting the way the food is fed. Determining the amount of food to feed is essential to the success of the plan and is based on the estimate of caloric restriction necessary to safely achieve weight loss. If body fat were the only tissue component lost during weight reduction, then simply starving dogs, *but not cats*, would be an acceptable option for weight loss from a strictly physiologic perspective. There are several disadvantages; however, to using starvation for weight reduction in dogs including loss of lean body mass; therefore, it is not recommended (Burkholder and Toll, 2000).

Even when body weight is lost using more conventional weight-loss programs, 10 to 25% of the loss comes from lean tissues (Burgess, 1991; Butterwick and Markwell, 1996). This loss of lean body mass ultimately decreases an animal's RER and the number of calories required for DER, unless the level of activity is increased to that associated with athletic training. Therefore, one underlying objective in setting the number of daily calories for weight loss is to restrict calories enough to produce weight loss, but still provide enough calories, protein, vitamins and minerals to prevent or minimize nutrient deficiencies and subsequent loss of lean body tissue. As mentioned above, foods properly formulated for weight loss minimize loss of lean body mass (See Assess and Select the Food section above).

Studies in people indicate that loss of more than 2% of body weight per week is unhealthy (Weinsier et al, 1984, 1995). A greater proportion of lean body mass is lost when more than 2% of body weight is lost per week. This ultimately reduces the RER and works against the goal of maintaining the greatest metabolic rate possible in a patient undergoing weight reduction. A 2% loss of initial body weight per week is a reasonable estimate of the maximum acceptable rate of weight loss. However, the impact of losing more than 2% of the initial body weight per week on the proportion of fat vs. lean tissue loss and on the metabolic rate has not been reported from weight-loss studies using dogs or cats. Very few animals fed reduced-calorie foods by the methods discussed above will lose more than 2% of their initial body weight per week. At the other extreme, a rate of loss of at least 0.5% of the initial body weight per week is needed to maintain owner interest and complete the weight-reduction program within a reasonable period. When weight is lost at the rate of 0.5% per week, it may take a year or more to achieve the target body weight, especially in cats. Owners should be apprised of this to manage their expectations and maintain their involvement.

How to Estimate the Amount of Food to Feed for Controlled Weight Loss

Several methods exist for determining the caloric need, and therefore, the quantity of food necessary for weight loss. Four of the more common methods are reviewed below. They are recommended for energy-restricted foods for dogs and energy-restricted and metabolic weight-loss foods for cats. They include: 1) using product information, 2) calculations based on estimated ideal weight, 3) calculations based on current food intake and 4) calculations based on current (obese) weight. All generate estimates, and thus, should be considered starting points, which will likely need adjustment with time. For dogs, the goal is an average weight loss of 1 to 2% of the obese body

Box 27-9. Pet Owner Communication.

Educating pet owners about obesity is important to the successful outcome of weight-control programs. Clients usually enroll their pets in weight-loss programs because of veterinary recommendation, access to support and supervision by the hospital's health care team and the perception that weight loss will improve their pet's health. Retention in a weight-loss program improves when the program includes daily recording of food intake in a diary by the client and scheduling regular trips to the hospital for progress checks. However, there is a point of diminishing returns. Owner education programs that provide monthly classes for nutrition-related topics failed to improve average weight loss or body condition scores compared to weight-control programs without the monthly classes. An obesity-treatment program that included an appropriate feeding plan and monthly hospital rechecks during weight-loss and subsequent weight-maintenance periods was sufficient to achieve good results.

Recommendations for feeding, exercising and rechecking the patient need to be provided in clear, concise terms. These directions should be verbal and written, and the owner should be able to demonstrate understanding by verbal recall. Pet food companies have brochures that explain obesity and its associated health risks. Some brochures provide space to write individual instructions for feeding, exercise and recheck appointments and provide ways of visually documenting progress (**Table 1**). A veterinary practice may also elect to design and distribute its own printed or computer-generated material for this purpose.

Customized Pet Weight-Loss Plan

A weight-reduction program has been designed to improve your pet's quality of life. An optimal body weight, specific food(s) and amount(s) have been determined for your pet, along with a recommended exercise regimen.

To successfully manage a weight-reduction program for your pet, you should:

1. Feed only the prescribed food(s).
2. Feed your pet alone; away from other pets.
3. Do not feed table scraps, treats, snacks or other food unless your veterinary health-care team approves them and the amount(s) to be fed.
4. Exercise your pet as prescribed.
5. Do not handle, prepare or eat food in the presence of your pet.
6. Have your pet rechecked on a regular basis by a member of your veterinary health-care team to monitor progress of the weight-loss program.

To be filled out by your veterinary health-care team:

Patient's name________________________________ Dog___ Cat___

Beginning date: _____/_____/_____

Beginning body weight: __________lb/kg Target (optimal) body weight __________ lb/kg

Prescribed food(s)____

Amount of food per meal ____________________ Number of meals per day____________________

Amount and type of exercise per day ____

Estimated time to reach optimal weight *if all instructions are followed* __________months

Weigh your pet every __________weeks, and record the weight in the chart below.

Weight Loss Chart

weight per week until the patient reaches the desired weight. Also, in dogs, as in people, gradual weight loss is more likely to result in maintenance of the target body weight, once achieved (Laflamme and Kuhlman, 1995).

For cats, a safer and more realistic goal is 0.5 to 1% per week. Again, a weight loss of 0.5% per week for either dogs or cats is acceptable as long as the owner knows that it will take much longer to achieve the desired results.

PRODUCT INFORMATION

For dogs and cats, the simplest and probably the most common method for determining the amount to feed for weight loss is to obtain the food dose recommendation from the company that manufactures the food. This information may be available on the product label, from published company literature, on the company website or by using "calculators" or proprietary software programs. However, the last method often requires an estimate of the patient's ideal or optimal weight. Free web-based programs are available for estimating ideal weight (**Box 27-10**). A simple way to estimate ideal body weight is to use **Table 27-3**. This is accomplished by correlating the patient's current weight with its current BCS and then finding the weight in the same line that corresponds to the ideal BCS (3/5). This and other methods are listed in **Table 27-11**.

CALCULATION BASED ON ESTIMATED IDEAL WEIGHT

A second method also depends on an estimate of the patient's ideal weight (**Table 27-12**) but requires a few simple calculations. Pets at ideal body weight in a thermoneutral environment will typically expend about 70% of their DER for maintenance of lean body tissue (RER). Maintaining adipose tissue in obese pets requires relatively little energy; therefore, most calories consumed by an overweight patient, regardless of the degree of obesity, are used to support lean body tissues. Although the lean body mass of an overweight patient is greater than the lean body mass of the same patient at its optimal weight, the relationship is not linear. This method, then, assumes the RER for the optimal weight and RER for obese

**This information is for feeding purposes only. Treats should not make up more than 10% of the total caloric intake and these calories should be accounted for by reducing the amount of kcal fed as food, accordingly.

weight are similar enough to be representative of one another. If lean body mass is similar at ideal and obese body conditions, the energy required to maintain each body condition should also be similar; this assumption is the basis for this approach to calculating the initial food dosage for controlled weight loss. Because the lean body mass for a patient at its optimal weight will be less than when it is overweight, this method provides a more aggressive initial food dosage for weight loss than calculations based on the patient's obese weight. Also, as mentioned above, web-based programs exist for determining ideal or target weight of obese patients (**Box 27-10**).

For dogs and cats, use RER for optimal weight as an initial estimate of calories required for appropriate weight loss. RER can be obtained directly from **Table 27-3** or calculated as shown in **Table 27-13**. RER should provide approximately 70 to 80% of DER for optimal weight or 60 to 70% of DER for obese weight, assuming the animal is only 20% over optimal weight. This level of restriction should provide about 1 to 2% loss of obese body weight per week. Because this level of restriction will make caloric intake nearly equal to the calories required to support lean body mass at optimal weight, energy for physical activity must subsequently be supplied by further catabolizing fat stores. See **Box 27-8** for a discussion of exercise for weight loss.

After the caloric intake for weight loss is calculated, it is divided by the calorie content of the selected food to determine the actual daily amount to feed. **Table 27-12** provides an example of this method for calculating initial food dosage.

CALCULATION BASED ON CURRENT FOOD INTAKE

A third method requires knowledge of the number of calories the patient is currently eating based on information obtained from the patient history (**Box 27-1**) and feeding a reduced number of calories in the food form selected for weight loss. (See Assess and Select the Food section, above.) **Table 27-**

Box 27-10. Web-Based Programs for Obesity Management.

www.PetFit.com
This is a commercial pet food company sponsored free program for determining ideal (target) body weight for overweight/obese dogs and cats. The visuals in this program include a profile and dorsal view of a dog and cat with a slide bar beneath. The body condition score of the initial view is 3/5. The patient's current weight is entered and the slide bar is moved to the right (or left) to match the dimensions of the patient. After the operator is satisfied with the match, an ideal body weight is automatically calculated.

Balance IT (info@dvmconsulting.com)
Balance IT is a fee-based program designed to help veterinary health care teams with calculation-based weight-loss feeding plans. The user can select/enter all the foods a patient is currently fed (based on the diet history) and the program will then determine the caloric needs of the patient for weight loss. Users can set the desired weight-loss rates and select the commercial weight-loss food they wish to feed (along with any treats up to 10% of daily calories). The program calculates the amount to feed and enters this information into a report to be printed for clients. Based on weight rechecks, the software adjusts the amount to feed the patient.

14 provides more details and an example of this method. **Box 27-10** includes a web-based program that will perform calculations based on the current food information obtained from the diet history. This can be an excellent way to calculate the initial food dose if the recorded amount fed in the feeding history is complete and accurate. If the food history is incomplete, the owner can be instructed to return home and record actual amounts fed for a three-day period and either phone in the information or schedule a followup visit. Potential shortcomings of this approach include losing the attention and commitment of the owners due to busy schedules, inaccurate owner reports due to concerns of having been "feeding too much" and having to convert volume measures to calories if energy density on a volume basis is not readily available.

CALCULATION BASED ON OBESE WEIGHT

A fourth method for determining the amount to feed for controlled weight loss is based on obese weight, which is more straightforward to obtain than optimal weight. This method also includes a calculation for the amount of desired weekly weight loss.

With this method, the DER for obese weight is calculated. Then the caloric equivalent of adipose tissue to be lost per week is determined using a target of 1 to 2% of weight loss per week. This weekly amount of desired calorie deficit is converted to a daily amount and is subtracted from the previously calculated DER to provide the daily number of calories to feed for controlled weight loss. After the caloric intake for weight loss is calculated, it is divided by the calorie content of the selected food to determine the actual daily amount to feed. **Table 27-15** provides an example calculation using this method. Because the amount of lean body mass does not increase linearly with the degree of obesity, this method could overestimate the initial food dose for weight loss of very obese patients.

A reminder: all four methods generate what should be considered as starting points. Individual animals of the same weight have a wide variation of energy requirements (Figure 1-5). Thus, in actual practice, individual animals are encountered that need the same, markedly fewer and, occasionally, markedly more calories than product literature or calculations suggest. Caloric restriction may be insufficient to produce weight loss or may even produce weight gain in some patients (Laflamme et

Table 27-11. Methods for determining ideal/optimal body weight.

1. Consult the patient's medical record to determine if a body condition score (BCS) of 3/5 was recorded with a simultaneous ideal body weight.
2. Consult the patient's medical record to see if the patient's body weight was recorded at about the time the patient reached one year of age. Such a body weight would likely be near ideal (but not always). Thus, this method might not be as reliable as Method 1 above.
3. Consult **Table 27-3** in this text.
   a. Determine patient's current BCS and obtain current body weight.
   b. Locate the current BCS and body weight in **Table 27-3.**
   c. Note the weight in **Table 27-3** that coincides with a BCS of 3/5 in the same column.
4. Consult web-based programs (**Box-27-10**).

Table 27-12. Using ideal body weight to determine initial food dosage for controlled weight loss.

The following steps represent the process for estimating the initial amount to feed for weight loss using ideal body weight:
1. Determine the patient's current weight and BCS.
2. Consult **Table 27-3**; for current BCS, find current weight and read associated ideal weight (BCS 3/5) from same column.
3. Determine RER for ideal weight (also from **Table 27-3**, immediately below ideal weight) = initial estimated daily energy intake.
4. Divide RER by the as fed energy density of selected food = initial daily food dose.

An example case follows:
An obese dog weighs 30 kg and has a BCS of 5/5. Consulting **Table 27-3**, we determine that the dog's ideal body weight (BCS 3/5) is 22.5 kg. In **Table 27-3**, the RER for a 22.5-kg dog is located immediately below the weight. In this case it is 723 kcal/day.*
The food selected for weight loss provides 220 kcal/cup; 723 kcal/day ÷ 220 kcal/cup = 3.3 cups/day. This amount is a starting point and may need to be modified to achieve the desired weight loss.
Recheck body weight after two to three weeks. The weight-loss target should be between 0.5 and 2% per week of initial obese body weight.
Key: BCS = body condition score (Figures 1-2 and 1-3), RER = resting energy requirement.
*To convert to kJ, multiply kcal by 4.184.

Table 27-13. Two alternative methods for estimating resting energy requirement (RER).*

1) RER (kcal/day) = $70(BW_{kg})^{0.75}$. This calculation can be performed with a calculator that has a fractional exponent key or by cubing the body weight and taking its square root twice.
2) RER (kcal/day) = $30(BW_{kg}) + 70$. Results using this formula correlate well with results derived from Formula 1 above for body weights greater than 2 kg. Alternatively Table 5-2 provides this information for dogs weighing up to 70 kg.
*__Table 27-3__ provides RER estimates without requiring calculations.

Table 27-14. Using the food history to determine the initial food dosage for controlled weight loss.

The following steps represent the process for estimating the initial amount to feed for weight loss based on the amount of calories currently being fed to maintain the patient's obese weight.
1. Determine the food/treats currently being fed and, as close as possible, the exact amounts (volume and/or weight) being fed (**Box 27-1**).
2. Calculate the total calories currently being fed by obtaining calorie content information for the pet foods, treats and snacks from Chapters 13 (dogs) and 20 (cats) or product information; use Appendices 16 through 19 for the energy content of human food sources or consult product label information. This is done by multiplying the volume or weight of the food, treats and snacks by their caloric content and summing them. The sum is the calorie intake used to maintain the pet's current body weight.
3. Multiply the calorie sum obtained in Step 2 by 70% to obtain the initial number of calories to feed dogs and cats for controlled weight loss.
4. Convert the calorie target to a food dosage by dividing the calorie target by the energy density of the food selected for weight loss (kcal/cup for dry or kcal/can for moist). The answer will be the amount of food to feed per day.

An example case follows:
An obese dog weighs 30 kg and has a body condition score of 5/5.* According to the pet owner, the dog is fed only commercial food. The food history indicates the following daily intake: two cups of dry food (Brand A), one can (14.75 oz.) of moist food (Brand B) and four to five Brand C treats. Manufacturer's information regarding these foods indicates the following calorie content: 350 kcal/cup of dry food, 400 kcal/14.75-oz. can moist food, 50 kcal per treat. The total daily calorie intake is:
350 kcal/cup x two cups = 700 kcal**
+ 400 kcal/can x one can = 400 kcal
+ 5 treats x 50 kcal/treat = 250 kcal
Sum = 1,350 kcal/day

To determine the target number of calories to feed per day:
70% x 1,350 kcal = 945 kcal/day
To convert this to an amount of a selected weight-loss food to feed daily (in this case, the owner chose to feed a combination of moist (300 kcal/can) and dry (220 kcal/cup) weight-loss foods plus low-calorie treats (16 kcal/treat):
1 can x 300 kcal/can = 300 kcal
945 kcal weight-loss target – 300 kcal = 645 kcal left for dry food and treats
Feed 10 treats/day x 16 kcal/treat = 160 kcal
645 kcal – 160 kcal for treats = 485 kcal remaining for dry food
485 kcal ÷ 220 kcal/cup dry food = 2.2 cups dry food
Recheck body weight after two to three weeks to determine if adjustments need to be made.
Weight-loss target should be between 0.5 and 2% per week of initial obese body weight.
*(Figures 1-2 and 1-3)
**To convert to kJ, multiply kcal by 4.184.

Table 27-15. Using obese body weight and desired rate of weight loss to determine initial amount to feed for controlled weight loss.

The following steps represent the process for estimating the initial amount to feed for weight loss using obese body weight and a desired rate of weight loss:
1. Obtain current (obese) body weight.
2. Calculate DER for current body weight = estimated current daily energy intake.
3. Calculate the energy content of body fat (7,920 kcal/kg adipose tissue) to be lost weekly, assuming a target weight loss of between 0.5 to 2% initial body weight per week.
4. Divide the weekly amount of adipose calories by 7 to obtain desired daily calorie deficit.
5. Subtract the daily calorie deficit from the DER to obtain the number of calories to feed per day.
6. Divide the number of calories to feed per day by the energy density of the selected food to determine the amount of food to feed per day.

An example case follows:
An obese dog has a body weight of 30 kg and a BCS of 5/5.
The DER for the dog's obese weight is calculated using the formula DER = RER x 1.4. RER (kcal/day) = $30(BW_{kg}) + 70$. RER = 30(30 kg) + 70 = 970 kcal/day. DER = 1.4 x RER = 1.4 x 970 = 1,358 kcal/day. RER can also be obtained directly from **Table 27-3**.
A targeted weight loss of 1.5% of the dog's obese weight per week would be 0.45 kg/week.
The energy density of adipose tissue is 7,920 kcal/kg; 7,920 kcal/kg x 0.45 kg = 3,564 kcal/week or 509 kcal/day (3,564 kcal/week ÷ 7 days/week).
The calculated daily energy intake for this rate of weight loss = 1,358 kcal/day – 509 kcal = 849 kcal/day.
The food selected for weight loss provides 220 kcal/cup; 849 kcal/day ÷ 220 kcal/cup = 3 and 7/8 cups/day. This amount is a starting point and may need to be modified to achieve the desired weight loss. Recheck body weight after two to three weeks.
Key: DER = daily energy requirement, BCS = body condition score (Figures 1-2 and 1-3), RER = resting energy requirement, BW = body weight.

al, 1997). Patients will need to be rechecked regularly, initially every two to three weeks, so that modifications, if necessary, can be made to their food intake (Saker and Remillard, 2005). **Figure 27-1** is an algorithm for monitoring progression of weight loss and making decisions to keep weight loss progressing toward the target (ideal) weight. The pet owner's clear understanding that the initial amount to feed might need revision is more important than whether the veterinarian's initial recommendation is correct. Continually managing the client's expectations is very important.

Finally, a cautionary reminder about food restriction in cats: restricting calories for DER at optimal weight of a cat by more than 70% effectively makes caloric intake less than RER because DER for neutered adult cats is only 1.2 to 1.4 x RER. RER represents a theoretical minimum for daily energy consumption for cats because of the risk for hepatic lipidosis (Biourge et al, 1994). However, experimental and clinical trials using caloric restrictions between 59 and 80% of RER produced acceptable rates of weight loss in overweight cats with no biochemical evidence of hepatic lipido-

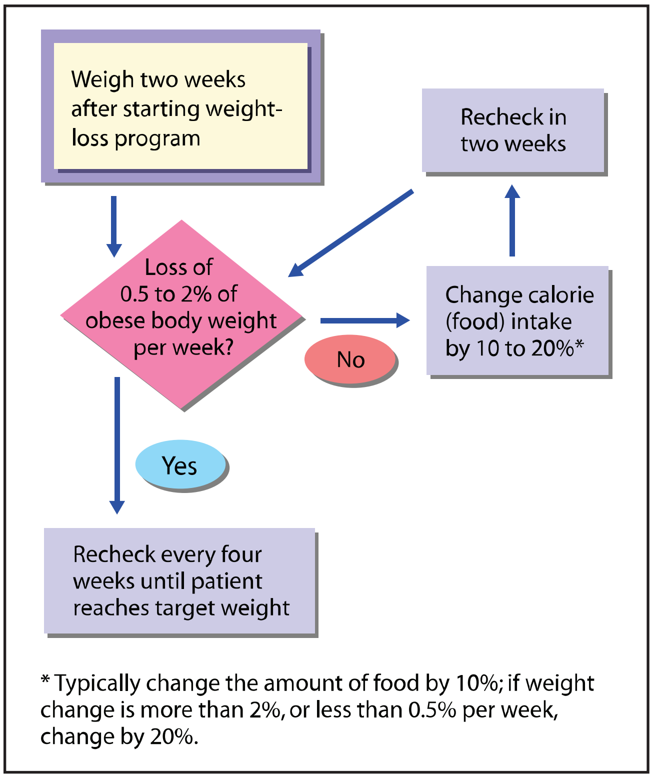

Figure 27-1. Algorithm for decision making and patient monitoring during weight loss.

Figure 27-2. A commercial feeding system for cats and small dogs. Close proximity of a special collar unlocks the feeder door and the pet wearing the collar simply pushes the door open and enters the feeder. More than one pet can have access to one feeder. (Courtesy of NekoFeeder, LLC. www.nekofeeder.com [802-264-6055] 6D Laurette Drive, Essex Junction, VT.)

sis (Markwell et al, 1996). Thus, when feeding obese cats for weight loss, be sure they are eating at least 50% of their estimated food dose to prevent development of hepatic lipidosis. A weight loss goal of 0.5 to 1% per week is safer.

Feeding Methods for Weight Reduction

Consideration should be given to how the owner feeds the pet. Feeding foods free choice may work for individual cats and dogs that can self-regulate their daily intake of food to match their DER. However, free-choice feeding rarely works for weight loss or for maintenance of reduced body weight even with the most calorie-restricted foods.

Dogs and cats on weight-reduction programs should be fed multiple small meals during the day rather than a single large meal to take advantage of the obligatory energy cost for digesting and absorbing food. The optimal number of meals for maximizing caloric expenditure from TEF has not been determined. However, the total daily food should be divided into at least two portions fed eight to 12 hours apart. Most pet owners can feed two meals per day without disrupting their schedules. Clients who can conveniently feed three or more meals per day should do so.

Meal sizes should be in portions that are practical to measure (i.e., to the nearest one-fourth cup or can). If the daily amount of food does not divide evenly into portions that are readily measurable, some meals will contain less and others more food. The meals containing more food should be fed when the owner will be with the pet for the longest time between meals. The pet should be kept out of the kitchen and dining areas during preparation and consumption of family meals. These practices can help reduce the pet's begging and the owner's urge to give the pet additional food or treats.

As with any food change, it is best to transition the patient to the new weight-loss food gradually over a period of several days (Table 1-1).

In multi-pet households, care must be taken to ensure that obese patients being treated for weight loss do not have access to other pets' food. This can be challenging. Commercial feeders are available for pets that limit access to food. Internet searches can be conducted to locate sources of commercial automatic feeders that might make it easier to feed an individual dog or cat for weight loss in a multi-pet household. **Figure 27-2** shows an example of a commercial feeder for cats and small dogs that selectively restricts access to food. Also, feeders for cats in multi-cat households can be constructed from a cardboard box. The box should be of sufficient size for one cat and its bowl of food. An opening small enough to allow a thin cat, but not the overweight cat, to enter and exit is cut into the closed box. The food intended for the thinner

Chapter 28

Disorders of Lipid Metabolism

Richard B. Ford
Chris L. Ludlow

"It is a scientific fact that your body will not absorb cholesterol if you take it from another person's plate."
Dave Barry

CLINICAL IMPORTANCE

Hyperlipidemia (also called hyperlipoproteinemia) refers to a disturbance of lipid metabolism that results in an elevated concentration of blood lipids, particularly triglycerides, cholesterol or both. In the fasted state, hyperlipidemia is an abnormal laboratory finding that represents either accelerated synthesis or retarded degradation of lipoproteins (Brown and Goldstein, 1987). Among dogs and cats, the most common, clinically important type of hyperlipidemia is characterized by an excess concentration of triglycerides in blood, a condition referred to as hypertriglyceridemia (Ford, 1993, 1996). The serum and plasma of affected animals typically appear milky white and turbid, or lipemic. In cases of extreme hypertriglyceridemia, the patient's serum can be so lipemic that it is opaque, or lactescent (**Figure 28-1**).

Hypercholesterolemia is an excess concentration of cholesterol in blood. Most of the circulating cholesterol in dogs and cats is carried on high-density lipoprotein (HDL), the smallest lipoprotein (Ford, 1996; Mahley and Weisgraber, 1974; Mahley et al, 1974). Because HDL particles are small and do not refract light, patients with extreme cholesterol elevations will not have lipemic serum unless the triglyceride concentration is also elevated.

The clinical importance of hyperlipidemia in companion animal medicine centers around four facts: 1) lipemic serum may positively or negatively interfere with quantitative analyses of other serum analytes, 2) hyperlipidemia in fasted (>12 hours) dogs or cats is abnormal and should be addressed as a significant clinical finding, 3) hyperlipidemic patients are at risk for developing significant clinical illness, including acute pancreatitis and 4) specific dietary and/or drug intervention can eliminate or at least diminish the morbidity associated with hyperlipidemia.

PATIENT ASSESSMENT

History and Physical Examination

The major clinical manifestations of hyperlipidemia include intermittent vomiting, diarrhea and abdominal discomfort and seizures in dogs; cutaneous xanthomata (**Figure 28-2**) and peripheral neuropathy in cats and lipid keratopathies (**Figure 28-3**) and lipemia retinalis in both species (**Figure 28-4**). Some hyperlipidemic dogs and cats do not manifest clinical signs but are considered to be at risk for developing overt signs in the future. Atherosclerosis is a rare manifestation of hyperlipidemia in dogs and cats as opposed to people.

Dogs with Hyperlipidemia

Table 28-1 lists the clinical signs associated with hypertriglyceridemia in dogs. The most common presenting complaints are vague and intermittent but usually center around vomiting and diarrhea. Accompanying signs include non-localizing abdominal discomfort and occasional pain, accompanied by a transient

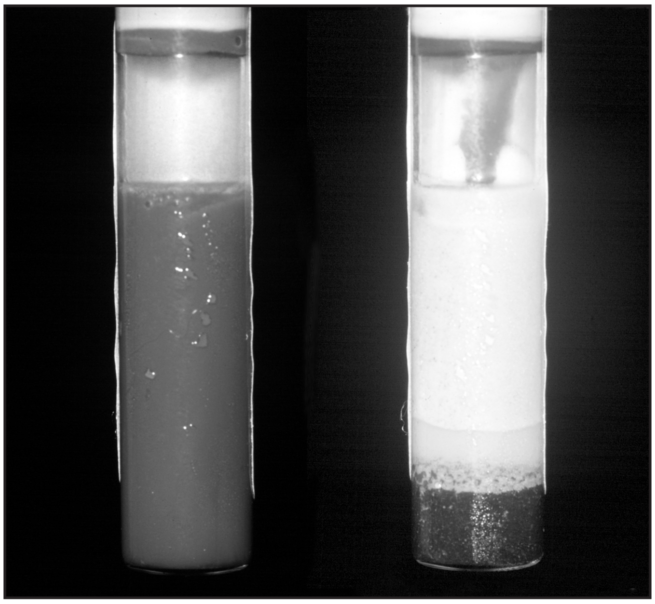

Figure 28-1. Blood samples from a Doberman pinscher with hypothyroidism and severe lipemia. The picture on the left was taken immediately after the sample was drawn. Note that the lipid content is so high that even in black and white photography the blood has a "tomato soup" appearance. The blood sample on the right was allowed to separate forming a "cream layer" of triglyceride-rich chylomicrons on top.

Figure 28-2. Xanthomas on the pinna of a cat with hyperlipidemia. Xanthomas are tumors composed of lipid-laden foam cells, which are histiocytes containing cytoplasmic lipid material. These lesions resolved with use of a low-fat, high-fiber food.

decrease in appetite. The owner may report episodic signs, lasting a few hours to a few days that may resolve spontaneously with fasting. Abdominal distention is occasionally reported. There appears to be no gender predilection. Affected dogs are usually four years of age and older although younger dogs may be affected.

On physical examination, dogs may appear lethargic and may or may not manifest abdominal pain. Clinical signs and history are compatible with acute pancreatitis; however, abdominal radiographs, ultrasound and laboratory evidence supporting a diagnosis of pancreatitis are typically lacking. The term pseudopancreatitis has been used to describe the clinical manifestations associated with hypertriglyceridemia (Ford, 1993, 1996).

Lipemia retinalis, a condition characterized by pale pink retinal arterioles and venules, is an incidental finding seen on funduscopic examination of lipemic dogs and cats (**Figure 28-4**). This condition does not affect vision. Laboratory analysis of affected animals will verify extreme hypertriglyceridemia, typically greater than 1,000 mg/dl.

Sustained hypertriglyceridemia is a principal risk factor among people and dogs for developing acute pancreatitis (Brown and Goldstein, 1987; Ford, 1993; Armstrong and Ford, 1989; DeBowes, 1987; Sanfey and Cameron, 1985; Whitney et al, 1987; Williams, 1995). Dogs with acute abdominal pain and vomiting should be evaluated for hyperchylomicronemia at the time of presentation and during the recovery phase when food intake is restored.

Hypertriglyceridemia should be considered in patients presenting with a history of seizures. A small number of patients, many of them miniature schnauzers, diagnosed with idiopathic epilepsy have elevated fasting triglyceride concentrations and lipemic serum (Rogers et al, 1975, 1975a). In some dogs, dietary therapy has successfully reduced blood triglyceride levels and eliminated seizures without concomitant use of anticonvulsant drugs. Interestingly, seizures associated with hyperlipidemia are not necessarily associated with other signs typically attributed to hyperlipidemia (e.g., vomiting and diarrhea).

Although owners of hypertriglyceridemic dogs rarely express concern about their pet's inactivity or lethargy at the time of initial presentation, owners often remark that the pet's activity level increased as a result of lowering circulating triglyceride levels.[a]

Cats with Hyperlipidemia

Clinical signs in hyperlipidemic cats are different than those reported to occur in dogs (**Table 28-1**). The most common clinical finding in affected cats is cutaneous xanthoma, a painless, raised lesion caused by accumulation of lipid-laden macrophages or foam cells in the skin (**Figure 28-2**) (Jones and Watson, 1995; Jones et al, 1983; Jones, 1995). Xanthomas are most likely to occur over bony prominences and areas of skin subject to chronic pressure or direct injury.

Xanthomata may also occur in other tissues such as liver, spleen, kidney, heart, skeletal muscle and intestines. Uniquely, xanthomata can form at the point where spinal nerves emerge through the vertebral foramina (Jones, 1993), the point at which nerves and vascular tissue are subject to mild injury associated with the movement of adjacent vertebrae. Peripheral neuropathy caused by neuronal xanthoma is characterized by motor paralysis. Signs vary depending on the specific nerves involved. Horner's syndrome, tibial nerve paralysis and radial nerve paralysis have been reported most often (Jones, 1993, 1995). In cases in which mixed motor and

sensory nerves have been affected, sensation to painful stimuli was retained.

Lipemia retinalis is more common in cats than dogs (**Figure 28-4**). Other ocular manifestations of hyperchylomicronemia in cats are uncommon but include iridocyclitis, arcus lipoides corneae and lipemic aqueous and lipid keratopathy (**Figure 28-3**). These lesions are thought to occur subsequent to existing ocular disease in lipemic cats (Jones, 1995; Crispin, 1993).

Laboratory Evaluation

Veterinarians assessing a dog or cat for hyperlipidemia should submit serum or plasma rather than whole blood (**Box 28-1**). Plasma or serum samples for cholesterol and triglyceride determinations can be refrigerated or frozen for several days without significant effect.

The presence of excess triglycerides, particularly if associated with retention of chylomicrons, is an important source of either positive (falsely increased) or negative (falsely decreased) interference for analytes determined by colorimetric methods (Whitney et al, 1987). The effect of lipemia on individual analytes is variable and depends on the degree of lipemia, the analyte being measured and the analytic method used. Lipemia also causes in vitro hemolysis, a phenomenon induced by the effect of lipid on erythrocyte membrane fragility, which may also induce interference when performing laboratory profiles (Allerman, 1990). The extent to which in vitro hemolysis affects determination of hemoglobin and hematocrit values has not been established. The amount of red-cell hemolysis appears to be proportional to the length of time red cells are in contact with the lipemic serum and the degree of lipemia. The type and extent of interference induced by lipemia varies from one laboratory to another, depending on the analytical instrumentation and methodologies used. Visual inspection of the patient's serum provides valuable physical evidence about the presence or absence of an excessive concentration of triglycerides. In fasting patients (i.e., 24-hour fast or longer), lipemia or lactescent serum denotes hypertriglyceridemia and is usually associated with triglyceride concentrations in excess of 2,000 mg/dl (canine normal = 50 to 150 mg/dl, feline normal = 50 to 100 mg/dl). A diagnosis of hypertriglyceridemia should be based on laboratory determination of serum triglycerides in uncleared serum. By laboratory methods used in North America, serum triglyceride concentrations greater than 500 mg/dl are abnormal for fasted dogs and cats. Although a correlation has not been observed between triglyceride concentrations and the severity of clinical signs, dogs with a triglyceride concentration of 1,000 mg/dl or higher are at risk for developing clinical signs and, as such, are candidates for dietary intervention (Armstrong and Ford, 1989; Rogers et al, 1975a; Chapman, 1980). Maintaining triglyceride levels less than 500 mg/dl in lipemic (familial) patients may be difficult with nutritional management alone. A more reasonable target range for dietary control is 500 to 1,000 mg/dl postprandially. Furthermore, clinical signs of hypertriglyceridemia appear to be uncommon in patients with postprandial triglyceride levels less than 1,000 mg/dl.

Figure 28-3. Lipid keratopathy in a rabbit. Note the white lipid accumulation in the corneal stroma. Corneal vascularization may precede or follow lipid deposition. Lipid keratopathy has been described in several species including human beings, rabbits, cats and dogs.
